The most common skin lesion in AIDS is Kaposi's sarcoma (KS). Lesions may be localized or widespread. Large lesions can cause pain and restrict movement. They can impede circulation, causing open, weeping, painful lesions. Another cause of impaired skin integrity is infection with herpes simplex virus (HSV) or varicella zoster virus (VZV) (shingles).

Planning: Expected Outcomes. The patient is expected to have healing of any existing lesions and avoid increased skin breakdown or secondary infection. Indicators include:

- Absence of new lesions or open skin areas
- Existing lesions become smaller in diameter
- Absence of pus, induration, or redness in, from, or around skin lesions

Interventions. Often, KS responds well to effective antiretroviral drug therapy. With time and HAART, many lesions disappear and do not reappear as long as the patient remains on HAART. For lesions that do not respond to HAART, KS

can be treated with local radiation, intralesional or systemic chemotherapy, cryotherapy, or topical retinoids. Systemic therapy is used in patients with rapidly progressive disease or with major involvement of the intestinal tract, lungs, or other organs. Therapies include chemotherapy (single agent or combination), interferon-alpha, and interferon-alpha plus zidovudine.

Treatment of painful KS lesions includes analgesics and comfort measures. Keep open, weeping KS lesions clean and dressed to reduce the risk for secondary infection. Many patients with skin KS are concerned about their appearance and the risk for being identified as HIV positive. Makeup (if lesions are not open), long-sleeved shirts, and hats may help maintain a normal appearance.

For the patient with an HSV abscess, provide good skin care directly or delegate this care to UAP. Stress the importance of keeping the area clean and dry. Teach UAP to clean abscesses at least once per shift with normal saline and allow them to air-dry. This infection is painful and requires analgesics, assistance with position, and other comfort measures. Modified Burow's solution (Domeboro) soaks promote healing for some patients. HSV infection is treated with acyclovir (Zovirax) or valacyclovir (Valtrex).

Minimizing Confusion

Neurologic changes with disturbed thought processes are major areas of concern for patients with HIV infection or AIDS. These changes may be due to psychological stressors accompanying the disease or to organic disorders caused by opportunistic infections, cancer, or HIV encephalitis.

Planning: Expected Outcomes. The patient is expected to show improved mental status. Indicators include that the patient demonstrates these behaviors:

- Identifies self and significant others
- Identifies correct month and year
- Recalls immediate, recent, and remote information accurately

Interventions. Patients with AIDS suffer from enormous loss and psychological stress, which complicates the assessment of any changes in behavior or affect. Assess baseline neurologic and mental status by using neurologic assessment tools (see Chapter 43) to compare any changes. Evaluate the patient for subtle changes in memory, ability to concentrate, affect, and behavior. It is important to determine whether the cause of the neurologic changes is treatable.

Reorient the confused patient to person, time, and place as needed. Coordinate with all members of the health care team to ensure that reorientation methods are performed by everyone who interacts with the patient. Remind the patient of your identity and explain what is to be done at any given time. Give simple directions; use short, uncomplicated sentences; explain activities in simple language; and involve him or her in planning the daily schedule. Ask relatives or significant others to bring in familiar items from home. Arrange all items in the patient's environment in the same location as at home. Using calendars, clocks, and radios and putting the bed close to a window also may help keep the patient oriented.

Drug therapy is used for different conditions that can alter thought processes in the person with AIDS. Psychotropic drugs are used to treat ongoing behavioral problems or emotional disorders. Antidepressants and anxiolytics may be prescribed.

Safety measures are crucial to the well-being of the neurologically impaired patient with AIDS. He or she may not be aware of activities or surroundings and may need help with bathing, dressing, eating, ambulating, and other ADLs. Make the environment, whether a hospital room or long-term care facility, safe and comfortable.

Some patients with AIDS have seizures. Institute seizure precautions, including keeping siderails in the up position and having oxygen and suctioning equipment available. Anticonvulsants may be added to the drug therapy.

Assess the patient with neurologic manifestations for increased intracranial pressure (ICP). If not recognized and managed early, ICP can lead to permanent brain damage and death. Increased ICP in patients with HIV disease is most commonly managed with corticosteroids.

! NURSING SAFETY PRIORITY

Critical Rescue

Document and report immediately any changes in level of consciousness (one of the earliest signs of increased ICP), vital signs, pupil size or reactivity, or limb strength to the physician for appropriate intervention.

Support the family and friends of the patient who has neurologic impairment. There is great trauma in seeing a loved one unable to care for himself or herself or showing childlike behavior. Answer questions honestly and sensitively. Teach UAP, the family, and significant others how to reorient the patient. Encourage them to continue to provide the patient with news of family happenings or current events. Coordinate with the social worker to identify community resources for the patient and family.

Supporting Self-Esteem

The patient with AIDS may have changes in self-esteem and self-concept. Contributing to this are dramatic changes in appearance that alter the person's body image. Many patients also have abrupt, significant changes in their relationships with others and in day-to-day activities, including a job or other productive activities. All changes can disrupt the self-concept.

Planning: Expected Outcomes. The patient is expected to identify his or her positive aspects and accept himself or herself. Indicators include that he or she often or consistently demonstrates these behaviors:

- Maintains eye contact
- Accepts compliments from others
- Expresses feelings of self-worth

Interventions. Provide a climate of acceptance for patients with AIDS by promoting a trusting relationship. Help them express feelings and identify positive aspects of themselves. Allow for privacy, but do not avoid or isolate the patient. Encourage self-care, independence, control, and decision making by helping him or her set short-term, attainable goals and offering praise when goals are achieved.

Guided imagery is a form of complementary therapy used by many patients to increase their sense of control and enhance self-esteem. Imagery can focus on helping them cope with distressing side effects or painful procedures. Other uses include picturing battle scenes in which the virus is killed by immune system cells.

Maintaining Social Contact

Many patients with AIDS face discrimination, rejection, and isolation. Friends or health care workers sometimes avoid or refuse to have anything to do with them. Misunderstanding and fear lead to inappropriate isolation of the patient with AIDS.

Planning: Expected Outcomes. The patient is expected to identify behaviors that cause social isolation and demonstrate behaviors that reduce social isolation. Indicators include that the patient often or consistently demonstrates these behaviors:

- Interacts with close friends and family members
- Cooperates with others
- Uses assertive behaviors as appropriate

Interventions. Interventions for social isolation focus on promoting interactions and on education to reduce fear of AIDS transmission.

Promote patient interaction first by establishing a therapeutic nurse-patient relationship, and do not isolate the patient. Spend time with him or her, even when not performing a procedure or assessment, just to be present. Model this behavior for UAP, and encourage them to spend extra time with the patient. Show understanding and concern while helping the patient find ways to reduce feelings of rejection and isolation. Reduce barriers to social contact. Assess his or her social support resources. Teach family and significant others about HIV transmission and the use of Standard Precautions to reduce anxiety and increase contact with the patient (see [Chapter 25](#)).

Encourage the patient to state feelings about self, coping skills, and a sense of control over the situation. Help him or her identify support systems, including those already in place and those that need to be arranged.

Teaching about HIV transmission is the most important aspect for prevention of HIV. All people, regardless of age, gender, ethnicity, or sexual orientation, are susceptible to HIV infection. HIV infection is preventable because of the mode of viral transmission and the fragile nature of the virus. (See discussion on pp. 361-364 in the Health Promotion and Maintenance section.)

Community-Based Care

HIV infection is now considered a manageable chronic disease (Kirton, 2011). The usual course of illness is one of intermittent acute infections and periods of relative wellness over months or years. This period is often followed by chronic, progressive debilitation. Because of the cyclic nature of HIV disease and AIDS, the patient often spends long periods at home between hospital admissions or clinic visits. In some instances, especially as the illness becomes more severe, he or she may need referral to a long-term care facility, home care agency, or hospice. In collaboration with the social worker, dietitian, and other available resources, work with patients to plan what will be needed and how they will manage at home with self-care and ADLs.

Home Care Management

Before the patient is discharged to home, assess his or her status and ability to perform self-care activities. Some patients do not need home care but do need to maintain a link with primary care providers. Home care can range from help with ADLs for those with weakness, debility, or limited function

CHART 21-10 FOCUSED ASSESSMENT

The Person with AIDS

Assess cardiovascular and respiratory status:

- Vital signs
- Presence of acute chest pain or dyspnea
- Presence of cough
- Presence of fever
- Activity tolerance

Assess nutritional status:

- Food intake
- Weight loss or gain
- General condition of skin
- Financial resources

Assess neurologic status:

- Cognitive changes
- Motor changes
- Sensory disturbances

Assess gastrointestinal status:

- Mouth and oropharynx
- Presence of dysphagia
- Presence of abdominal pain
- Presence of nausea, vomiting, diarrhea

Assess psychological status:

- Presence of anxiety
- Presence of depression

Assess activity and rest:

- Activities of daily living (ADLs)
- Mobility and ambulation
- Fatigue
- Sleep pattern
- Presence of pain

Assess home environment:

- Safety hazards
- Structural barriers affecting functional ability

Assess patient's and caregiver's adherence and understanding of illness and treatment, including:

- Manifestations to report to nurse
- Medication schedule and side or toxic effects

Assess patient's and caregiver's coping skills.

to around-the-clock nursing care, drugs, and nutritional support for severely or terminally ill patients. Assess available resources, including family members and significant others willing and able to be caregivers. Help the family make arrangements for outside caregivers or respite care, if needed. Patients may need referrals or help in planning housing, finances, insurance, legal services, funeral arrangements, and spiritual counseling. Coordinate with the case manager to ensure these issues are addressed.

Home care aides may be involved in daily or weekly care of the patient with AIDS in the home. Usually a home care nurse makes an initial visit for assessment purposes, and care is followed up by home care aides. If the patient becomes more debilitated, a nurse re-assesses his or her status. [Chart 21-10](#) lists focused assessment areas for the patient with AIDS at home.

Teaching for Self-Management

Teaching the patient, family, and friends is a high priority when preparing for discharge. Instruct about modes of transmission and preventive behaviors (e.g., guidelines for safer sex; not sharing toothbrushes, razors, and other potentially blood-contaminated articles). Caregivers also need instruction about best practices for infection control precautions to

CHART 21-11 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Infection Control for Home Care of the Person with AIDS**Direct Care**

- Follow Standard Precautions and good handwashing techniques.
- Do not share razors or toothbrushes.

Housekeeping

- Wipe up feces, vomitus, sputum, urine, or blood or other body fluids and the area with soap and water. Dispose of solid wastes and solutions used for cleaning by flushing them down the toilet. Disinfect the area by wiping with a 1:10 solution of household bleach (1 part bleach to 10 parts water). Wear gloves during cleaning.
- Soak rags, mops, and sponges used for cleaning in a 1:10 bleach solution for 5 minutes to disinfect them.
- Wash dishes and eating utensils in hot water and dishwashing soap or detergent.
- Clean bathroom surfaces with regular household cleaners, and then disinfect them with a 1:10 solution of household bleach.

Laundry

- Rinse clothes, towels, and bedclothes if they become soiled with feces, vomitus, sputum, urine, or blood. Then dispose of the soiled water by flushing it down the toilet. Launder these clothes with hot water and detergent with 1 cup of bleach added per load of laundry.
- Keep soiled clothes in a plastic bag.

Waste Disposal

- Dispose of needles and other "sharps" in a labeled puncture-proof container such as a coffee can with a lid, using Standard Precautions, to avoid needle stick injuries. Decontaminate full containers by adding a 1:10 bleach solution. Then seal the container with tape and place it in a paper bag. Dispose of the container in the regular trash.
- Remove solid waste from contaminated trash (e.g., paper towels or tissues, dressings, disposable incontinence pads, disposable gloves); then flush the solid waste down the toilet. Place the contaminated trash items in tied plastic bags, and dispose of them in the regular trash.

prevent transmission while caring for the patient in the home ([Chart 21-11](#)), nursing techniques to use in the home, and coping or support strategies.

Teach the patient, family, and friends how to protect the patient from infection, how to identify the presence of infections, and what to do if these appear. Teach about the use of self-care strategies, such as good hygiene, balanced rest and exercise, skin care, mouth care, and safe administration and potential side effects of all prescribed drugs. During diet teaching, stress good nutrition; the need to avoid raw or rare fish, fowl, or meat; thorough washing of fruits and vegetables; and proper food refrigeration.

Teach the patient to avoid large crowds, especially in enclosed areas, not to travel to countries with poor sanitation, and to avoid cleaning pet litter boxes. [Chart 21-7](#) lists more strategies to teach the patient and family how to avoid infections.

Psychosocial Preparation

Patients with AIDS often fear social stigma and rejection. Be aware that this fear is realistic, and help identify ways to avoid

problems, as well as identify coping strategies for difficult situations. Support family members and friends in efforts to help the patient and provide protection from discrimination.

Encourage patients to continue as many usual activities as possible. Except when too ill or too weak, they can continue to work and participate in most social activities. Support them in their selection of friends and relatives with whom to discuss the diagnosis. Stress that sexual partners and care providers should be informed; beyond that, it is up to the patient. Some patients have severe depression or anxiety about the future. Almost all feel the burden of having a fatal disease widely considered unacceptable and feel compelled to maintain some secrecy about the illness. Referrals to community resources, mental health/behavioral health professionals, and support groups can help the patient verbalize fears and frustrations and cope with the illness.

Health Care Resources

In many cities, community groups exist to assist people with AIDS. Often composed of volunteers, they offer excellent services to the community. The types and number of services vary by agency and city, but many include HIV testing and counseling, clinic services, buddy systems, support groups, respite care, education and outreach, referral services, and even housing. Patients may also need referrals to other local resources, such as home care agencies, companies that provide home IV therapy, community mental health/behavioral health agencies, Meals on Wheels, transportation services, and others. In addition, educational materials and support groups are available through Internet access.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Evidence-Based Practice

The patient is a 62-year-old man with AIDS who is about to be discharged after having had PCP for the past 2 weeks. He works as a bank officer. His social and recreational activities include playing cards with friends every weekend, tutoring grade school students in math, reading to older adult shut-ins, and serving meals at a soup kitchen. His place of employment has offered to let him work part-time to keep him from becoming too fatigued. Although he is glad about this, he tells you that his greatest joy is helping others. With tears in his eyes he says he will miss participating in his usual activities but knows that it is best to keep other people safe.

1. Is his concern for others realistic? Why or why not?
2. Explain which activities may pose a health risk for others, and explain how this risk could be reduced by modification.
3. Which activities pose a health risk to him?
4. Explain what modifications could be made to reduce such risks.
5. What specifically can you do to support him at this time?

EVALUATION: OUTCOMES

The overall outcomes for care of patients with AIDS are to maintain the highest possible level of function for as long as possible, reduce infections, and maintain quality of life and dignity during the course of progressive illness. Evaluate the care of the patient with AIDS on the basis of the identified priority problems. Expected outcomes include that he or she should:

- Adhere to the prescribed drug therapy regimen more than 95% of the time
- Practice safer sex techniques all of the time

- Remain free from opportunistic infections
- Have adequate respiratory function
- Achieve an acceptable level of physical comfort
- Attain adequate weight and nutritional and fluid status
- Maintain skin integrity
- Remain oriented
- Maintain self-esteem
- Maintain a support system and involvement with others

Specific indicators for these outcomes are listed for each patient problem in the Planning and Implementation section (see earlier).

THERAPY-INDUCED IMMUNE DEFICIENCIES

Some acquired secondary immune deficiencies may be related to other conditions that cause the loss of immunoglobulins or destruction of lymphocytes. The most common cause of secondary immune deficiency is the use of drugs and other treatment modalities for various diseases. Sometimes immunosuppression is a desired effect, as in organ transplantation or for the treatment of autoimmune disorders. Often immunosuppression is an undesirable, complicating side effect of therapy that is used for another intent, such as cancer chemotherapy, and may even require changing the therapeutic regimen. Various therapies cause different types and degrees of immunosuppression. The challenge is to have maximum therapeutic effect without leaving the patient overly immunosuppressed and susceptible to serious complications.

Drug-Induced Immune Deficiencies

Several drug classes have major immunosuppressive effects. Some induce general immunosuppression; others are more specific and target one part of the immune system more than another.

Cytotoxic drugs are mostly those used in the treatment of cancer and autoimmune disorders. Most of these drugs interfere with all rapidly dividing cells. White blood cells (WBCs), including neutrophils, lymphocytes, and phagocytes, which are responsible for providing protection against infection, rapidly divide and are susceptible to this type of destruction. The result is a decrease in the number of these important cells, especially the neutrophils, greatly increasing the patient's risk for infection. Cytotoxic drugs interfere with the ability of lymphocytes to produce and release products such as lymphokines and antibodies, causing general immunosuppression. Most cytotoxic drugs are used for cancer and autoimmune disorders.

Corticosteroids are hormones used to treat many autoimmune diseases, neoplasms, and endocrine disorders. Corticosteroids have both anti-inflammatory and immunosuppressive effects. They inhibit inflammation by stabilizing blood vessel membranes and decreasing permeability, blocking the movement of neutrophils and monocytes. These drugs disrupt the synthesis of arachidonic acid, the main precursor for a variety of inflammatory chemicals.

Corticosteroids keep T-cells in the bone marrow, reducing the number of circulating T-cells and resulting in lymphopenia and suppressed cell-mediated immunity. They also interfere with immunoglobulin G (IgG) production and reduce antibody-antigen binding. These drugs have many effects that

alter disease activity, as well as numerous side effects, including:

- Central nervous system changes, such as euphoria, insomnia, or psychosis
- Cardiovascular changes, such as edema and hypertension
- GI effects, such as gastric irritation, ulcers, and increased appetite (with weight gain)
- Other changes (e.g., hyperglycemia, muscle weakness, delayed wound healing, bone density loss, body fat redistribution)

Cyclosporine (Sandimmune, Neoral) is a specific immunosuppressant that selectively suppresses the helper/inducer T-cells by blocking their growth and development. Cyclosporine is used to prevent organ transplant rejection and graft-versus-host disease. This drug is occasionally used for disorders such as uveitis, rheumatoid arthritis, and other autoimmune disorders.

Disease-modifying immunosuppressive drugs represent a large group of newer biological response modifier agents that specifically slow the damage caused by a variety of autoimmune diseases, such as rheumatoid arthritis and psoriasis. Examples include alefacept (Amevive), etanercept (Enbrel), infliximab (Remicade), and many others. Regardless of their specific action in reducing cell damage, they always decrease the general immune responses to some degree and increase the risk for infection, both newly acquired infections and dormant pre-existing infections. The health problems for which these drugs are most commonly prescribed are rheumatoid arthritis and psoriasis. Specific disease-modifying drugs are discussed in the chapters presenting the health problems for which they are prescribed.

Radiation-Induced Immune Deficiencies

Although chemotherapy is more immunosuppressive than radiotherapy, radiation also is toxic to dividing and resting cells. Lymphocytes and neutrophils are most sensitive to radiation. Some radiation exposures can induce profound lymphopenia and neutropenia, causing general immunosuppression. Whether immune deficiency occurs after radiation therapy depends on the location and dose of radiation. Exposure to the ilium and femur in adults can cause generalized immunosuppression because these bone areas are the primary blood cell-producing sites.

Management of the patient with treatment-induced immune deficiency aims to improve immune function and protect him or her from infection. The most severe immunosuppression occurs while he or she is receiving the immunosuppressive drugs or during radiation treatment. The severity and duration of the immunosuppression are related to the dosage of specific drugs. Although this impairment is usually temporary, with good recovery of immune and inflammatory responses within weeks or months of therapy completion, the potential for severe infections makes this problem a major treatment concern. Common infections occurring during this period include those of fungal origin, especially yeast, residual viral breakthrough, and a variety of bacteria.

Coordinate with patients and other health care professionals to provide safe care to those at risk for infection. [Chart 21-8](#) lists specific nursing actions to prevent infection among patients with drug-induced or any type of immunosuppression. Good handwashing by all health care personnel before

contact with the patient is essential for infection prevention. Health care professionals must use aseptic technique with any invasive procedure as required by The Joint Commission's National Patient Safety Goals (NPSGs).

In some instances, drug-induced immunosuppression can be reduced or avoided by giving hematopoietic growth factors to stimulate bone marrow production of immune system cells. Although not appropriate for all types of disorders, this treatment can reduce the patient's risk for infection during drug therapy. Growth factors are expensive, however, and the cost may not be covered by insurance. See [Chapters 24 and 42](#) for further discussion about this treatment.

Many patients remain at home during periods of immunosuppression. Teach the patient and family best practices to reduce the patient's risk for infection (see [Chart 21-7](#)).

For patients receiving long-term therapy with immunosuppressive drugs, drug dosages are altered according to their responses. The lowest dose that achieves the desired effect is given.

CONGENITAL (PRIMARY) IMMUNE DEFICIENCIES

Congenital, or primary, immune deficiencies are disorders in which the person is born with a defect in the development or function of one or more immune components. As a result, the immune response does not adequately protect him or her from infection, cancer, or other disease. Most congenital immune deficiencies are rare.

Some congenital immune deficiencies are inherited as an X-linked trait (e.g., Bruton's agammaglobulinemia or Wiskott-Aldrich syndrome), and some are recessive (e.g., ataxia-telangiectasia). For many congenital immune deficiencies, however, the genetic defect and inheritance pattern have not been clearly identified.

Congenital immune deficiencies are classified according to the type of immune function that is impaired: antibody mediated, cell mediated, or combined. Because cell-mediated and combined immune deficiencies are so severe that the affected person usually does not survive childhood, only antibody-mediated problems (seen in adults) are discussed in this chapter.

SELECTIVE IMMUNOGLOBULIN A DEFICIENCY

Selective immunoglobulin A (IgA) deficiency is the most common congenital immune deficiency seen in adults, occurring in 1 per 600 to 800 people (McCance et al., 2010). The patient may be asymptomatic or have chronic recurrent upper respiratory tract infections, skin infections, urinary tract infections, vaginal infections, and diarrhea. Selective IgA deficiency does not reduce life span. Because IgA is the major antibody in secretions, bacterial infections are seen mostly in the respiratory, GI, and urogenital tracts. Some patients with IgA deficiency also have malabsorption syndrome.

Treatment for IgA deficiency is limited to vigorous treatment of infections. Unlike other immunoglobulin deficiencies, IgA deficiency is not managed with exogenous immunoglobulin for two reasons. First, exogenous immunoglobulin contains very little IgA and would not help boost

IgA levels. Second, because patients with IgA deficiency make normal amounts of all other antibodies, they are at high risk for severe allergic reactions to exogenous immunoglobulin. If malabsorption syndrome occurs with IgA deficiency, the patient needs nutritional supplements (e.g., partial or total enteral or parenteral nutrition).

! NURSING SAFETY PRIORITY

Drug Alert

Never administer intravenous immunoglobulin (IVIG) to a patient who has selective immunoglobulin A deficiency.

BRUTON'S AGAMMAGLOBULINEMIA

A classic congenital antibody-mediated immune deficiency is Bruton's disease or Bruton's agammaglobulinemia. Boys born with this disease usually start to have problems at about 6 months of age, after maternal antibodies, transferred through the placenta, have been lost. The first manifestations are recurrent otitis, sinusitis, pneumonia, furunculosis, meningitis, and septicemia with organisms such as *Pneumococcus*, *Streptococcus*, and *Haemophilus*. Laboratory assessment shows an absence of circulating immunoglobulin (antibodies).

Except for patients with poliomyelitis, chronic echovirus infection, or a lymphoreticular cancer, the prognosis for

Bruton's disease is good if antibody replacement is started early. Immune serum globulin is regularly given to these patients, usually about 100 to 400 mg/kg IV every 3 to 4 weeks (Scherf & White-Reid, 2008). The dosage and schedule are individualized. Antibiotics are used for specific infections. Long-term prophylactic antibiotic therapy may also be used. Often, severe sinus and pulmonary problems later develop in some patients.

COMMON VARIABLE IMMUNE DEFICIENCY

The patient with common variable immune deficiency, or hypogammaglobulinemia, has recurrent bacterial infections similar to those seen with Bruton's disease. The patient has low levels of circulating antibodies (immunoglobulins) of all classes.

Hypogammaglobulinemia differs from Bruton's disease in that it usually first appears later (in adolescence or young adulthood), it occurs almost equally in men and women, and the infections are less severe. Common problems include giardiasis (intestinal infection with *Giardia lamblia*), pneumonia, sinusitis, gastric cancer, bronchiectasis, and gallstones.

Treatment is similar to that for Bruton's disease. Regular infusions of immune serum globulin and regular or intermittent use of antibiotics protect the affected person against infection.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use Standard Precautions for all patients regardless of age, gender, race or ethnicity, sexual orientation, education level, and profession.
- Ask patients about advance directives, and document the status.
- Use good handwashing techniques before providing any care to a patient who is immune deficient.
- Ensure the confidentiality of the patient's HIV status.

Health Promotion and Maintenance

- Identify patients at high risk for infection because of work environment or leisure activities.
- Urge all patients who are HIV positive to use condoms and other precautions during sexual intimacy even if the partner is also HIV positive.
- Teach patients with protein-calorie malnutrition what foods to include in the diet.
- Teach the patient and family about the manifestations of infection and when to seek medical advice.

Psychosocial Integrity

- Treat all patients, regardless of diagnosis, with dignity.
- Do not assume that any visitor or family member knows the patient's diagnosis.

- Pace your interview to match the learning needs and energy level of each patient.
- Encourage the patient to express his or her feelings about a change in health status or the diagnosis of an "incurable" disease.
- Refer patients newly diagnosed with HIV infection to local resources and support groups.
- Urge all patients who are HIV positive to inform their sexual partners of their HIV status.
- Explain all diagnostic procedures, restrictions, and follow-up care to the patient scheduled for tests.
- Allow patients who have a change in physical appearance to mourn this change.

Physiological Integrity

- Urge patients to adhere to their antiviral drug regimen.
- Pace nonurgent health care activities to reduce the risk for fatigue among patients with AIDS.
- Teach patients the expected side effects and possible adverse reactions to prescribed drugs.
- Assess the immune-deficient patient every shift for manifestations of infection. Document the assessment findings, and report any manifestation of infection immediately to the health care provider.
- Assess the skin integrity of the perianal region of a patient with AIDS-related diarrhea after every bowel movement.

Care of Patients with Immune Function Excess: Hypersensitivity (Allergy) and Autoimmunity

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Verify that known hypersensitivities of each patient are documented in the medical record and communicated to all members of the health care team.
2. Coordinate with other members of the health care team to ensure a safe environment for the patient with a latex allergy.
3. Implement measures to prevent anaphylaxis.

Health Promotion and Maintenance

4. Encourage all patients with a severe allergy or history of anaphylaxis to wear a medical alert bracelet or other identification.

5. Teach patients with allergies how to avoid known allergens and, if needed, how to self-inject epinephrine.

Physiological Integrity

6. Describe allergy testing techniques.
7. Compare the characteristics and manifestations of type I, type II, type III, type IV, and type V hypersensitivity reactions.
8. Prioritize care for the patient experiencing anaphylaxis.
9. Explain the rationale for types of drug therapy for autoimmune disorders.
10. Identify the manifestations of hypersensitivity reactions.
11. Prioritize care for the patient experiencing anaphylaxis.

Most of the time, the inflammatory and immune responses are helpful for *protection* against infection and cancer development. However, when inflammation or immune responses are prolonged or excessive or occur at an inappropriate time, normal tissues are damaged. These responses are “overreactions” to invaders and foreign antigens and are known as *hypersensitivity* or *allergic responses*. When these responses fail to recognize and protect self cells, normal body tissues are attacked and harmed. This type of reaction is known as an *autoimmune response*. Hypersensitivity and autoimmune responses can severely damage cells, tissues, and organs (Abbas et al., 2010).

HYPERSENSITIVITIES/ALLERGIES

Hypersensitivity or **allergy** is an increased or excessive response to the presence of an **antigen** (foreign protein or allergen) to which the patient usually has been previously exposed. These responses cause problems that range from uncomfortable (e.g., itchy, watery eyes or sneezing) to life threatening (e.g., allergic asthma, anaphylaxis, bronchoconstriction, or circulatory collapse). The terms *hypersensitivity* and *allergy* are used interchangeably. Hypersensitivity reactions are classified into five basic types, determined by differences in timing, pathophysiology, and clinical manifestations

TABLE 22-1 MECHANISMS AND EXAMPLES OF TYPES OF HYPERSENSITIVITIES

MECHANISM	CLINICAL EXAMPLES
Type I: Immediate Reaction of IgE antibody on mast cells with antigen, which results in release of mediators, especially histamine	Hay fever Allergic asthma Anaphylaxis
Type II: Cytotoxic Reaction of IgG with host cell membrane or antigen adsorbed by host cell membrane	Autoimmune hemolytic anemia Goodpasture's syndrome Myasthenia gravis
Type III: Immune Complex-Mediated Formation of immune complex of antigen and antibody, which deposits in walls of blood vessels and results in complement release and inflammation	Serum sickness Vasculitis Systemic lupus erythematosus Rheumatoid arthritis
Type IV: Delayed Reaction of sensitized T-cells with antigen and release of lymphokines, which activates macrophages and induces inflammation	Poison ivy Graft rejection Positive TB skin tests Sarcoidosis
Type V: Stimulated Reaction of autoantibodies with normal cell-surface receptors, which stimulates a continual overreaction of the target cell	Graves' disease B-cell gammopathies

IgE, Immunoglobulin E; IgG, immunoglobulin G; TB, tuberculosis.

(Table 22-1). Each type may occur alone or along with one or more other types (McCance et al., 2010).

TYPE I: RAPID HYPERSENSITIVITY REACTIONS

Type I, or rapid, hypersensitivity, also called *atopic allergy*, is the most common type of hypersensitivity. This type results from the increased production of the immunoglobulin E (IgE) antibody class. Acute inflammation occurs when IgE responds to an antigen, such as pollen, and causes the release of histamine and other vasoactive amines from basophils, eosinophils, and mast cells. Examples of type I reactions include anaphylaxis and allergic asthma (discussed in Chapter 32); atopic allergies such as hay fever and allergic rhinitis; and allergies to specific allergens such as latex, bee venom, peanuts, iodine, shellfish, drugs, and thousands of other environmental antigens. Allergens can be contacted in these ways:

- Inhaled (plant pollens, fungal spores, animal dander, house dust, grass, ragweed)
- Ingested (foods, food additives, drugs)
- Injected (bee venom, drugs, biologic substances such as contrast dyes)
- Contacted (latex, pollens, foods, environmental proteins)

Some reactions occur just in the areas exposed to the antigen, such as the mucous membranes of the nose and eyes, causing

symptoms of rhinorrhea, sneezing, and itchy, red, watery eyes. Other reactions may involve all blood vessels and bronchiolar smooth muscle causing widespread blood vessel dilation, decreased cardiac output, and bronchoconstriction. This condition is known as **anaphylaxis**. When symptoms of anaphylaxis occur in a patient who has not been previously exposed to the allergen, the condition is known as an **anaphylactoid** reaction (Watson, 2010).

ALLERGIC RHINITIS

Pathophysiology

Allergic rhinitis, also called *hay fever*, is triggered by reactions to airborne allergens, especially plant pollens, molds, dust, animal dander, wool, food, and air pollutants. Some acute episodes are “seasonal,” tending to recur at the same time each year. They often coincide with the timing of large environmental exposure and last only a few weeks. Chronic rhinitis, or perennial rhinitis, tends to occur intermittently (with no predictable seasonal pattern) or continuously when a person is exposed to certain allergens. In “nonallergic rhinitis,” the same manifestations are present although no allergic cause is identified and the immune system does not appear to be involved.

On first exposure to an **allergen** (an antigen that provokes allergic sensitization), the person responds by making antigen-specific IgE. This antigen-specific IgE binds to the surface of basophils and mast cells (see Fig. 19-9 on p. 311 in Chapter 19). These cells have many granules containing vasoactive amines (including histamine) that are released when stimulated. Once the antigen-specific IgE is formed, the person is sensitized to that allergen.

In a type I allergic reaction, the already sensitized person is re-exposed to the provoking allergen. The resulting response has a primary phase and a secondary phase. In the primary phase, the allergen binds to two adjacent IgE molecules on the surface of a basophil or mast cell, which breaks or distorts the cell membrane. These changes cause the cell membrane to open and release the vasoactive amines within the granules into the tissue fluids (Fig. 22-1).

The most common vasoactive amine is *histamine*, a short-acting biochemical. Histamine causes capillary leak, nasal and conjunctival mucus secretion, and itching (pruritus), often occurring with erythema (redness). These symptoms last for about 10 minutes after histamine is first released. When the allergen is continuously present, mast cells continuously release histamine and other proteins, prolonging the response.

The secondary phase results from the release of other proteins. These other proteins draw more white blood cells to the area and stimulate a more general inflammatory reaction through actions of leukotriene and prostaglandins (other mediators of inflammation; see Chapter 19). This reaction occurs in addition to the allergic reaction stimulated in the primary phase. The resulting inflammation increases the clinical manifestations and is probably responsible for continuing the response.

The tendency to produce IgE in response to antigen exposure is based on genetic inheritance, but no single gene has been found to be responsible. Although allergic tendencies are inherited, specific allergies are *not* inherited (Nussbaum et al., 2007). For example, a mother who has

FIG. 22-1 Degranulation and histamine release. **A**, Mast cell with IgE. **B**, Mast cell degranulation and histamine release when allergen binds to IgE.

an allergy to penicillin but not to peanuts may have a child with an allergy to peanuts but not to penicillin. About 50% of patients with allergic rhinitis have one parent with type I allergies. Atopic allergies, including allergic rhinitis, affect about 10% of the population in North America (McCance et al., 2010).

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

An accurate and detailed history helps identify possible allergic rhinitis. Ask the patient to describe the onset and duration of problems in relation to possible allergen exposure. Ask about work, school, and home environments and about possible exposures through hobbies, leisure time, or sports activities. Because a tendency toward type I allergic responses can be inherited, ask about the presence of allergies among close relatives.

Physical Assessment/Clinical Manifestations

The patient with allergic rhinitis usually has **rhinorrhea** (a “runny” nose), a “stuffy” nose, and itchy, watery eyes. He or she may breathe through the mouth, and the voice has a nasal sound. Drainage from the nose is usually clear or white. The nasal mucosa appears swollen and pink. The patient may have a headache or feel pressure over the frontal and maxillary sinuses. Placing a penlight directly on the skin over the sinuses and observing for a glow (*transillumination*) usually shows reduced glow when rhinitis is present. If nasal secretions drip posteriorly, he or she may have a dry, scratchy throat and pharyngitis. The patient often feels as though he or she has a cold that has lasted longer than a week. Fever is rare unless an infection occurs with the rhinitis.

Laboratory Assessment

A complete blood count (CBC) and differential indicate the presence of an allergic response by an increase in eosinophils. A patient with severe seasonal allergic rhinitis may have an eosinophil count as high as 12% (normal being 1% to 2%). Some patients have an increased total white blood cell (WBC) count, but the percentage of neutrophils remains normal (55% to 70%). If an acute infection occurs with allergic rhinitis, both the total WBC count and the number of neutrophils increase.

Other laboratory tests that indicate the presence of an allergic reaction include serum immunoglobulin E (IgE) levels and the radioallergosorbent test (RAST). A normal level of IgE for adults is about 39 IU/mL (or <100 IU/mL). This level can increase greatly with allergies. The usual IgE test does not indicate the specific allergen—only the tendency to have allergic responses. The radioimmunosorbent test (RIST) shows the blood level of IgE directed against a specific antigen and thus can determine specific allergies. The expense of this study limits its use in allergy testing.

Allergy Testing

Skin testing can show which specific allergens are the cause of most type I reactions. Skin testing can be performed as scratch testing and intradermal testing. Patch testing is often reserved for contact dermatitis and other manifestations of type IV hypersensitivities.

A scratch or prick test can show an *immediate* hypersensitivity reaction to an allergen. Scratch tests are used in routine allergy testing to determine the cause of allergic rhinitis, asthma, urticaria (hives), or any other type I reactions. Allergens introduced through a scratch or prick cause a localized reaction (wheal) when the test result is positive. Results are usually determined after 15 to 20 minutes.

Patient Preparation. For best results, systemic glucocorticoids and antihistamines are discontinued for up to 4 weeks

before the test to avoid suppressing an allergic response during the test. Nasal sprays to reduce mucous membrane swelling are permitted, except for sprays that contain an antihistamine. Some allergists recommend that aspirin and other NSAIDs also be withheld before allergy testing.

Procedure. The best site for scratch testing is the inside of the forearm or on the back. Other sites are used if a rash or skin problem is present on the arms or back. Gently clean the skin with soap and water, and remove surface oils with alcohol.

Small drops of sera containing different known allergens are placed on the skin. The skin is scratched or pricked through the drop with a bifurcated skin testing needle. Control drops are also applied to determine how a person reacts to substances that do not normally stimulate a reaction (negative control) and to substances that normally should stimulate a reaction (positive control). Normal saline drops are negative controls, and histamine drops are positive controls. The allergen-tested areas are examined for the presence and size of positive reactions. These areas are then compared with the control areas. Areas showing erythema and wheal formation are considered positive for that antigen. Degree of sensitivity is estimated by the size of the response.

Serious reactions in response to scratch testing are rare. Ensure that emergency equipment, including manual resuscitation bag, oxygen, suction equipment, IV infusion set, and drugs for anaphylaxis (epinephrine and diphenhydramine), is available during a scratch test.

Follow-up Care. After testing is completed, wash the solution from the skin. Topical steroids and oral antihistamines may be given to reduce itching and increase patient comfort. If an antihistamine that causes sedation is given, another person must drive the patient home.

Repeat open application testing (ROAT) is a form of self-administered patch testing that can help determine which hygiene or beauty products are responsible for a person's contact dermatitis (Gelpi & Jacob, 2008). (Hygiene, laundry, and beauty products are the most frequent causes of contact dermatitis.) Often, just one application of a suspected allergen does not produce a positive result. With ROAT, the person showers and then draws a 3-cm circle on the inner aspect of the upper arm. The person then selects one product as a suspected allergen and applies it to the circled area. The product is applied to the area twice daily for 7 days. The patient is instructed to protect the area from sunlight and to check it daily for a reaction. A positive reaction may include the presence of increased redness, small bumps, water blisters, or skin scaling. Once a product is identified as an allergen, the patient avoids using it.

Intradermal testing is reserved for substances that are strongly suspected of causing allergy but did not test positive with scratch testing. Intradermal testing increases the risk for an adverse reaction, including anaphylaxis, but it is usually a safe procedure. Ensure that emergency equipment is in the room with the patient. Small amounts of testing sera (0.1 mL) are injected intradermally on the patient's upper arm and the area is observed for erythema and wheal formation. The degree of allergy is estimated by the size of the response. Patient preparation and follow-up care are the same as for scratch testing.

Oral food challenges are used for patients who have allergic rhinitis when the allergen is eaten and does not come into

direct contact with the nasal mucosa. This type of testing is used to identify specific allergens if skin testing is not conclusive and if keeping a food diary has failed to determine the offending food items. The test requires the patient to eliminate suspected foods for 7 to 14 days before testing. After this time, the patient is directed to eat specific suspected food for at least 1 day and to monitor for manifestations of allergy. When many food allergies are present, the patient may have to eat only one food type per day of testing. *Oral food challenges are not performed with foods that are known to cause anaphylactic reactions in the patient.*

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client's complete blood count (CBC) with differential has the following values. Which value indicates to the nurse that the client is having some type of allergic reaction?

- A. Total white blood cell (WBC) count 100%
- B. Eosinophils 11%
- C. Lymphocytes 38%
- D. Neutrophils 66%

INTERVENTIONS

Common interventions for allergy management include avoidance therapy, drug therapy, complementary and alternative therapies, and desensitization therapy. Many patients use a combination of these types of therapy for management of allergic rhinitis and other manifestations of type I allergy.

Avoidance Therapy

Avoidance therapy can be successful when specific allergens have been identified. Urge the patient to avoid direct or close contact with these agents. Some allergens, such as certain foods or drugs, may be easy to avoid. Other substances, such as pollen, mold, or dust mites, may require environmental changes.

Teach patients that many airborne allergens can be reduced by air-conditioning and air-cleaning units. In addition, removing cloth drapes, upholstered furniture, and carpeting reduces airborne allergens. Covering mattresses and pillows with plastic or an ultrafine mesh cover also reduces exposure to dust mites and mold, as does laundering bed linens weekly in hot water and detergent.

Pet-induced allergies pose special challenges. Sometimes simple interventions, such as keeping pets out of the bedroom and thorough cleaning of the room to remove animal hair and dander, may reduce symptoms. Frequent bathing of the pet or keeping the pet outdoors can decrease allergen exposure. Depending on the severity of the allergy and how well other methods provide relief, pets with fur, feathers, or dander may need to be removed from the household.

Drug Therapy

Drug therapy for symptom relief may be tried when avoidance therapy is impractical. It can be effective in reducing the allergic response and making the patient more comfortable. Drug therapy involves the use of steroidal and nonsteroidal agents (to reduce inflammation), vasoconstrictors, antihistamines, mast cell stabilizers, and drugs that inhibit the release or action of leukotrienes. Some drugs reduce the response, and other drugs prevent the response.

Decongestants are available as systemic oral drugs or nasal sprays. These drugs do not clear the allergen or prevent the release of mediators such as histamine. They have actions similar to adrenergic drugs and work by causing vasoconstriction in the inflamed tissue, thereby reducing the edema. Decongestants often contain ephedrine, phenylephrine, or pseudoephedrine. Secretions are reduced when vasoconstricting drugs are combined with an anticholinergic drug, such as scopolamine or atropine. Many combination decongestants are available by prescription and as over-the-counter cold and allergy drugs. Side effects include dry mouth, increased blood pressure, and sleep difficulties.

! NURSING SAFETY PRIORITY

Drug Alert

Because effects are systemic, teach patients with high blood pressure, glaucoma, or urinary retention to consult with a health care professional before taking any decongestant.

Antihistamines block histamine from binding to the receptor. This action prevents vasodilation and capillary leak. Many antihistamines also decrease secretions. Some antihistamines, such as diphenhydramine (Benadryl, Allerdryl 🍁) and chlorpheniramine (Allergy, Aller-Chlor, Chlor-Trimeton), often induce sedation. Newer antihistamines, such as desloratadine (Clarinet), cetirizine (Zyrtec), and fexofenadine (Allegra), are less sedating. Not every patient responds to each drug in the same way.

Corticosteroids decrease inflammatory and immune responses in many ways, one of which is by preventing the synthesis of mediators. Corticosteroid nasal sprays can prevent the symptoms of rhinitis. Systemic corticosteroids can produce severe side effects. These drugs are avoided for rhinitis and are used only on a short-term basis for other problems associated with type I reactions.

Mast cell stabilizing drugs include nasal sprays, such as cromolyn sodium (Nasal crom), that prevent mast cell membranes from opening when an allergen binds to IgE. Thus these drugs prevent the symptoms of allergic rhinitis but are not useful during an acute episode.

Leukotriene modifiers may be used to treat allergic rhinitis. Zileuton (Zyflo) prevents leukotriene synthesis. (See [Chapter 19](#) for a discussion of the role of leukotriene in inflammatory and allergic responses.) Zafirlukast (Accolate) blocks the leukotriene receptor. Both are oral agents and work best in the prevention of allergic rhinitis.

Complementary and Alternative Therapy

Complementary and alternative therapies have helped some patients with rhinitis obtain relief, especially through the use of aromatherapy. Possible mechanisms of action include competition and desensitization. Some patients with pollen allergies report decreased problems after eating unprocessed honey.

Desensitization Therapy

Desensitization therapy, commonly called “allergy shots,” may be needed when allergens are identified and cannot be avoided easily. It involves subcutaneous injections of small amounts of the allergen. After the allergen has been identified, a very dilute injection solution (1:100,000 or 1:1,000,000)

of the allergen is compounded. A 0.05-mL dose of this solution is injected subcutaneously. Usually an increasing dose is given weekly (or more often) until the patient is receiving a 0.5-mL dose. The patient is then started on the lowest dose of the next higher concentration of allergen solution. The process is repeated with increasing concentrations of allergen solutions until the patient is receiving the maximum dose of the greatest concentration (usually 1:100), depending on his or her response. Injections are usually given at weekly intervals during the first year, every other week for the second year, and then every 3 to 4 weeks for the third year. The recommended course of treatment is about 5 years.

Desensitization appears to reduce allergic responses by competition. In theory, the very small amounts of allergen first injected are too low to bind to the IgE already present but are enough to induce immunoglobulin G (IgG) production against that allergen. Because IgG is not associated with either mast cells or basal cells, allergens that bind to IgG do not trigger allergic responses. IgG removes the allergen from the body by precipitation (see [Chapter 19](#)). By gradually increasing the allergen injection, large amounts of IgG are produced against the allergen. When the patient is then exposed to the allergen in the environment, the IgG binds to it and clears it from the body before IgE can bind to it and trigger an allergic reaction. Because so much more IgG can be produced compared with IgE, IgG is successful in the competition to bind the allergen.

ANAPHYLAXIS

Pathophysiology

Anaphylaxis, the most dramatic and life-threatening example of a type I hypersensitivity reaction, occurs rapidly and systemically. It affects many organs within seconds to minutes after allergen exposure. Anaphylaxis is not common, although the incidence appears to be rising along with the general increase in the incidence of allergic reactions. The episodes can vary in severity, and *it can be fatal*. *The major factor in fatal outcomes for anaphylaxis is a delay in the administration of epinephrine* (Walker et al., 2010; [Watson, 2010](#); [White, 2010](#)). Many substances can trigger anaphylaxis in a susceptible person ([Table 22-2](#)). Drugs and dyes are more common causes of anaphylaxis in acute care settings; food and insect stings/bites are more common causes of anaphylaxis in community settings.

Health Promotion and Maintenance

Anaphylaxis has a rapid onset and a potentially fatal outcome (even with appropriate medical intervention); thus prevention is critical. *Teach the patient with a history of allergic reactions to avoid allergens whenever possible, to wear a medical alert bracelet, and to alert health care personnel about specific allergies*. Some patients must carry an emergency anaphylaxis kit (e.g., a kit with injectable epinephrine, sometimes called a “bee sting kit”) or an epinephrine injector, such as the EpiPen or Twinject automatic injector. The EpiPen device is a spring-loaded injector that delivers 0.3 mg of epinephrine per 2-mL dose ([Fig. 22-2](#)). Teach patients who have been prescribed the device how to care for and use it ([Chart 22-1](#)).

The medical records of patients with a history of anaphylaxis should prominently display the list of specific allergens. Ask the patient about drug allergies before giving any drug or

TABLE 22-2 COMMON AGENTS THAT CAUSE ANAPHYLAXIS**Drugs/Foreign Proteins**

Antibiotics (penicillin, cephalosporins, tetracycline, sulfonamides (especially Bactrim and Septra), streptomycin, vancomycin, chloramphenicol, amphotericin B, others)
 Adrenocorticotrophic hormone, insulin, vasopressin, protamine*
 Allergen extracts, muscle relaxants, hydrocortisone, vaccines, local anesthetics (lidocaine, procaine)*
 Angiotensin-converting enzyme (ACE) inhibitors
 Angiotensin receptor blockers (ARBs)
 Chemotherapy agents (antineoplastic drugs)
 Monoclonal antibodies
 Whole blood, cryoprecipitate, immune serum globulin*
 Radiocontrast media*
 Opiates

FOODS

Peanuts
 Shellfish
 Eggs
 Legumes, nuts
 Grains
 Berries
 Preservatives
 Bananas

OTHER AGENTS

Pollens
 Molds
 Latex
 Other

Insects/Animals

Hymenoptera: bees, wasps, hornets
 Fire ants
 Snake venom

*Anaphylaxis caused by these substances is probably a result of direct mast cell degranulation rather than an IgE-mediated hypersensitivity event.

**FIG. 22-2** EpiPen and EpiPen Jr. self-injectors for epinephrine.

therapeutic agent. If he or she has a known allergy, be sure to document this response in the medical record and communicate the allergy to other members of the health care team. Skin tests should be performed before giving any substance that has a high incidence of causing anaphylactic reactions, such as iodine-containing dyes. Be aware of common cross-reacting agents. For example, a patient who is allergic to penicillin is also likely to react to cephalosporins because both have a similar chemical structure. People who have an allergy to bananas, avocados, and some nuts are more likely to have a latex allergy, although this is not universal.

**CULTURAL AWARENESS**

The types of substances that are common causes of severe allergic and anaphylactic reactions vary geographically. For example, peanut allergies are common in North America. However, in China, where peanuts are a common food, it is not a common allergen. Peanut preparation is more likely to be by boiling or frying in China, which may have an impact on its ability to produce an allergic response. In Israel, the most common food allergen is sesame (White, 2010).

CHART 22-1 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT**Care and Use of Automatic Epinephrine Injectors**

- Practice assembly of injection device with a non-drug-containing training device provided through the injection device manufacturer.
- Keep the device with you at all times.
- When needed, inject the drug into the top of your thigh, slightly to the outside, holding the device so that the needle enters straight down.
- You can inject the drug right through your pants; just avoid seams and pockets where the fabric is thicker.
- Use the device when *any* symptom of anaphylaxis is present and call 911. It is better to use the drug when it is not needed than to not use it when it is needed!!!
- Whenever you need to use the device, get to the nearest hospital for monitoring for at least the next 4 to 6 hours.
- Have at least two drug-filled devices on hand in case more than one dose is needed.
- Protect the device from light and keep at room temperature.
- Store the device in the case provided by the manufacturer (when at home, store in the refrigerator).
- Keep safety cap in place until you are ready to use the device.
- Check the device for:
 - Expiration date—if the date is close to expiring or has expired, obtain a replacement device*
 - Drug clarity—if the drug is discolored, obtain a replacement device
 - Security of cap—if the cap is loose or comes off accidentally, obtain a replacement device

*Some manufacturers have an automatic notification service to let you know your device is about to expire.

Take precautionary measures if an agent must be used despite a history of allergic reactions. Start an IV solution, and place intubation equipment and a tracheostomy set at the bedside. The patient is often premedicated with diphenhydramine (Benadryl, Allerdryl) or a corticosteroid. The allergy-causing substance is given first intradermally, then subcutaneously, and then intramuscularly in increasing doses at 20- to 30-minute intervals so the initial dose by the next route does not exceed the final dose by the previous route.

PATIENT-CENTERED COLLABORATIVE CARE**ASSESSMENT**

Problems with anaphylaxis management include that it is rare and initial symptoms may be subtle, such as sudden severe abdominal cramping and diarrhea. A set of three criteria, listed in Chart 22-2, for diagnosis of anaphylaxis was developed and accepted in 2006 by an international symposium (Sampson et al., 2006). A patient is considered to have anaphylaxis whenever any *one* of these three criteria is met.

A patient having an anaphylactic reaction first has feelings of uneasiness, apprehension, weakness, and impending doom. Often the patient is anxious and frightened. These feelings are followed, often quickly, by generalized itching and urticaria (hives). Erythema and sometimes **angioedema** (diffuse swelling) of the eyes, lips, or tongue occur next

CHART 22-2 KEY FEATURES

Anaphylaxis**Clinical Criteria 1**

Onset within minutes to hours of skin or mucous membrane problems involving swollen lips, tongue, soft palate, uvula; widespread hives; pruritus; or flushing along with any *one* of these new onset symptoms:

- Respiratory distress or ineffectiveness:
 - Dyspnea
 - Bronchospasms
 - Wheezes
 - Stridor
 - Hypoxia
 - Cyanosis
 - Peak expiratory rate flow lower than the patient's usual
- Hypotension or any indication of reduced perfusion resulting in organ dysfunction:
 - Loss of consciousness
 - Incontinence
 - Hypotonia
 - Absent deep tendon reflexes

Clinical Criteria 2

Onset within minutes to hours of *two* or more of these symptoms after a patient has been exposed to a potential allergen:

- Skin or mucous membrane problems involving swollen lips, tongue, soft palate, uvula; widespread hives; pruritus; or flushing
- Respiratory distress or ineffectiveness as evidenced by any dyspnea, bronchospasms, wheezes, stridor, hypoxia, cyanosis, or peak expiratory rate flow lower than the patient's usual
- Hypotension or any indication of reduced perfusion resulting in organ dysfunction, such as loss of consciousness, incontinence, hypotonia, or absent deep tendon reflexes
- Persistent GI problems such as nausea or vomiting, cramping, abdominal pain

Clinical Criteria 3

Onset within minutes to hours of hypotension with systolic blood pressure lower than 90 mm Hg or 30% lower than the patient's baseline systolic pressure.

Modified from Sampson, H., Muñoz-Furlong, A., Campbell, R., Adkinson, N.F., Jr., Bock, S.A., Branum, A., et al. (2006). Second symposium on the definition and management of anaphylaxis: Summary report—Second National Institute of Allergy and Infectious Disease/Food Allergy and Anaphylaxis Network symposium. *Journal of Allergy and Clinical Immunology*, 117(2), 391-397.

(Fig. 22-3). Intensely itchy skin wheals or hives may appear and sometimes merge to form large, red blotches.

Histamine and other biochemicals cause bronchoconstriction, mucosal edema, and excess mucus production. Respiratory symptoms include congestion, rhinorrhea, dyspnea, and increasing respiratory distress with audible wheezing.

On auscultation, crackles, wheezing, and reduced breath sounds are heard. Patients may have laryngeal edema as a “lump in the throat,” hoarseness, and stridor (a crowing sound). Distress increases as the tongue and larynx swell and more mucus is produced. Stridor and anxiety increase as the airway begins to close. Increasing bronchoconstriction can lead to reduced chest excursion and impaired air movement. Respiratory failure may follow from laryngeal edema, suffocation, or lower airway constriction causing hypoxemia (poor blood oxygenation).

The patient is usually hypotensive and has a rapid, weak, irregular pulse. These findings are caused by vasodilation and extensive capillary leak. He or she is faint and diaphoretic with increasing anxiety and confusion.

FIG. 22-3 Angioedema of the face, lips, and mouth.

! NURSING SAFETY PRIORITY**Critical Rescue**

If you suspect a patient is having an anaphylactic reaction, immediately call the Rapid Response Team, because most anaphylactic deaths are related to treatment delay. If the patient is not treated immediately, he or she may lose consciousness. Dysrhythmias, shock, and cardiopulmonary arrest may occur within minutes as intravascular volume is lost and the heart becomes hypoxic.

INTERVENTIONS

Emergency interventions are listed in Chart 22-3. Assess respiratory function first. Emergency respiratory management is critical during an anaphylactic reaction, because the severity of the reaction increases with time. Not only can the upper airway be affected, but also bronchoconstriction of the lower airways can quickly impair airflow and lead to hypoxic arrest. Immediately establish or stabilize the airway. If an IV drug is suspected to be causing the anaphylaxis, stop the drug immediately but do not remove the venous access because restarting an IV may be very difficult if the patient experiences a rapid decline in blood pressure. Instead, change the IV tubing and hang normal saline. More emergency interventions for patients with anaphylaxis are listed in Chart 22-3.

The patient with anaphylaxis is usually anxious or frightened and often expresses a sense of impending doom. Stay with the patient and reassure him or her that the appropriate interventions are being instituted.

Epinephrine (1:1000) 0.3 to 0.5 mL is the first-line drug for anaphylaxis. It is given IM or IV when symptoms of anaphylaxis appear (see Chart 22-3). This drug constricts blood vessels, improves cardiac contraction, and dilates the bronchioles. The same dose may be repeated every 5 minutes if needed. Other drugs used to treat anaphylaxis are listed in Chart 22-4.

CHART 22-3 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Emergency Care of the Patient with Anaphylaxis

- Immediately assess the respiratory status, airway, and oxygen saturation of patients who show any symptom of an allergic reaction.
- Call the Rapid Response Team.
- Ensure that intubation and tracheotomy equipment is ready.
- Apply oxygen using a high-flow, non-rebreather mask at 90% to 100%.
- Immediately discontinue the IV drug of a patient having an anaphylactic reaction to that drug. **Do not** discontinue the IV, but change the IV tubing and hang normal saline.
- If the patient does not have an IV, start one immediately and run normal saline.
- Be prepared to administer epinephrine IV or IM.
 - Epinephrine 1:1000 concentration, 0.3 to 0.5 mL IV push
 - Repeat as needed every 5 minutes until the patient responds
- Keep the head of the bed elevated about 10 degrees if hypotension is present; if blood pressure is normal, elevate the head of the bed to 45 degrees or higher to improve ventilation.
- Raise the feet and legs.
- Stay with the patient.
- Reassure the patient that the appropriate interventions are being instituted.

! NURSING SAFETY PRIORITY

Critical Rescue

Administer epinephrine as quickly as possible. Most deaths from anaphylaxis are related to delay in epinephrine administration.

Antihistamines such as diphenhydramine (Benadryl, Allerdryl ) 25 to 100 mg are second-line drugs and usually are given IV or IM for angioedema and urticaria. If needed, an endotracheal tube may be inserted or an emergency tracheostomy may be performed.

If the patient can breathe independently, give oxygen to reduce hypoxemia. Start oxygen therapy via a high-flow non-rebreather facemask at 90% to 100% before arterial blood gas results are obtained. Monitor pulse oximetry to determine oxygenation adequacy, with the goal of maintaining oxygen saturation greater than 90%. Arterial blood gases may be ordered to determine therapy effectiveness. Use suction to remove excess mucus and other secretions, if indicated. Continually assess the patient's respiratory rate and depth. Assess breath sounds continually for bronchospasm, wheezing, crackles, and stridor. Elevate the bed to 45 degrees unless severe hypotension is also present.

For bronchospasms, the patient may be given an inhaled beta-adrenergic agonist such as metaproterenol (Alupent) or albuterol (Proventil) via high-flow nebulizer every 2 to 4 hours. Corticosteroids are added to emergency interventions;

CHART 22-4 COMMON EXAMPLES OF DRUG THERAPY

Anaphylaxis

DRUG	MECHANISM	SIDE EFFECTS
Sympathomimetics (First-Line Drugs)		
Epinephrine (Adrenalin)	Rapidly stimulates alpha- and beta-adrenergic receptors of autonomic nervous system (alpha: vasoconstriction; beta: bronchodilation).	Pallor, tachycardia and palpitations, nervousness, muscle twitching, sweating, anxiety, insomnia, hypertension, headache, hyperglycemia.
Isoproterenol (Isuprel)	Stimulates beta-adrenergic receptors, relaxing bronchial smooth muscles and dilating vessels.	Same as for epinephrine.
Ephedrine sulfate (Vatrolol)	Similar to isoproterenol, but with longer duration of action.	Same as for epinephrine.
Antihistamines (Second-Line Drugs)		
Diphenhydramine HCl (Allerdryl 🇨🇦, Benadryl)	Competes with histamine for H ₁ receptors on effector cells, thus blocking effects of histamine on bronchioles, gastrointestinal tract, and blood vessels.	Drowsiness, confusion, insomnia, headache, vertigo, photosensitivity, diplopia, nausea, vomiting, dry mouth.
Corticosteroids (Second-Line Drugs)		
Hydrocortisone sodium succinate (Solu-Cortef) (IV/IM)	Anti-inflammatory; inhibits mast cell degranulation.	Fluid and sodium retention, hypertension, cushingoid state, gastric distress, adrenal suppression, psychosis, osteoporosis, susceptibility to infection.
Dexamethasone (Decadron) (IV/IM)		
Methylprednisolone sodium succinate (Solu-Medrol) (IV/IM)		
Prednisone (orally)		
Vasopressors (Support Drugs)		
Norepinephrine (Levophed)	Raises blood pressure and cardiac output in severely decompensated states.	Headache, tachycardia, fibrillation, decreased urine output, hypertension, metabolic acidosis.
Dopamine (Intropin)	Raises blood pressure and cardiac output in severely decompensated states.	Dysrhythmias, tachycardia, hypertension, dyspnea, nausea and vomiting, azotemia, headache.

pulmonary arterial and capillary wedge pressure monitoring are performed. Observe the patient for fluid overload from the rapid drug and IV fluid infusions, and report changes to the health care provider immediately. The patient is discharged from the hospital when respiratory and cardiovascular systems have returned to baseline.

DECISION-MAKING CHALLENGE

Safety; Quality Improvement; Patient-Centered Care

You are the nurse manager on a subacute/rehabilitation unit at a large metropolitan hospital. You overhear the nursing assistant tell the LPN assigned to a 68-year-old patient who had a knee replacement 8 days ago that the patient has a swollen mouth this morning and had difficulty swallowing his toast. You check his chart and discover that he has a documented severe allergy to penicillin only and has not been prescribed that drug before or after surgery. A quick look at his chart indicates he is taking lisinopril (Zestril) and warfarin (Coumadin) daily and is taking hydrocodone (Vicodin) PRN for pain. When you enter his room, you see that his lips and tongue are very swollen and he is drooling. His face and chest are flushed, and he tells you that he feels “itchy all over.”

1. Which manifestations are symptoms of an allergic reaction?
2. Which vital signs are most important for you to assess immediately? Provide a rationale for your answer.
3. Should you notify the patient's surgeon, his internist, or the Rapid Response Team about this change in his condition? Provide a rationale for your answer.
4. What may have precipitated this event and what, if any, steps could be taken to either prevent a similar episode or identify it earlier?
5. Are there any additional resources that could improve the nursing response to this situation? Explain your response.

LATEX ALLERGY

Latex allergy is a type I hypersensitivity reaction in which the specific allergen is a protein found in processed natural latex rubber products. When the allergen enters the body through inhalation or direct contact with blood vessels (e.g., as might occur during surgery), interaction with IgE occurs, leading to a type I reaction. For some people, latex allergen contact is limited to the skin or mucous membranes, causing contact dermatitis, a type IV delayed hypersensitivity reaction (see p. 392). Others may have a “mixed” allergic response to latex, with symptoms of both type I and type IV hypersensitivities. Others may have only one or the other type of reaction.

The incidence of latex hypersensitivity in the general population is increasing. People at greatest risk are those with a high exposure to natural latex products, such as patients with spina bifida, people who routinely use latex condoms, and health care workers who use latex gloves. The incidence of latex allergy among health care workers is falling, largely as a response to reduced use of latex products and subsequent exposure in the workplace.

Ask all patients about their use of and known reactions to natural latex products. Document all food allergies because some have cross-reactivity for latex allergy. In addition, consider your own exposure and risk for reactions to natural latex products.

Avoiding products that contain natural latex proteins can prevent reactions and initial sensitivity. More products, such as surgical gloves, tubing, and vial closures, are now being made from synthetic substances that do not contain latex

proteins. One such product is the glove ElastyLite. Interventions for the patient who has a type I or a type IV reaction to latex are the same as for reactions caused by other allergens.

NURSING SAFETY PRIORITY

Action Alert

Use only latex-free products in the care of a patient with a known latex allergy.

TYPE II: CYTOTOXIC REACTIONS

In a type II (cytotoxic) reaction, the body makes special autoantibodies directed against self cells that have some form of foreign protein attached to them. The autoantibody binds to the self cell and forms an immune complex (see Fig. 19-10 on p. 311 in Chapter 19). The self cell is then destroyed along with the attached protein by phagocytosis or lysis (see Chapter 19). Clinical examples of type II reactions include immune hemolytic anemias, immune thrombocytopenic purpura, hemolytic transfusion reactions (when a patient receives the wrong blood type during a transfusion), Goodpasture's syndrome, and drug-induced hemolytic anemia.

Treatment of type II cytotoxic reactions begins with discontinuing the offending drug or blood product. Plasmapheresis (filtration of the plasma to remove specific substances) to remove autoantibodies may be beneficial. Otherwise, treatment is symptomatic. Complications such as hemolytic crisis and kidney failure can be life threatening.

TYPE III: IMMUNE COMPLEX REACTIONS

In a type III reaction, excess antigens cause immune complexes to form in the blood (Fig. 22-4). These circulating complexes usually lodge in small blood vessel walls. Common sites include the kidneys, skin, joints, and other small blood

FIG. 22-4 An immune complex in a type III hypersensitivity reaction.

vessels. The deposited complexes trigger inflammation, and tissue or vessel damage results.

Many immune complex disorders (mostly connective tissue disorders) are caused by type III reactions. For example, the manifestations of rheumatoid arthritis are caused by immune complexes that lodge in joint spaces followed by destruction of tissue and, later, scarring and fibrous changes. Systemic lupus erythematosus (SLE) has immune complexes lodged in the vessels (vasculitis), the glomeruli (glomerulonephritis), the joints (arthralgia, arthritis), and other organs and tissues. (See [Chapter 20](#) for a discussion of SLE.)

Serum sickness is a group of symptoms that occurs after receiving serum or certain drugs. It is caused by a collection of immune complexes deposited in blood vessel walls of the skin, joints, and kidneys. The most common causes of serum sickness today are penicillin, other antibiotics, and some animal serum-based drugs. Serum sickness is less common now that vaccines are made with human proteins. Agents known to cause serum sickness include antilymphocyte globulin and antithymocyte globulin, used to treat organ transplant rejection.

The patient with serum sickness has fever, arthralgia (achy joints), rash, lymphadenopathy (enlarged lymph nodes), malaise, and possibly polyarthritis and nephritis about 7 to 12 days after receiving the causative agent. Teach him or her about the possibility of serum sickness and what symptoms to look for whenever you give a foreign serum. Also keep emergency equipment and drugs close at hand in case he or she has an anaphylactic reaction.

Serum sickness is usually self-limiting, and symptoms subside after several days. Treatment is usually symptomatic; antihistamines are given for itching and aspirin for arthralgias. Prednisone is given if symptoms are severe.

TYPE IV: DELAYED HYPERSENSITIVITY REACTIONS

In a type IV reaction, the reactive cell is the T-lymphocyte (T-cell). Antibodies and complement are not involved. Sensitized T-cells (from a previous exposure) respond to an antigen by releasing chemical mediators and triggering macrophages to destroy the antigen. Unlike a type I reaction, which occurs immediately, a type IV response typically occurs hours to days after exposure. A type IV reaction consists of a local collection of lymphocytes and macrophages, causing edema, induration, ischemia, and tissue damage at the site.

An example of a small type IV reaction is a positive purified protein derivative (PPD) test for tuberculosis. In a patient previously exposed to tuberculosis, an intradermal injection of this agent causes sensitized T-cells to clump at the injection site, release lymphokines, and activate macrophages. Induration and erythema at the site of the injection appear after about 24 to 72 hours.

Other examples of type IV reactions include contact dermatitis, poison ivy skin rashes, local response to insect stings, tissue transplant rejections, and sarcoidosis.

Patch testing for this type of hypersensitivity involves applying test chemicals that contain the allergen(s) to which the patient has been exposed. The patches remain in place for 48 hours. After removal, the skin areas in contact with the chemical are examined closely for the presence of localized

redness, swelling, and blisters. If a reaction occurs, the patient is given a list of items containing that chemical to be avoided.

Removal of the offending antigen is the major focus of management. The reaction is self-limiting in 5 to 7 days, and the patient is treated symptomatically. Monitor the reaction site and sites distal to the reaction for circulation adequacy. Diphenhydramine (Benadryl) is of minimal benefit for type IV reactions because histamine is not the main mediator. In addition, IgE does not cause this type of reaction and desensitization does not reduce the response. Corticosteroids can reduce the discomfort and help resolve the reaction more quickly.

TYPE V: STIMULATORY REACTIONS

A type V reaction involves excessive stimulation of a normal cell surface receptor by an autoantibody, resulting in a continuous “turned-on” state for the cell. An example of this type of reaction is Graves’ disease, a form of hyperthyroidism. In Graves’ disease, an autoantibody binds to the thyroid-stimulating hormone (TSH) receptor sites on the thyroid gland. This binding continually stimulates thyroid cells to produce thyroid hormones, causing the patient to have severe hyperthyroidism (see [Chapter 66](#)). The manifestations occur even though the thyroid gland itself is completely normal. In a sense, the tissue responding to the autoantibody is “out of control” from the body’s normal feedback system of checks and balances.

For type V reactions involving only one organ, the management focuses on removing enough of the responding (stimulated) tissue to return the function to normal. With Graves’ disease, thyroid tissue is either surgically removed or destroyed with radiation. For type V reactions in which antibody stimulation is more widespread, treatment focuses on reducing the production of autoantibodies through immunosuppression.

AUTOIMMUNITY

Autoimmunity is a process whereby a person develops an inappropriate immune response. In this response, antibodies or lymphocytes are directed against healthy normal cells and tissues. (Antibodies directed against self tissues or cells are known as [autoantibodies](#).) For unknown reasons, the immune system fails to recognize certain body cells or tissues as self and thus triggers immune reactions. The responses, both antibody- and cell-mediated, are similar to normal immune responses against invading organisms, but these reactions are now directed against normal body cells ([Rosen & Casciola-Rosen, 2009](#)). Causes of loss of recognition of self cells are not known but have been associated with viral infection, cancer, and some hematologic disorders.

Examples of diseases that have an autoimmune cause include systemic lupus erythematosus (SLE), polyarteritis nodosa, scleroderma, rheumatoid arthritis, autoimmune hemolytic anemia, rheumatic fever, and Hashimoto’s thyroiditis ([Table 22-3](#)). Other diseases, such as type 1 diabetes mellitus, may have multiple causes, one of which is autoimmune.

Management of autoimmunities depends on the organ or organs affected. *There is no cure.* Anti-inflammatory drugs

TABLE 22-3 KNOWN OR PROBABLE AUTOIMMUNE DISORDERS

DISORDER	AUTOANTIGEN
Systemic Or Non-Organ Specific	
Systemic lupus erythematosus	DNA, DNA proteins
Rheumatoid arthritis	IgG, possibly cartilage
Progressive systemic sclerosis	DNA proteins
Mixed connective tissue disorder	DNA proteins
Scleroderma	Endothelial cells; epithelial cells
Organ Specific	
Autoimmune hemolytic anemia	Erythrocytes
Autoimmune thrombocytopenic purpura	Platelets
Crohn's disease	Crypt epithelial cells
Diabetes mellitus, type I	Islet cells, insulin, insulin receptor
Dermatomyositis	Unknown
Glomerulonephritis	Glomerular basement membranes
Goodpasture's syndrome	Glomerular basement membranes, pulmonary basement membranes
Graves' disease	Thyroid-stimulating hormone receptor
Hashimoto's thyroiditis	Thyroid cell surface
Idiopathic Addison's disease	Adrenal cell
Myasthenia gravis	Acetylcholine receptor, acetylcholine
Pernicious anemia	Intrinsic factor, parietal cell, B ₁₂ complexes
Psoriasis	Stratum corneum
Reiter's syndrome	Possibly collagen, conjunctival cells
Sjögren's syndrome	Salivary gland cells, vaginal mucous cells, lacrimal gland cells
Uveitis	Uveal tract cells (eye)
Vasculitis	Unknown, possibly collagen or endothelial cells

IgG, Immunoglobulin G.

and immunosuppressive drugs are commonly used along with symptomatic treatment.

WOMEN'S HEALTH CONSIDERATIONS

Virtually all autoimmune disorders, especially rheumatic disorders, occur much more commonly among women than men (McCance et al., 2010). The risk for autoimmune disease among women compared with men ranges from 5:1 to 20:1. The frequency of autoimmune disorders in women varies by ethnicity.

SJÖGREN'S SYNDROME

Pathophysiology

Sjögren's syndrome (SS) is a group of problems that often appear with other autoimmune disorders. Problems include dry eyes (sicca syndrome), dry mucous membranes of the nose and mouth (xerostomia), and vaginal dryness. These

problems are caused by autoimmune destruction of the lacrimal, salivary, and vaginal mucus-producing glands (Kruszka & O'Brian, 2009). Often, the patient with SS also has rheumatoid arthritis or fibromyalgia.

Most patients with SS are women 35 to 45 years old. SS occurs more frequently among patients with certain tissue types, specifically HLA-DRW52, HLA-DR3, and HLA-B8. Although an exact triggering agent has not been identified, viral infection is strongly suspected. The three viruses thought to be triggers for the autoimmune changes leading to SS are the human immunodeficiency virus type 1 (HIV-1), human T-cell lymphotropic virus type 1 (HTLV-1), and Epstein-Barr virus (EBV).

Insufficient tears cause inflammation and ulceration of the cornea. Insufficient saliva decreases digestion of carbohydrates, promotes tooth decay, and increases the incidence of oral and nasal infections. Vaginal dryness increases the incidence of infection and may cause pain during sexual intercourse.

PATIENT-CENTERED COLLABORATIVE CARE

The patient with Sjögren's syndrome (SS) usually has blurred vision, burning and itching of the eyes, and thick mattering in the conjunctiva. Difficulty swallowing food is common, and he or she often has changes in taste sensation. Ask about nosebleeds (epistaxis) and frequent upper respiratory infections.

Physical examination reveals enlarged lymph nodes. If rheumatoid arthritis (RA) accompanies SS, the patient has swollen, painful joints and limited joint mobility (see Chapter 20 for a complete discussion of RA). Laboratory assessment may show increased presence of general antinuclear antibodies, anti-SS-A or anti-SS-B antibodies, and elevated levels of IgM rheumatoid factor.

There is no cure for SS. The intensity and the progression of the disorder can be slowed by suppressing immune and inflammatory responses. Drugs used to modulate the immune system in patients with SS include low-dose chemotherapy with methotrexate (Rheumatrex) or cyclophosphamide (Cytoxan). Both drugs have serious long-term side effects, especially on liver and bone marrow function. Other immunosuppressive drugs used to manage SS are corticosteroids, cyclosporine (Gengraf, Neoral, Sandimmune), and hydroxychloroquine (Plaquenil). A monoclonal antibody being investigated for benefit to patients with severe inflammatory manifestations of SS is rituximab (Rituxan) (Kruszka & O'Brian, 2009).

A variety of artificial tears and artificial saliva can help reduce the dry eye and dry mouth symptoms. Teach patients to use humidifiers in the home to increase environmental moisture. Use of water-soluble vaginal lubricants and moisturizers can increase patient comfort and reduce the incidence of vaginitis. Some patients relieve dry mouth with systemic pilocarpine (Salagen). This drug mimics parasympathetic nervous system effects, causing increased salivation. A drug that helps the patient increase tear production is cyclosporine (Restasis) eyedrops.

Another intervention for dry eyes is to block the tear outflow channel (nasal punctum). The punctum can be blocked temporarily with small plugs or can be closed

surgically. Either method allows the tears produced to remain in contact with the eye longer.

GOODPASTURE'S SYNDROME

Pathophysiology

Goodpasture's syndrome is an autoimmune disorder in which autoantibodies are made against the glomerular basement membrane and neutrophils. The two organs with the most damage are the lungs and the kidneys. A person with the disorder may have lung and/or kidney problems. Lung damage is manifested as pulmonary hemorrhage. Kidney damage manifests as glomerulonephritis that may rapidly progress to complete kidney failure (see [Chapters 70 and 71](#)). Unlike other autoimmune disorders, Goodpasture's syndrome usually occurs in adolescent males or young men (McCance et al., 2010). The exact cause or triggering agent is unknown.

PATIENT-CENTERED COLLABORATIVE CARE

Goodpasture's syndrome usually is not diagnosed until serious lung or kidney problems are present. Manifestations include shortness of breath, hemoptysis (bloody sputum), decreased urine output, weight gain, generalized nondependent edema, hypertension, and tachycardia. Chest x-rays show areas of consolidation. The most common cause of death is uremia as a result of kidney failure.

Spontaneous resolution of Goodpasture's syndrome has occurred but is rare. Interventions focus on reducing the immune-mediated damage and performing some type of kidney supportive or replacement therapy.

Drug therapy is the mainstay of treatment for Goodpasture's syndrome. High-dose corticosteroids are most often

used. Other drug therapy to suppress the autoimmune response is the same as that for Sjögren's syndrome (SS).

Additional therapy to reduce immune responses involves plasmapheresis (filtration of the plasma to remove some proteins) to remove the autoantibodies. If the lungs and kidneys do not have permanent damage, patients undergoing plasmapheresis have shown clinical improvement. Some patients using plasmapheresis need infusions of intravenous immunoglobulin (IVIG) to maintain antibody protection against infection.

Depending on the level of kidney function remaining, the patient may need ongoing dialysis. Therapy usually begins with hemodialysis. For long-term therapy, peritoneal dialysis or hemodialysis may be used depending on the patient's health status, ability to self-manage the infusion and drainage systems, and lifestyle (see [Chapter 71](#)).

Kidney transplantation is an option for some patients with Goodpasture's syndrome. After transplantation, kidney function is normal. In rare instances, patients have been disease-free after transplantation. In others, the kidney problems are improved but the lung destruction continues. Some of the drugs used to prevent kidney rejection also suppress the autoimmune response.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

Which precaution is most important for the nurse to teach a client receiving long-term immunosuppressive therapy for an autoimmune disease?

- A. Avoid crowds and people who are ill.
- B. Call your health care provider at the first sign of an infection.
- C. Assess your response to this medication at least once per month.
- D. Be sure to tell your dentist you are taking this therapy before having any dental work.

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing an excess protective response in the form of a severe allergic reaction?

- Possible skin rash, blisters, wheals, especially on the skin at the IV site
- Swelling of the face, lips, tongue (angioedema)
- Difficulty breathing, hoarseness, stridor, wheezing
- Cyanosis
- Increasing anxiety

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate protection as a result of loss of skin integrity?

Perform and interpret physical assessment, including:

- Taking vital signs, especially respiratory rate and depth and blood pressure
- Auscultating all lung fields
- Monitoring oxygen saturation by pulse oximetry

- Checking the accuracy of pulse oximetry readings
- Assessing cognition (Mini-Mental State Examination [MMSE])
- Assessing for the use of accessory muscles
- Assessing for the presence of thick or excessive secretions
- Assessing the patient's ability to cough and clear the airway

Respond by:

- Removing or discontinuing the offending agent
- Ensuring a patent airway
- Notifying Rapid Response Team
- Applying oxygen, and assessing the patient's responses to this intervention
- Maintaining IV access, changing IV tubing, hanging normal saline
- Keeping the patient's head elevated between 10 and 45 degrees

NURSING CONCEPT REVIEW—cont'd

- Preparing to administer IV diphenhydramine and epinephrine
- Staying with the patient

On what should you REFLECT?

- Observe patient for evidence of drug therapy and oxygen therapy effectiveness (adequate tissue perfusion and oxygenation [see Chapter 29]).
- Think about what may have precipitated this episode and what steps could be taken to either prevent a similar episode or identify it earlier.
- Think about what additional resources could improve the nursing response to this situation.

GET READY FOR THE NCLEX® EXAMINATION!**KEY POINTS**

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Ensure that only latex-free products are used for a patient who has a known latex allergy.
- Verify that all allergies are documented in a prominent place in the patient's medical record.
- Keep emergency equipment and drugs (epinephrine, Benadryl, cortisol) in or near the room of a patient with known severe allergies or a history of anaphylaxis.

Health Promotion and Maintenance

- Urge all patients with severe allergies or those who have a history of anaphylaxis to wear a medical alert bracelet.
- Teach the patient and family about the manifestations of allergic reactions and when to seek medical advice.

Psychosocial Integrity

- Stay with the patient in anaphylaxis.
- Explain all diagnostic procedures, restrictions, and follow-up care to the patient scheduled for tests related to hypersensitivities.

- Reassure patients who are in anaphylaxis that the appropriate interventions are being instituted.

Physiological Integrity

- Immediately assess the respiratory status and airway of patients who show any symptom of an allergic reaction.
- Immediately discontinue the IV drug of a patient having an anaphylactic reaction to that drug. Do not discontinue the IV, but change the IV tubing and hang normal saline.
- Hold the dose of any prescribed drug when a patient develops angioedema.
- Give oxygen to any patient in anaphylaxis.
- Teach the patient who has a known drug allergy about which other drugs are likely to stimulate the same reactions.
- Teach the patient who carries an automatic epinephrine injector how to care for, assemble, and use the device. Obtain a return demonstration.

CHAPTER

23

Cancer Development

M. Linda Workman

Animation: Metastatic Spread of Breast Cancer

Audio Glossary

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Help people identify behaviors that reduce the risk for cancer development and cancer death.
2. Teach the recommended screening practices and schedules for specific cancer types.

Physiological Integrity

3. Explain why causes of specific cancers can be hard to establish.
4. Use knowledge of basic biology to understand how normal cells can become malignant.
5. Distinguish the features of normal cells from those of benign tumors and cancer cells.

6. Discuss the roles of oncogenes and suppressor genes in cancer development.
7. Compare the cancer development processes of initiation and promotion.
8. Interpret cancer grading, ploidy, and staging reports.
9. Explain how cancer metastasis occurs and the common sites of distant metastasis.
10. Discuss the role of immunity in protection against cancer.
11. Assess the individual patient's need for genetic testing for cancer predisposition based on family history.

Most common types of altered cell growth, such as moles or skin tags, are **benign** (harmless) and do not require intervention. **Malignant cell growth**, or cancer, however, is serious and, without intervention, leads to death. Cancer is a common health problem in the United States and Canada. Nearly 1.5 million people are newly diagnosed with cancer each year (American Cancer Society [ACS], 2011; Canadian Cancer Society, 2010). Some types of cancer can be prevented; others have better cure rates if diagnosed early. As a nurse, you can have a vital impact in educating the public about cancer prevention and early detection methods.

Although cancer is common today, it is not a new disorder. Some types of cancer are more common today, especially among more affluent societies, than in centuries past. Two reasons for this increase are the longer life expectancy of people in more affluent countries and increased exposure to substances that cause cancer.

Cancer will occur in about 1 of every 3 people currently living in North America (ACS, 2011; Canadian Cancer

Society, 2010), although cancer risk differs for each person. More than 10 million Americans with a history of cancer are alive today, nearly 5 million of whom are considered cured (ACS, 2011).

PATHOPHYSIOLOGY

Growth of cells and tissues is expected during infancy and childhood, and many human body cells continue to “grow” by **mitosis** (cell division) long after maturation is complete. Such cells are located in tissues in which constant damage or wear is likely and continued cell growth is needed to replace dead tissues. Cells of the skin, hair, mucous membranes, bone marrow, and linings of organs such as the lungs, stomach, intestines, bladder, and uterus, among others have the ability to divide throughout a person's life span. The growth of these cells is well controlled, ensuring that only the right number of cells is always present in any tissue or organ.

FIG. 23-1 Tissue growth by hypertrophy and hyperplasia.

FIG. 23-2 Distinctive morphology of some normal cells.

Some tissues and organs stop growing by cell division after development is complete. For example, heart muscle cells no longer divide after fetal life; the number of heart muscle cells is fixed at birth. The size of the heart increases as the person grows because each cell gets larger, but the number of heart muscle cells does not increase. Growth that causes tissue to increase in size by enlarging each cell is **hypertrophy**. Growth that causes tissue to increase in size by increasing the number of cells is **hyperplasia** (Fig. 23-1).

Any new or continued cell growth not needed for normal development or replacement of dead and damaged tissues is called **neoplasia**. This cell growth is always abnormal even if it causes no harm. Whether the new cells are benign or cancerous, neoplastic cells develop from normal cells (*parent cells*). Thus cancer cells were once normal cells but changed to no longer look, grow, or function normally. The strict processes controlling normal growth and function have been lost. To understand how cancer cells grow, it is helpful to first understand the regulation and function of normal cells.

Biology of Normal Cells

Many different normal cells work together to make the whole person function at an optimal level. For optimal function, each cell must perform in a predictable manner.

Specific morphology is the feature in which each normal cell type has a distinct and recognizable appearance, size, and shape, as shown in Fig. 23-2.

A *small nuclear-to-cytoplasmic ratio* means that the nucleus of a normal cell does not take up much space inside the cell. As shown in Fig. 23-2, the size of the normal cell nucleus is small compared with the size of the rest of the cell, including the cytoplasm.

Differentiated function means that every normal cell has at least one special function it performs to contribute to

FIG. 23-3 The cell cycle.

whole-body function. For example, skin cells make keratin, liver cells make bile, cardiac muscle cells contract, nerve cells conduct impulses, and red blood cells make hemoglobin.

Tight adherence occurs because normal cells make proteins that protrude from the membranes, allowing cells to bind closely and tightly together. One such protein is fibronectin, which keeps most normal tissues bound tightly to each other. Exceptions are blood cells. Red blood cells and white blood cells produce no fibronectin and do not usually adhere together.

Nonmigratory means that normal cells do not wander throughout the body (except for blood cells). This occurs in normal cells because they are tightly bound together, which prevents cell wandering from one tissue into the next.

Orderly and well-regulated growth is a very important feature of normal cells. They divide (undergo mitosis) for only two reasons: (1) to develop normal tissue or (2) to replace lost or damaged normal tissue. Even when they are capable of mitosis, normal cells divide only when body conditions, including the need for more cells, adequate space, and sufficient nutrients and other resources, are just right. Cell division (**mitosis**), occurring in a well-recognized pattern, is described by the cell cycle. Fig. 23-3 shows the phases of the cell cycle. The amount of time needed for one cell to divide completely into two cells is the **generation time**. For normal cells, the generation time varies by tissue and organ type.

Living cells not actively reproducing are in a reproductive resting state termed G_0 . During the G_0 period, cells actively carry out their functions but do not divide. Normal cells spend most of their lives in the G_0 state rather than in a reproductive state.

Mitosis makes one cell divide into two cells. These two new cells are identical to each other and to the cell that began mitosis. The steps of entering and completing the cell cycle are tightly controlled. Much of this control is regulated by proteins produced by “suppressor genes.”

Whether a cell enters and completes the cell cycle to form two new cells depends on the presence and absence of specific proteins. Proteins that promote cells to enter and complete cell division are produced by oncogenes and are known as *cyclins*. When cyclins are activated, they allow a cell to leave G_0 and enter the cycle. These activated cyclins then drive the cell to progress through the different phases of the cell cycle and divide. Proteins produced by suppressor genes regulate the amount of cyclins present and ensure that cell division occurs only when it is needed. Thus normal cell division is a balance between the proteins that promote cell division (cyclins) and the proteins that limit cell division (suppressor gene products).

Fig. 23-4 shows the activities of the phases of the cell cycle (described below):

- **G₁.** In this phase, the cell is getting ready for division by taking on extra nutrients, making more energy, and growing extra membrane. The amount of cytoplasm also increases.
- **S.** Because making one cell into two cells requires twice as much of everything, including DNA, the cell must double its DNA content through DNA synthesis. This process occurs in S phase.
- **G₂.** In this phase, the cell makes important proteins that will be used in actual cell division and in normal physiologic function after cell division is complete.
- **M.** The single cell splits apart into two cells (actual mitosis) during M phase.

Contact inhibition is the stopping of further rounds of cell division when the dividing cell is completely surrounded and touched (contacted) by other cells. Of the normal cells that

can divide, each cell divides only when some of its surface is not in direct contact with another cell. Once a normal cell is in direct contact on all surface areas with other cells, it no longer undergoes mitosis. Thus normal cell division is contact inhibited.

Apoptosis is programmed cell death. Not only do normal cells have to divide only when needed and perform their specific differentiated functions, some cells also have to die at the appropriate time to ensure optimum body function. Thus normal cells have a finite life span. With each round of cell division, the telomeric DNA at the ends of the cell’s chromosomes shortens (see Chapter 6). When this DNA is gone, the cell responds to signals for apoptosis. The purpose of apoptosis is to ensure that each organ has an adequate number of cells at their functional peak.

Normal chromosomes (euploidy) is a feature of most normal human cells. These cells have 23 pairs of chromosomes, the correct number for human beings.

Biology of Abnormal Cells

Body cells are exposed to a variety of conditions that can alter how the cells grow or function. When either cell growth or cell function is changed, the cells are considered abnormal. Table 23-1 compares features of normal, benign tumor, and cancer (malignant) cells.

Features of Benign Tumor Cells

Benign tumor cells are normal cells growing in the wrong place or at the wrong time. Examples include moles, uterine fibroid tumors, skin tags, endometriosis, and nasal polyps. Benign tumor cells have these characteristics:

- *Specific morphology* occurs with benign tumors. They look like the tissues they come from, retaining the specific morphology of parent cells.
- A *small nuclear-to-cytoplasmic ratio* is a feature of benign tumors just like completely normal cells.
- *Specific differentiated functions* continue to be performed by benign tumors. For example, in endometriosis, a type of benign tumor, the normal lining of the uterus (endometrium) grows in an abnormal place (e.g., on an ovary, on the peritoneum, or in the chest cavity). This displaced endometrium acts just like normal endometrium by changing each month under the influence of estrogen. When the hormone level drops and the normal endometrium sheds from the uterus, the displaced endometrium, wherever it is, also sheds.

FIG. 23-4 Cellular events during mitotic cell division.

TABLE 23-1 CHARACTERISTICS OF NORMAL AND ABNORMAL CELLS			
CHARACTERISTIC	NORMAL CELL	BENIGN TUMOR CELL	MALIGNANT CELL
Cell division	None or slow	Continuous or inappropriate	Rapid or continuous
Appearance	Specific morphologic features	Specific morphologic features	Anaplastic
Nuclear-to-cytoplasmic ratio	Small	Small	Large
Differentiated functions	Many	Many	Some or none
Adherence	Tight	Tight	Loose
Migratory	No	No	Yes
Growth	Well regulated	Expansion	Invasion
Chromosomes	Diploid (euploid)	Diploid (euploid)	Aneuploid*
Mitotic index	Low	Low	High*

*Depends on the degree of malignant transformation.

- *Tight adherence* of benign tumor cells to each other occurs because they continue to make fibronectin. In addition, many benign tissues are “encapsulated,” or surrounded with fibrous connective tissue, helping to hold the benign tissue together.
- *No migration* or wandering of benign tissues occurs because they remain tightly bound and do not invade other body tissues.
- *Orderly growth* with normal growth patterns occurs in benign tumor cells even though their growth is not needed. Growth may continue beyond an appropriate time or occur in the wrong place, but the rate of growth is normal. The benign tumor grows by hyperplastic expansion. *It does not invade.*
- *Normal chromosomes* are usually found in benign tumor cells, although there are exceptions. Most of these cells have 23 pairs of chromosomes, the correct number for humans.

Features of Cancer Cells

Cancer (**malignant**) cells are abnormal, serve no useful function, and are harmful to normal body tissues. Cancers commonly have these features:

- *Anaplasia* is the cancer cells’ loss of the specific appearance of their parent cells. As a cancer cell becomes more malignant, it becomes smaller and rounded. This appearance change can make diagnosis of cancer type difficult, because many different types of cancer cells look alike.
- *A large nuclear-cytoplasmic ratio* occurs in cancer cells with the cancer cell nucleus being larger than that of a normal cell and the cancer cell being small. The nucleus occupies much of the space within the cancer cell, creating a large nuclear-to-cytoplasmic ratio.
- *Specific functions are lost* partially or completely in cancer cells. *Cancer cells serve no useful purpose.*
- *Loose adherence* is typical for cancer cells because they do not make fibronectin. As a result, cancer cells easily break off from the main tumor.
- *Migration* occurs because cancer cells do not bind tightly together and have many enzymes on their cell surfaces. These features allow the cells to slip through blood vessel walls and between tissues, spreading from the main tumor site to many other body sites. This ability to spread (**metastasize**) is unique to cancer cells and a major cause of death. Cancer cells expand by mitosis and invade other tissues, both close by and more remote from the original tumor. Invasion and persistent growth make untreated cancer deadly.
- *Contact inhibition does not occur* in cancer cells, even when all sides of these cells are in continuous contact with the surfaces of other cells. This persistence of cell division makes the disease difficult to control.
- *Rapid or continuous cell division* occurs in many types of cancer cells because they re-enter the cell cycle for mitosis almost continuously. In addition, some cancer cells have a short generation time (2 to 4 hours), but most cancer cells have a generation time similar to that of the parent cells. These cells also do not respond to signals for apoptosis. Most cancer cells have a lot of the enzyme *telomerase*, which maintains telomeric DNA. As a result, cancer cells do not respond to

apoptotic signals and have an unlimited life span (are “immortal”).

- *Abnormal chromosomes* (**aneuploidy**) are common in cancer cells as they become more malignant. Chromosomes are lost, gained, or broken; thus cancer cells can have more than 23 pairs or fewer than 23 pairs. Cancer cells also may have broken and rearranged chromosomes.

CANCER DEVELOPMENT

Carcinogenesis/Oncogenesis

Carcinogenesis and **oncogenesis** are other names for cancer development. Table 23-2 lists key concepts about cancer development. The process of changing a normal cell into a cancer cell is called **malignant transformation**, occurring through the steps of initiation, promotion, progression, and metastasis.

Initiation is the first step in carcinogenesis. Normal cells can become cancer cells if their genes promoting cell division, **oncogenes**, are turned on excessively (overexpressed). Initiation is a change in gene expression caused by anything that can penetrate a cell, get into the nucleus, and damage the DNA. Such changes can activate oncogenes that should have only limited expression and can damage suppressor genes, which normally limit oncogene activity. Thus initiation leads to excessive cell division through DNA damage that results in either loss of suppressor gene function or enhancement of oncogene function.

Initiation is an irreversible event that can lead to cancer development. After initiation, a cell can become a cancer cell if the cellular changes that occurred during initiation continue and cell division is not impaired. A cancer cell is not a health threat unless it can divide. If it cannot divide, it cannot form a tumor. *If growth conditions are right, however, widespread metastatic disease can develop from just one cancer cell.*

Substances that change the activity of a cell’s genes so that the cell becomes a cancer cell are **carcinogens**. Carcinogens

TABLE 23-2 KEY CONCEPTS RELATED TO CANCER DEVELOPMENT

- Neoplastic cells originate from normal body cells.
- Transformation of a normal cell into a cancer cell involves mutation of the genes (DNA) of the normal cell.
- Oncogenes that are overexpressed can cause a cell to develop into a tumor.
- Only one cell has to undergo malignant transformation for cancer to begin.
- Benign tumors grow by expansion, whereas malignant tumors grow by invasion.
- Most tumors arise from cells that are capable of cell division.
- A key feature of cancer cells is the loss of apoptosis. These cells have an “infinite” life span.
- Primary prevention of cancer involves avoiding exposure to known causes of cancer.
- Secondary prevention of cancer involves screening for early detection.
- Tobacco use is a causative or permissive factor in 30% of all cancers.
- Tumors that metastasize from the primary site into another organ are still designated as tumors of the originating tissue.

may be chemicals, physical agents, or viruses. There are more than 50 substances known to cause cancer and about another two hundred that are suspected to be carcinogens. The National Toxicology Program's website lists these substances (<http://ntp.niehs.nih.gov/>; U.S. Department of Health and Human Services, 2011). Chapters presenting the care of patients with specific cancers discuss specific carcinogens (when known) within the Etiology sections.

Promotion is the enhancement of growth of an initiated cell. **Promoters** are substances that promote or enhance growth of the initiated cancer cell. Once a normal cell has been initiated by a carcinogen and is a cancer cell, it can become a tumor if its growth is enhanced. Many normal hormones and body proteins, like insulin and estrogen, can act as promoters and make altered cells divide more frequently. The time between a cell's initiation and the development of an overt tumor is called the **latency period**, which can range from months to years. Exposure to promoters can shorten the latency period.

Progression is the continued change of a cancer, making it more malignant over time. Many processes within the tumor must take place for progression to occur. After cancer cells have grown to the point that a detectable tumor is formed (a 1-cm tumor has at least 1 billion cells in it), other events must occur for this tumor to become a health problem. First, the tumor must develop its own blood supply. In the early stages, the tumor receives nutrition only by diffusion. After the tumor reaches 1 cm, however, diffusion is not efficient. The tumor then makes substances that trigger nearby capillaries to grow new branches into the tumor, ensuring the tumor's continued nourishment and growth.

As tumor cells continue to divide, some of the new cells change features from the original, initiated cancer cell and

form groups that differ from the original cancer cell. Some of the differences provide these cell groups with advantages (*selection advantages*) that allow them to live and divide no matter how the conditions around them change. These tumor changes may allow it to become more malignant. Over time, the tumor cells have fewer and fewer normal cell features.

The original tumor is called the **primary tumor**. It is usually identified by the tissue from which it arose (*parent tissue*), such as in breast cancer or lung cancer. When primary tumors are located in vital organs, such as the brain or lungs, they can grow excessively and either lethally damage the vital organ or interfere with that organ's ability to perform its vital function. At other times, the primary tumor is located in soft tissue that can expand without damage as the tumor grows. One such site is the breast. The breast is not a vital organ, and even if it had a large tumor in it, the primary tumor alone would not cause the patient's death. When the tumor spreads from the original site into vital areas, life functions can be disrupted and death may follow.

Metastasis occurs when cancer cells move from the primary location by breaking off from the original group and establishing remote colonies. These additional tumors are called **metastatic** or **secondary tumors**. *Even though the tumor is now in another organ, it is still a cancer from the original altered tissue. For example, when breast cancer spreads to the lung and the bone, it is still breast cancer in the lung and bone—not lung cancer and not bone cancer.* Metastasis occurs through many steps, as shown in Fig. 23-5.

Tumors first extend into surrounding tissues. The cancer cells secrete enzymes that open up areas of surrounding tissue. Pressure, created as the tumor increases in size, forces tumor cells to invade new territory.

FIG. 23-5 The steps of metastasis.

Spread to distant organs and tissues requires cancer cells to penetrate blood vessels. **Bloodborne metastasis** (tumor cell release into the blood) is the most common cause of cancer spread. Enzymes secreted by tumor cells also make large pores in the patient's blood vessels, allowing tumor cells to enter the blood and circulate throughout the body. Because tumor cells are loosely held together, clumps of cells break off of the primary tumor into blood vessels for transport.

Tumor cells circulate through the blood and enter tissues at remote sites. Clumps of cancer cells can become trapped in capillaries. These clumps damage the capillary wall and allow cancer cells to leave the capillary and enter the surrounding tissue.

When conditions in the remote site can support tumor cell growth, the cells stop circulating (arrest) and invade the surrounding tissues, creating secondary tumors. Table 23-3 lists the common sites of metastasis for specific tumor types.

Another way cancers metastasize is by *lymphatic spread*. Lymphatic spread is related to the number, structure, and location of lymph nodes and vessels. Primary sites that are rich in lymphatics have more early metastatic spread than areas with few lymphatics.

Cancer Classification

Cancers are classified by the type of tissue from which they arise (e.g., glandular, connective) (McCance et al., 2010). Terms that describe cancer by tissue origin are listed in Table 23-4. Other ways to classify cancer include biologic behavior, anatomic site, and degree of differentiation.

About 100 different types of cancer arise from various tissues or organs. Fig. 23-6 compares cancer distribution by

site and gender. Cancers are divided into two major categories: solid and hematologic.

Solid tumors develop from specific tissues (e.g., breast cancer and lung cancer). Hematologic cancers arise from blood cell-forming tissues (e.g., leukemias and lymphomas).

Cancer Grading, Ploidy, and Staging

Systems of grading and staging have been developed to help standardize cancer diagnosis, prognosis, and treatment.

Grading of a tumor classifies cellular aspects of the cancer.

TABLE 23-3 COMMON SITES OF METASTASIS FOR DIFFERENT CANCER TYPES

Breast Cancer	Prostate Cancer
Bone*	Bone (especially spine and legs)*
Lung*	Pelvic nodes
Liver	
Brain	
Lung Cancer	Melanoma
Brain*	GI tract
Bone	Lymph nodes
Liver	Lung
Lymph nodes	Brain
Pancreas	
Colorectal Cancer	Primary Brain Cancer
Liver*	Central nervous system
Lymph nodes	
Adjacent structures	

*Most common site of metastasis for the specific malignant neoplasm.

TABLE 23-4 CLASSIFICATION OF TUMORS BY TISSUE OF ORIGIN

PREFIX	TISSUE OF ORIGIN	BENIGN TUMOR	MALIGNANT TUMOR*
Adeno	Epithelial glands	Adenoma	Adenocarcinoma
Chondro	Cartilage	Chondroma	Chondrosarcoma
Fibro	Fibrous connective	Fibroma	Fibrosarcoma
Glio	Glial cells (brain)	Glioma	Glioblastoma
Hemangio	Blood vessel	Hemangioma	Hemangiosarcoma
Hepato	Liver	Hepatoma	Hepatocarcinoma Hepatoblastoma
Leiomyo	Smooth muscle	Leiomyoma	Leiomyosarcoma
Lipo	Fat/adipose	Lipoma	Liposarcoma
Lympho	Lymphoid tissues		Malignant lymphomas Hodgkin's lymphoma Non-Hodgkin's lymphoma Burkitt's lymphoma Cutaneous T-cell
Melano	Pigment-producing skin		Melanoma
Meningioma	Meninges	Meningioma	Malignant meningioma Meningioblastoma
Neuro	Nerve tissue	Neuroma Neurofibroma	Neurosarcoma Neuroblastoma
Osteo	Bone	Osteoma	Osteosarcoma
Renal	Kidney		Renal cell carcinoma
Rhabdo	Skeletal muscle	Rhabdomyoma	Rhabdomyosarcoma
Squamous	Epithelial layer of skin, mucous membranes, and organ linings	Papilloma	Squamous cell carcinoma of skin, bladder, lungs, cervix

*Carcinomas are tumors of glandular tissue; sarcomas are tumors of connective tissue; blastomas are tumors of less differentiated, embryonal tissues.

Leading Sites of New Cancer Cases and Deaths – 2011 Estimates*

*Excludes basal and squamous cell skin cancers and in situ carcinoma except urinary bladder.

Note: Percentages may not total 100% due to rounding.

FIG. 23-6 Cancer incidence and death by site and gender.

Ploidy classifies tumor chromosomes as normal or abnormal. **Staging** classifies clinical aspects of the cancer.

Grading is needed because some cancer cells are “more malignant” than others, varying in their aggressiveness and sensitivity to treatment. Some cancer cells barely resemble the tissue from which they arose, are aggressive, and spread rapidly. These cells are a “high-grade” cancer. On the basis of cell appearance and activity, grading compares the cancer cell with the normal parent tissue from which it arose. It is a means of evaluating the patient with cancer for prognosis and appropriate therapy. Grading also allows health care professionals to evaluate the results of management and compare local, regional, national, and international statistics.

Different clinical groups have established different grading systems for different types of cancer cells, but overall, they resemble the standard system listed in Table 23-5. This system rates cancer cells with the lowest rating given to those cells that closely resemble normal cells and the highest rating given to cancer cells that barely resemble normal cells. Grading systems for different cancers are presented in the clinical chapters in which care is discussed.

Ploidy is the description of cancer cells by chromosome number and appearance. Normal human cells have 46 chromosomes (23 pairs), the normal diploid number (**euploidy**). When malignant transformation occurs, changes in the genes and chromosomes also occur. Some cancer cells gain or lose whole chromosomes and may have structural abnormalities

TABLE 23-5 GRADING OF MALIGNANT TUMORS

GRADE	CELLULAR CHARACTERISTICS
G _x	Grade cannot be determined.
G ₁	Tumor cells are well differentiated and closely resemble the normal cells from which they arose. This grade is considered a low grade of malignant change. These tumors are malignant but are relatively slow growing.
G ₂	Tumor cells are moderately differentiated; they still retain some of the characteristics of normal cells but also have more malignant characteristics than do G ₁ tumor cells.
G ₃	Tumor cells are poorly differentiated, but the tissue of origin can usually be established. The cells have few normal cell characteristics.
G ₄	Tumor cells are poorly differentiated and retain no normal cell characteristics. Determination of the tissue of origin is difficult and perhaps impossible.

of the remaining chromosomes, a condition called **aneuploidy**. The degree of aneuploidy usually increases with the degree of malignancy. Some specific chromosome changes are associated with specific cancers, and their presence is used for diagnosis and prognosis. One example is the

TABLE 23-6 STAGING OF CANCER—TNM CLASSIFICATION

Primary Tumor (T)	
T _x	Primary tumor cannot be assessed
T ₀	No evidence of primary tumor
T _{is}	Carcinoma in situ
T ₁ , T ₂ , T ₃ , T ₄	Increasing size and/or local extent of the primary tumor
Regional Lymph Nodes (N)	
N _x	Regional lymph nodes cannot be assessed
N ₀	No regional lymph node metastasis
N ₁ , N ₂ , N ₃	Increasing involvement of regional lymph nodes
Distant Metastasis (M)	
M _x	Presence of distant metastasis cannot be assessed
M ₀	No distant metastasis
M ₁	Distant metastasis

“Philadelphia” chromosome abnormality often present in chronic myelogenous leukemia cells (see [Chapter 42](#)).

Staging determines the exact location of the cancer and its degree of metastasis at diagnosis. Staging is important because, for most cancers, the smaller the cancer is at diagnosis and the less it has spread, the greater the chances are that treatment will result in a cure. Cancer stage also influences selection of therapy. Staging is done by clinical staging, surgical staging, and pathologic staging. *Clinical staging* assesses the patient’s clinical manifestations and evaluates clinical signs for tumor size and possible spread. *Surgical staging* assesses the tumor size, number, sites, and spread by inspection at surgery. *Pathologic staging* is the most definitive type, determining the tumor size, number, sites, and spread by pathologic examination of tissues obtained at surgery.

The American Joint Committee on Cancer developed the **tumor, node, metastasis (TNM)** system to describe the general anatomic extent of cancers. The stages guide treatment and are useful for prognosis and comparison of treatment results. The TNM staging systems have specific prognostic value for each solid tumor type. [Table 23-6](#) shows a basic TNM staging system. TNM staging is not useful for leukemia or lymphomas. Staging for these cancers is discussed in [Chapter 42](#). Additional specific staging systems include Dukes’ staging of colon and rectal cancer and Clark’s levels method of staging skin cancer.

Tumor growth is assessed in terms of **doubling time** (the amount of time it takes for a tumor to double in size) and **mitotic index** (the percentage of actively dividing cells within a tumor). The smallest detectable tumor is about 1 cm in diameter and contains 1 billion cells. To reach this size, it must undergo at least 30 doublings. A tumor with a mitotic index of less than 10% is a slow-growing tumor; a tumor with an index of 85% is fast growing. Tumors have a wide range of growth rates. Fast-growing tumors, such as lymphomas, may double in 4 weeks; an adenocarcinoma of the lung may double in 20 to 40 weeks.

Cancer Etiology and Genetic Risk

Carcinogenesis takes years and depends on several tumor and patient factors. Three interacting factors influence cancer development: exposure to carcinogens, genetic

predisposition, and immune function. These factors account for variation in cancer development from one person to another, even when each person is exposed to the same hazards.

Oncogene activation is the main mechanism of carcinogenesis regardless of the specific cause. These oncogenes are turned on (expressed) under controlled conditions when cells need to divide for normal growth and replacement of dead or damaged tissues. At other times, they are turned off, controlled, or suppressed by products of “suppressor genes.”

When a normal cell is exposed to any carcinogen (initiator), the normal cell’s DNA can be damaged or mutated. The mutations often damage suppressor genes, preventing them from producing proteins that control the expression of oncogenes. As a result, the oncogenes are overexpressed and can cause the cells to change from normal cells to cancer cells. When oncogenes are overexpressed in a cell, excessive amounts of cyclins are produced and upset the balance between cell growth enhancement and cell growth limitation. The effect of these excessive cyclins is greater than the effect of the suppressor gene products, thus allowing uncontrolled cell division.

About 70 different oncogenes have been identified. *These oncogenes are not abnormal genes but are part of every cell’s normal makeup.* Oncogenes become a problem only if they are overexpressed as a result of exposure to carcinogenic agents or events. Both external and personal factors can activate oncogenes.

External Factors Causing Cancer

External factors, including environmental exposure, are responsible for about 80% of cancer in North America ([ACS, 2010](#)). Environmental carcinogens are chemical, physical, or viral agents that cause cancer ([USDHHS, 2010](#)).

Chemical carcinogenesis can occur from exposures to many known chemicals, drugs, and other products used in everyday life. Hundreds more are suspected of being carcinogenic.

Chemicals vary in how carcinogenic they are. For example tobacco and alcohol appear to be only mildly carcinogenic. For these substances, chronic, long-term exposure to large amounts is required before a cancer develops. However, these two substances can act as co-carcinogens, meaning that when they are taken together, they enhance each other’s carcinogenic activity.

Not all cells are susceptible to chemical carcinogenesis to the same degree. Normal cells that have the ability to divide are at greater risk for cancer development than are normal cells that are not capable of cell division. For example, cancers commonly arise in bone marrow, skin, lining of the GI tract, ductal cells of the breast, and lining of the lungs. All of these cells normally undergo cell division. Cancers of nerve tissue, cardiac muscle, and skeletal muscle are rare. These cells do not normally undergo cell division.

About 30% of cancers diagnosed in North America are related to tobacco use ([ACS, 2011](#); [ACS, 2010](#); [Canadian Cancer Society, 2010](#)). Tobacco is the single most important source of preventable carcinogenesis. It contains many different carcinogens and co-carcinogens. Long-term tobacco use first initiates and then promotes cancer. The risk for cancer development from tobacco use depends on a person’s immune function, genetic susceptibility, amount of tobacco exposure, type of tobacco exposure, and tobacco tar content.

TABLE 23-7 CANCER TYPES ASSOCIATED WITH TOBACCO USE

• Oral cavity	• Cervical	• Stomach
• Pharyngeal	• Kidney	• Myeloid leukemia
• Laryngeal	• Bladder	
• Esophagus		

Data from American Cancer Society. (2011). *Cancer facts and figures—2011*. Report No. 00-300M–No. 5008.11. Atlanta: Author.

Tissues with the greatest risk for tobacco-induced cancer are those that have direct contact with tobacco or tobacco smoke. Cigarette smoking and tobacco use also promote the development of other cancers. Table 23-7 lists the specific cancers that appear to be associated with tobacco use.

Physical carcinogenesis from physical agents or events causes cancer by the same mechanism as for chemical carcinogens (i.e., DNA damage). Two physical agents that are known to cause cancer are radiation and chronic irritation.

Even small doses of radiation affect cells to some degree. Some effects are temporary and can be repaired. Other effects cannot be repaired and either may be lethal to the damaged cell or induce cancer in the damaged cell. The two types of radiation that cause cancer are ionizing and ultraviolet (UV). Some ionizing radiation is found naturally in such elements as radon, uranium, and radium. Most rocks and soil contain various amounts of uranium and radium. Other sources of ionizing radiation include x-rays for diagnosis and treatment of disease, as well as cosmic radiation. UV radiation is a type of solar radiation, coming from the sun. Other sources of UV radiation include tanning beds and germicidal lights. UV rays do not penetrate deeply, and the most common cancer type caused by UV exposure is skin cancer.

Both ionizing and UV radiation mutate genes. Radiation exposure induces cancers more often among cells that can divide but can cause cancer among non-dividing cells as well.

Chronic irritation and tissue trauma are suspected to cause cancer. The incidence of skin cancer is higher in the scars of people with burn scars or other types of severe skin injury. Chronically irritated tissues undergo frequent cell division and thus are at an increased risk for DNA mutation.

Viral carcinogenesis occurs when viruses infect body cells and break the DNA strands. Viruses then insert their own genetic material into the human DNA. Breaking the DNA, along with viral gene insertion, mutates the normal cell's DNA and can either activate an oncogene or damage suppressor genes. Viruses that cause cancer are **oncoviruses**. Table 23-8 lists cancers of known viral origin.

Dietary factors related to cancer development are poorly understood although dietary practices are suspected to alter cancer risk. Because dietary factors are rarely independent of other possible carcinogenic agents, evidence of dietary contributions to cancer development is clouded. Suspected dietary factors include low fiber intake, high intake of red meat, and high animal fat intake. Preservatives, contaminants, preparation methods, and additives (dyes, flavorings, sweeteners) may have cancer-promoting effects. Chart 23-1 lists foods that have carcinogenic potential and those that are thought to be protective against cancer development.

TABLE 23-8 CANCERS ASSOCIATED WITH A KNOWN VIRAL ORIGIN

VIRUS	MALIGNANCIES
Epstein-Barr virus	Burkitt's lymphoma, B-cell lymphoma, nasopharyngeal carcinoma
Hepatitis B virus	Primary liver carcinoma
Hepatitis C virus	Primary liver carcinoma, possibly B-cell lymphomas
Human papilloma virus	Cervical carcinoma, vulvar carcinoma, and other anogenital carcinomas
Human lymphotropic virus type I	Adult T-cell leukemia
Human lymphotropic virus type II	Hairy cell leukemia

U.S. Department of Health and Human Services, Public Health Service, National Toxicology Program. (2011). *Report on carcinogens* (12th ed.). Retrieved July 2011 from <http://ntp.niehs.nih.gov/go/roc12>.

CHART 23-1 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT**Dietary Habits to Reduce Cancer Risk**

- Avoid excessive intake of animal fat.
- Avoid nitrites (prepared lunch meats, sausage, bacon).
- Minimize your intake of red meat.
- Keep your alcohol consumption to no more than one or two drinks per day.
- Eat more bran.
- Eat more cruciferous vegetables, such as broccoli, cauliflower, Brussels sprouts, and cabbage.
- Eat foods high in vitamin A (e.g., apricots, carrots, leafy green and yellow vegetables) and vitamin C (e.g., fresh fruits and vegetables, especially citrus fruits).

Personal Factors and Cancer Development

Personal factors, including immune function, age, and genetic risk, also affect whether a person is likely to develop cancer.

Immune function protects the body from foreign invaders and non-self cells (see Chapter 19). Non-self cells include cells that are no longer normal, such as cancer cells. The part of the immune system that protects against cancer is cell-mediated immunity. Natural killer (NK) and helper T-cells provide immune surveillance.

The role of the immune system in protecting against cancer is supported by an increased cancer incidence in immunosuppressed people. Adults older than 60 years have immune systems that function at less-than-optimal levels, and therefore this group has a higher incidence of cancer compared with that of the general population. Organ transplant recipients taking immunosuppressive drugs to prevent organ rejection also have a higher incidence of cancer. In patients with acquired immune deficiency syndrome (AIDS), cancer incidence may be as high as 70%.

Advancing age is the single most important risk factor for cancer (ACS, 2011). As a person ages, immune protection decreases and external exposures to carcinogens accumulate. Manifestations of cancer in older patients may be overlooked as changes of normal aging. Teach older adults to be aware of and report symptoms such as the seven warning signs of

TABLE 23-9 THE SEVEN WARNING SIGNS OF CANCER

C	C hanges in bowel or bladder habits
A	A sore that does not heal
U	U nusual bleeding or discharge
T	T hickening or lump in the breast or elsewhere
I	I ndigestion or difficulty swallowing
O	O bvious change in a wart or mole
N	N agging cough or hoarseness

cancer (Table 23-9) to health care providers. Health care providers should investigate all manifestations suggestive of disease. Cancer assessment considerations for the older adult are listed in Chart 23-2.

GENETIC/GENOMIC CONSIDERATIONS

Genetic risk for cancer occurs in a small percent of the population; however, people who have a genetic predisposition are at very high risk for cancer development (Crockett-Maillet, 2010). As previously discussed, suppressor gene damage and oncogene overexpression are risk factors related to carcinogenesis. Mutations in suppressor genes or oncogenes can be inherited when they first occur in germ-line cells (sperm and ova) and are then passed on to one's children, in whom all cells contain the inherited mutations. In some people, the sequence of a suppressor gene has been mutated, which reduces or halts its function and allows oncogene overexpression. In other people, the suppressor genes are normal and the oncogene is mutated and does not respond to suppressor gene signals. With either condition, the risk for cancer development increases among people who inherit these mutations.

These mutations or variations in gene sequence may be small single nucleotide polymorphisms (SNPs) or may be large areas of mutations. Both types of gene problems can be inherited or can occur as a result of exposure to carcinogens. Patterns of genetic risk for cancer have also been identified, including:

- Inherited predisposition for specific cancers
- Inherited conditions associated with cancer
- Familial clustering
- Chromosomal aberrations

Table 23-10 lists conditions associated with an increased genetic risk for cancer development.

Genetic testing for cancer predisposition is available to confirm or rule out a person's genetic risk for a few specific cancers. These tests are performed on blood and are expensive, and the cost often is not covered by insurance. Genetic testing should not be performed unless a family history clearly indicates the possibility of increased genetic risk and the patient wants to have the test results. *These tests do not diagnose the presence of cancer; they only provide risk information.*

A variety of issues and potential problems exist with genetic testing for cancer risk. Correct interpretation of the results is critical. Ideally, a genetic counselor is involved in giving the patient information before, as well as after, testing is performed. *When a patient tests positive for a cancer-causing gene mutation, his or her risk for cancer development is greatly increased; however, the cancer still may never develop.*

Other issues regarding genetic testing include who will have access to the information and whether to share the test

CHART 23-2 NURSING FOCUS ON THE OLDER ADULT

Cancer Assessment

CANCER TYPE	ASSESSMENT CONSIDERATION
Colorectal cancer	Ask the patient whether bowel habits have changed over the past year (e.g., in consistency, frequency, color). Is there any obvious blood in the stool? Test at least one stool specimen for occult blood during the patient's hospitalization. Encourage the patient to have a baseline colonoscopy. Encourage the patient to reduce dietary intake of animal fats, red meat, and smoked meats. Encourage the patient to increase dietary intake of bran, vegetables, and fruit.
Bladder cancer	Ask the patient about the presence of: Pain on urination Blood in the urine Cloudy urine Increased frequency or urgency
Prostate cancer	Ask the patient about: Hesitancy Change in the size of the urine stream Pain in the back or legs History of urinary tract infections
Skin cancer	Examine skin areas for moles or warts. Ask the patient about changes in moles (e.g., color, edges, sensation).
Leukemia	Observe the skin for color, petechiae, or ecchymosis. Ask the patient about: Fatigue Bruising Bleeding tendency History of infections and illnesses Night sweats Unexplained fevers
Lung cancer	Observe the skin and mucous membranes for color. How many words can the patient say between breaths? Ask the patient about: Cough Hoarseness Smoking history Exposure to inhalation irritants Shortness of breath Activity tolerance Frothy or bloody sputum Pain in the arms or chest Difficulty swallowing

results with family members. Many patients fear that if they test positive for a cancer-causing gene, they may face discrimination for insurance coverage or in the workplace. Genetic testing has implications for the entire family, not just the patient being tested. For more information on genetic testing, see Chapter 6.

When risks for cancer development are assessed, however, ethnicity and genetic predisposition cannot be considered alone. Behavior and socioeconomic factors must also be assessed. The American Cancer Society (2009, 2011) reports

TABLE 23-10 CONDITIONS ASSOCIATED WITH A GENETIC PREDISPOSITION FOR CANCER

CONDITION	SPECIFIC CANCER TYPE
Inherited cancers*	Breast cancer Prostate cancer Ovarian cancer
Familial clustering	Breast cancer Melanoma
Bloom syndrome	Leukemia
Familial polyposis	Colorectal cancer
Chromosomal aberrations	
Down syndrome (47 chromosomes)	Leukemia
Klinefelter syndrome (47,XXY)	Breast cancer
Turner's syndrome (45,XO)	Leukemia Gonadal carcinoma Meningioma Colorectal cancer

*Not all breast, prostate, or ovarian cancers are inherited.

Data from American Cancer Society. (2011). *Cancer facts and figures—2011*. Report No. 00-300M—No. 5008.11. Atlanta: Author.

CULTURAL AWARENESS

The incidence of cancer varies among races. [American Cancer Society \(ACS\) data \(2009\)](#) show that African Americans have a higher incidence of cancer than white people do and the death rate is higher for African Americans. Since 1960, the overall incidence among African Americans has increased 27%, whereas for white people it has increased 12%. Cancer sites and cancer-related mortality vary along racial lines as well. One explanation for this difference is that more African Americans have less access to health care. Thus they are more often diagnosed with later-stage cancer that is more difficult to cure or control. However, this disparity in health care access does not explain all differences.

Table 23-11 shows common cancers among white, African American, Asian, and Hispanic populations. Understanding these variations can help in planning prevention and early detection strategies that are ethnically specific.

that cancer incidence and survival are often related to socioeconomic factors. These factors include the availability of health care services or the belief that seeking early health care has a positive effect on the outcome of cancer diagnosis.

CANCER PREVENTION

Cancer prevention activities can focus on primary prevention or secondary prevention. **Primary prevention** is the use of strategies to prevent the actual occurrence of cancer. This method of cancer prevention is most effective when there is a known cause for a cancer type. **Secondary prevention** is the use of screening strategies to detect cancer early, at a time when cure or control is more likely.

Primary Prevention

Avoidance of known or potential carcinogens is an effective primary prevention strategy. This method is effective when a cause of cancer is known and avoidance is easily accomplished. For example, teach people to use skin protection during sun exposure to avoid skin cancer. Much lung cancer can be avoided by not using tobacco and by eliminating environmental asbestos exposure. Teach everyone about the dangers of cigarette smoking and other forms of tobacco use. Provide information on smoking cessation strategies and support systems. Teach people who are exposed to asbestos (or any other carcinogen) in the workplace to use personal protective equipment that reduces direct contact with this substance. As more cancer causes are identified, avoidance may become even more effective.

Modifying associated factors appears to have a positive influence in reducing cancer risk. Absolute causes are not known for many cancers, but some conditions appear to increase risk. Examples are the increased incidence of cancer among people who consume alcohol; the association of a diet high in fat and low in fiber with colon cancer, breast cancer, and ovarian cancer; and a greater incidence of cervical cancer among women who have multiple sexual partners ([Wells, 2008](#)). Modifying behavior to reduce the associated factor may decrease the risk for cancer development. Therefore teach all people to limit their intake of alcohol to no more than one ounce per day and to include more fruits, vegetables, and whole grains in their diets. Instruct women about the importance of limiting the number of sexual partners and to use safer sex practices to avoid exposure to viruses that can increase the risk for cervical cancer.

Removal of “at risk” tissues reduces cancer risk for a person who has a known high risk for developing a specific type of cancer. Examples include removing moles to prevent conversion to skin cancer, removing colon polyps to prevent colon cancer, and removing breasts to prevent breast cancer. Not all “at risk” tissues can be removed (e.g., those that are part of essential organs).

Chemoprevention is a newer form of potential cancer prevention. This strategy uses drugs, chemicals, natural nutrients, or other substances to disrupt one or more steps important to cancer development. These agents may be able to reverse existing gene damage or halt the progression of the transformation process. Currently, hundreds of agents are under investigation for chemoprevention. At this time, only a few agents have been found effective and are commonly prescribed. These include the use of aspirin and celecoxib (Celebrex) to reduce the risk for colon cancer, the use of vitamin D and tamoxifen to reduce the risk for breast cancer, and the use of lycopene to reduce the risk for prostate cancer ([ACS, 2010](#)).

An emerging issue in this area is that studies of chemoprevention performed using animal models do not always correlate to a reduction of carcinogenesis in humans. In addition,

there is person-to-person variability in human response to chemoprevention. It is likely that individual genetic factors influence the effectiveness of any agent in the prevention of carcinogenesis.

The goal of chemopreventive strategies is prevention of cancer development. Target populations for whom chemoprevention might be effective include:

- Healthy people with no known specific cancer risk
- People at greater-than-normal risk because of increased environmental exposure or decreased immune function
- People with precancerous lesions
- People with a history of cancer

Vaccination is a new method of primary cancer prevention. Although vaccines against colon cancer and others are being explored, currently the only vaccine approved for cancer prevention is Gardasil. This vaccine prevents infection from several forms of the human papilloma virus (HPV). As more viruses are identified as being cancer causing, it is hoped that vaccines will be developed to prevent those viral infections.

Secondary Prevention

Regular screening for cancer does not reduce cancer incidence but can greatly reduce some types of cancer deaths. Teach all adults the benefits of participating in specific routine screening techniques annually as part of health maintenance. General screening recommendations are listed in chapters discussing cancers by organ system. The age and type of participation in specific screening tests are different for people who have an identified increased risk for a specific cancer type. Examples of recommended screenings include (ACS, 2009, 2011):

- Yearly mammography for women older than 40 years
- Yearly clinical breast examination for women older than 40 years
- Colonoscopy at age 50 years and then every 10 years
- Yearly fecal occult blood for adults of all ages
- Yearly prostate-specific antigen (PSA) test and digital rectal examination (DRE) for men older than 50 years

Because cancer development clearly involves gene changes (either inherited gene mutations or acquired gene damage), researchers have suggested that altering damaged genes could prevent cancer development. Currently, people can be screened for some gene mutations that increase the risk for cancer. A few examples of these known gene mutations include the *BRCA1* gene, which increases the risk for both breast and ovarian cancer; the *BRCA2* gene, which increases the risk for breast cancer; and the *APC*, *MLH1*, and *MSH2* genes, which increase the risk for colon cancer.

When taking a patient history and the person appears to have a strong family history of either breast cancer or colon cancer, create a three-generation pedigree to more fully explore the possibility of genetic risk. If a pattern of risk emerges, inform the person about the possible benefits of genetic screening and advise him or her to talk with a genetics professional for more information. Screening can help a person at increased genetic risk for cancer to alter lifestyle factors, participate in early detection methods, or even have at-risk tissue removed. Genetic screening has some personal risks as well as potential benefits (see Chapter 6). Although it is not yet possible to “fix” or remove an abnormal gene in humans, gene therapy in the future is not out of the realm of possibility.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Health Promotion and Maintenance

- Teach patients to use sunscreen and to wear protective clothing during sun exposure.
- Encourage patients to participate in the recommended cancer-screening activities for their age-group and cancer risk category.
- Inform all patients who smoke that smoking increases the risk for development of many cancer types.
- Assist anyone interested in smoking cessation to find an appropriate smoking cessation program.
- Assess the patient’s knowledge about causes of cancer and his or her screening/prevention practices.
- Assist patients who fear a cancer diagnosis to understand that finding cancer at an early stage increases the chances for cure.
- Ask all patients about their exposures to environmental agents that are known or suspected to increase the risk for cancer.
- Obtain a detailed family history (at least three generations) and use this information to create a pedigree to assess the patient’s risk for familial or inherited cancer.

- Teach anyone, especially older adults, the “seven warning signs of cancer” (see Table 23-9).

Physiological Integrity

- Cancer cells originate from normal body cells.
- Transformation of a normal cell into a cancer cell involves mutation of the genes (DNA) of the normal cell.
- Oncogenes that are overexpressed can cause a cell to develop into a tumor.
- Only one cell has to undergo malignant transformation for cancer to begin.
- Benign tumors grow by expansion, whereas malignant tumors grow by invasion.
- Most tumors arise from cells that are capable of cell division.
- A key feature of cancer cells is the loss of apoptosis. These cells have an “infinite” life span.
- Primary prevention of cancer involves avoiding exposure to known causes of cancer.
- Secondary prevention of cancer involves screening for early detection.
- Tobacco use is a causative factor in 30% of all cancers.
- Tumors that metastasize from the primary site into another organ are still designated as tumors of the originating tissue.

Concept Map Creator

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Modify the environment to protect patients who have neutropenia or thrombocytopenia.
2. Use personal protective equipment (PPE) when administering IV and oral chemotherapy and when handling excreta of a patient within 48 hours of receiving chemotherapy.
3. Coordinate with the health care team to adjust the environment for protection of the patient having photodynamic therapy.
4. Maintain radiation precautions when caring for a patient receiving radiation therapy using implanted sources.

Health Promotion and Maintenance

5. Teach patients and family members how to avoid injury and infection when blood counts are low.
6. Teach patients and family members skin protection measures for radiation therapy and photodynamic therapy.
7. Teach patients and family members the proper scheduling of antiemetic therapy to ensure prevention or relief of chemotherapy-induced nausea and vomiting.

Psychosocial Integrity

8. Teach patients and family members about what to expect during therapeutic procedures.

9. Encourage patients and family members to express their concerns about the diagnosis of cancer, its prognosis, and its treatment.
10. Assess the patient's and family's use of coping strategies related to cancer, cancer treatment, possible role changes, and possible outcomes of the disease and its treatment.
11. Teach patients strategies to improve body image changes occurring with cancer treatment.

Physiological Integrity

12. Interpret laboratory data and clinical manifestations to determine the presence of cancer treatment side effects and oncologic emergencies.
13. Prioritize nursing interventions for the patient with neutropenia or thrombocytopenia.
14. Prioritize nursing care for the patient receiving radiation therapy.
15. Explain the rationale for hormonal manipulation therapy.
16. Discuss the uses of biological response modifiers and growth factors as supportive therapy in the treatment of cancer.
17. Explain the basis and effects of targeted therapy for cancer.
18. Identify patients at risk for oncologic emergencies.
19. Teach patients and families the manifestations of oncologic emergencies and when to notify the health care provider.

TABLE 24-1 TEXT LOCATION OF SPECIFIC CANCER CONTENT

CANCER TYPE	CHAPTER	PAGES

Stomach (gastric)	58	1234-1238

Cancer is a common problem in North America and other affluent societies. Most people fear cancer and consider a cancer diagnosis to involve suffering and death. In affluent countries, more than 50% of people diagnosed with cancer are cured and thousands of others live 5 years or longer (American Cancer Society, 2011; Canadian Cancer Society, 2010). *Regardless of treatment type, cancer always affects a person's physical and psychological functioning.*

Providing care to patients and families experiencing cancer is complex and challenging. This chapter describes the general interventions for cancer and the problems associated with cancer treatment. For specific treatment regimens and patient problems that occur with specific cancer types, consult the chapters in which the cancer is described. Table 24-1 lists common cancer types and the specific locations within this text where the interventions are presented.

GENERAL DISEASE-RELATED CONSEQUENCES OF CANCER

Cancer can develop in any organ or tissue and destroys normal tissue, which decreases function of that tissue or organ. Even when cancers occur in nonvital tissues or organs, they can cause death by **metastasizing** (spreading) into vital organs and disrupting critical physiologic processes (see Chapter 23). Cancers that are left untreated often cause:

- Reduced immunity and blood-producing functions
- Altered GI structure and function
- Motor and sensory deficits
- Decreased respiratory function

These impairments cause great physical and emotional distress. Without intervention, cancer invasion of normal tissues leads to death.

REDUCED IMMUNITY AND BLOOD-PRODUCING FUNCTIONS

Impaired immune and blood-producing functions occur most often in patients with leukemia and lymphoma but

also can occur with any cancer that invades the bone marrow. Tumor cells enter the bone marrow and reduce the production of healthy white blood cells (WBCs), which are needed for normal immune function. Thus patients who have cancer, especially leukemia, are at an increased risk for infection.

When cancer invades the bone marrow, it also causes anemia by decreasing the number of red blood cells (RBCs) and causes thrombocytopenia by decreasing the number of platelets (Fitch et al., 2009). These changes may be caused by the cancer itself or by cancer treatment, especially chemotherapy. The patient feels weak and fatigued and is at risk for bleeding.

ALTERED GI STRUCTURE AND FUNCTION

Cancer can alter GI function and impair nutrition. Abdominal tumors may obstruct or compress structures anywhere in the GI tract, reducing the ability to absorb nutrients and eliminate wastes. Tumors often also increase metabolic rate and increase the need for nutrients at a time when the patient has less energy for meal preparation or eating.

Tumors that invade the liver profoundly damage this organ, which has many important metabolic functions. Cancer-related reduced liver function leads to malnutrition and death.

Many patients with cancer have anorexia that often interferes with their ability to meet energy needs. **Cachexia** (extreme body wasting and malnutrition) develops from an imbalance between food intake and energy use (increased catabolism). This problem may occur even when nutritional intake appears adequate (Granda-Cameron et al., 2010). Changes in taste can result from the cancer or the treatment and reduce appetite.

Nutritional support for the patient with cancer, especially one undergoing cancer therapy, is complex. A diet high in protein and carbohydrates is often prescribed to help him or her maintain weight and to provide the nutrients needed for energy and cellular repair. Patients and families often believe cancer can be cured more easily if weight is gained or maintained. Currently no one nutritional plan meets the needs of all patients with cancer.

MOTOR AND SENSORY DEFICITS

Motor and sensory deficits occur when cancers invade bone or the brain or compress nerves. In patients with bone metastasis, the primary cancer started in another organ (e.g., lung, prostate, breast). The bone sites most often affected are the vertebrae, ribs, pelvis, humerus, scapula, sternum, skull, and clavicle. Bone metastasis causes pain, fractures, spinal cord compression, and hypercalcemia, each of which reduces mobility.

Patients may have sensory changes if the spinal cord is damaged or if nerves are compressed. Sensory, motor, and cognitive functions are impaired when cancer spreads to the brain. Any tumor, benign or malignant, growing in the brain can destroy healthy brain tissue and cause death.

The patient with cancer may also have pain, especially chronic pain. Pain does not always accompany cancer, but it can be a major problem for those with terminal cancer. Chapter 5 provides an in-depth discussion of the causes and management of cancer pain. The Concept Map on p. 42 presents nursing care issues related to chronic cancer pain.

REDUCED OXYGENATION

Cancer can disrupt oxygenation in several ways and often results in death. For example, tumors in the airways cause airway obstruction. If lung tissue is involved, lung capacity is decreased. Tumors can also press on blood and lymph vessels in the chest, blocking blood flow through the chest and lungs, which results in pulmonary edema and dyspnea. Tumors can thicken the alveolar membrane and damage pulmonary blood vessels, reducing gas exchange. With any lung tumor (primary or metastatic), patients have hypoxia and poor tissue oxygenation.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

A client diagnosed with widespread lung cancer asks the nurse why he must be careful to avoid crowds and people who are ill. What is the nurse's best response?

- "With lung cancer, you are more likely to develop pneumonia and could pass this on to other people who are already ill."
- "When lung cancer is in the bones, it becomes a bone marrow malignancy, which stops producing immune system cells."
- "The large amount of mucus produced by the cancer cells is a good breeding ground for bacteria and other microorganisms."
- "When lung cancer is in the bones, it can prevent production of immune system cells, making you less resistant to infection."

CANCER MANAGEMENT

The purpose of cancer management is to prolong survival time or improve quality of life. Without cancer therapy, most patients with cancer would die within months of diagnosis. Cancer therapy includes surgery, radiation, chemotherapy, hormonal manipulation, photodynamic therapy, immunotherapy, and targeted therapy. These therapies may be used separately or in combination to kill cancer cells. The types of therapy used depend on the specific type of cancer, whether the cancer has spread, and the health of the patient. Treatment regimens (*protocols*) have been established for most types of cancer. These regimens are based on experiments with cancer cells and animals and on experience with other patients with cancer.

SURGERY

Overview

Surgery for cancer involves the removal of diseased tissue. If cancer is confined to the removed tissue, surgery alone can result in a "cure" for that cancer. Although many cancers have spread too far at the time of diagnosis for surgery alone to result in a cure, it is often a useful part of diagnosis, treatment, follow-up, and rehabilitation.

Cancer surgery may be used for prophylaxis, diagnosis, cure, control, palliation, assessing therapy effectiveness, and reconstruction. **Prophylactic surgery** removes "at-risk" tissue to prevent cancer development. It is performed when a patient has either an existing premalignant condition or a family history that strongly predisposes the person to development of a specific cancer. For example, removing a benign polyp from the colon before it can develop into colon cancer is a prophylactic action. **Diagnostic surgery** (biopsy) is the removal of all or part of a suspected lesion for examination and testing. It provides proof of the presence of cancer.

Curative surgery removes all cancer tissue. Surgery alone can result in a cure rate of 27% to 30% when all visible and microscopic tumor is removed or destroyed. **Cancer control**, or **cytoreductive surgery**, removes part of but not the entire tumor. It is also known as "debulking" surgery and alone cannot result in a cure. It decreases the number of cancer cells and increases the chances that other therapies can be successful. **Palliative surgery** focuses on improving the quality of life during the survival time, not on cure. Examples include removal of tumor tissue that is causing pain, obstruction, or difficulty swallowing. The specific procedure used depends on the patient's specific problem. **Second-look surgery** is a "redagnosis" after treatment. The purpose is to assess the disease status in patients who have been treated and have no symptoms of remaining tumor. The results of this surgery are used to determine whether a specific therapy should be continued or discontinued. This type of surgery is most commonly used with ovarian cancer. **Reconstructive** or **rehabilitative surgery** increases function, enhances appearance, or both. Examples include breast reconstruction after mastectomy, replacement of the esophagus, bowel reconstruction, revision of scars, and placement of penile implants.

Side Effects of Surgical Therapy

Unlike surgery performed for many other reasons, cancer surgery often involves the loss of a specific body part or its function. Sometimes whole organs are removed, such as the kidney, lung, breast, testes, leg, or tongue. *Any organ loss reduces function.* The amount of function lost and how much the loss affects patients depend on the location and extent of the surgery. Some cancer surgery results in major scarring or disfigurement. Patients are anxious about the chances of surviving the cancer and also may be grieving about a change in appearance or lifestyle.

PATIENT-CENTERED COLLABORATIVE CARE

The physical care needs of the patient having surgery for cancer are similar to those related to surgery for other reasons (see **Chapters 16, 17, and 18**). For cancer surgery, two additional priority care needs are psychosocial support and assisting the patient to achieve or maintain maximum function.

Often cancer surgery occurs within days of the diagnosis, before the patient and family have time to adjust. Assess the patient's and family's ability to cope with the uncertainty of cancer and its treatment and with the changes in body image and role. For example, surgery involving the genitals, urinary tract, colon, and rectum may permanently damage these organs, resulting in changes in the patient's means of sexual expression or control of elimination. Procedures to create a urinary or fecal diversion may damage nerves, causing erectile dysfunction in men and painful intercourse in women. Removal of a lung reduces the patient's respiratory capacity and forever limits his or her ability to engage in physical activities.

Coordinate with the health care team to support the patient. Encourage the patient and family to express their concerns. Help the patient accept changes in appearance or function by encouraging him or her to look at the surgical site, touch it, and participate in dressing changes. Provide information about support groups such as those sponsored by the American Cancer Society (www.cancer.org) or Canadian Cancer

Society (www.cancer.ca). Some cancer organizations have support groups for patients and separate support groups for patients' spouses and children. Discuss having a person who has coped with the same issues come for a visit. Such visits can be valuable in showing the patient that many aspects of life can be the same after cancer treatment. If the patient is open to this type of support, arrange for a visit. For patients who have persistent sadness or depression as a result of appearance changes from cancer surgery, a referral to a mental health counselor and drug therapy may be needed (Weaver, 2009).

Reduced function may be an outcome for some types of cancer surgery. For example, a modified radical mastectomy for breast cancer can lead to muscle weakness and reduced arm function on the surgical side. Performing specific exercises after surgery can reduce functional loss. These exercises can be painful, and the patient needs encouragement to perform them. Teach the patient about the importance of performing and increasing the intensity of the exercises to regain as much function as possible and prevent complications. Coordinate with the physical therapist, occupational therapist, and family members to plan strategies individualized to each patient to regain or maintain optimal function.

RADIATION THERAPY

Overview

The purpose of radiation therapy for cancer is to destroy cancer cells and have minimal damaging effects on the surrounding normal cells. The effects of radiation are seen only in the tissues in the path of the radiation beam; thus this type of therapy is a *local* treatment. For example, radiation to the chest for breast cancer or lung cancer causes skin changes and hair loss only on the area of the chest actually being irradiated. The person does *not* lose his or her scalp hair. Some effects are apparent within days or weeks, whereas other effects on deeper tissues may not be apparent for months to years after radiation therapy is completed.

Most radiation therapy for cancer is ionizing radiation. When cells are exposed to it, particles within the cell's nucleus are rearranged, resulting in a tremendous release of intracellular energy. Ionizing radiation is given off by many elements, including radium, and radioactive isotopes of specific elements. For example, a radioactive isotope of cobalt is used in radiation therapy for cancer.

As a radioactive element breaks down (decays), radiation energy is released as high energy particles (alpha particles and beta particles) and high energy photons (gamma rays). **X-rays**

are radiation that is generated by machine. X-ray photons and gamma ray photons are identical in their effects on cells.

Cells damaged by radiation either die outright or become unable to divide. Radiation damage can occur anytime a cell is exposed to radiation, not just when it is actively dividing. However, the damage is greater to dividing cells than to non-dividing cells when exposed to radiation.

Three different types of energy, or rays, are produced by radioactive elements: gamma rays, alpha particles, and beta particles. These energies vary in their ability to penetrate tissues and damage cells (Fig. 24-1). *Gamma rays* are used most commonly for radiation therapy because of their ability to deeply penetrate tissues (Camporeale, 2008). *Beta particles* are weaker and must be placed within or very close to the cancer cells for cancer therapy (see discussion of brachytherapy on pp. 412-413). *Alpha particles* are not used as cancer therapy.

The amount of radiation delivered to a tissue is called the **exposure**; the amount of radiation absorbed by the tissue is called the **radiation dose**. The dose is always less than the exposure because some energy is lost as scatter on the way to the tissue. The three factors determining the absorbed dose are the intensity of exposure, the duration of exposure, and the closeness of the radiation source to the cells (Camporeale, 2008).

The intensity of the radiation decreases with the distance from the radiation source (Fig. 24-2). This factor is known as the *inverse square law*. For example, the radiation dose received at a distance of 2 meters from the radiation source is only one fourth of the dose received at a distance of 1 meter from the radiation source; the dose of radiation received at 3 meters is only one ninth of the dose received at 1 meter.

If the dose of radiation is high enough, all cells are killed immediately. This does not happen with cancer radiation therapy because cells within a tumor absorb the radiation dose slightly differently. Therefore their overall response to the radiation is slightly different. A few cells die immediately, and more die within the next 24 hours as they attempt to divide. Some cells become sterile as a result of this single treatment. Still other cells repair the radiation-induced damage and recover.

Radiation therapy usually is given as a series of divided doses because of the varying responses of all cancer cells within a given tumor. Most often, small doses of radiation are given on a daily basis for a set time period to allow greater destruction of cancer cells while reducing the damage to normal tissues. Absorbed radiation doses are described in units called **gray** (gy). (The older term for radiation dose was

FIG. 24-1 Penetrating capacity of different types of radiation.

FIG. 24-2 The inverse square law of radiation exposure.

rad for radiation absorbed dose. One gy is the same as 100 rad.) One gy is equal to one joule of energy absorbed by one kg of a material. The total dose of radiation used depends on tumor size and location and on the radiation sensitivity of the tumor and nearby tissues. Some normal tissues are more sensitive than others to radiation. For example, breast tissue tolerates much higher doses of radiation than the liver does. A total dose of 50 to 60 gy might be prescribed for a breast cancer. However, only 12 gy might be prescribed for a liver tumor, because a higher dose would destroy healthy liver cells as well as the tumor.

Radiation Delivery Methods and Devices

Radiation delivery types for cancer therapy are teletherapy and brachytherapy. The type used depends on the patient's general health and on the shape, size, and location of the tumor to be irradiated. The ideal radiation dose is one that can kill the cancer cells with an acceptable level of damage to normal tissues (damage to normal tissues cannot be avoided).

Teletherapy is radiation delivered from a source outside of the patient. Because the source is external, the patient is not radioactive and is not hazardous to others.

One newer method of teletherapy is intensity modulated radiation therapy (IMRT). This type of radiation breaks up the single beam into thousands of smaller beams that allow better focus on the tumor.

Another newer method of teletherapy is stereotactic body radiotherapy (SBRT). This method uses three-dimensional tumor imaging to identify the exact tumor location, which allows more precise delivery of higher radiation doses and spares more of the surrounding tissue. Usually, the total dosage is delivered in one to five separate treatment sessions. Currently, this approach is most commonly used for small, localized lung cancers (Smink & Schneider, 2008).

Regardless of the teletherapy delivery method, the exact location of the tumor is determined for therapy accuracy. Once the pattern of radiation delivery is determined, the patient must always be in exactly the same position for all treatments (Camporeale, 2008). Ensure that the patient can get into and maintain this position. Position-fixing devices and markings, either on the patient's body or on the devices, ensure the proper position each day of treatment. The

markings may be small permanent "tattoos," ink outlines on the skin, or a marked covering laid over the skin during positioning. Position-fixing devices include customized external vacuum-type body molds, foam-based body molds, and fiberglass splints (Smink & Schneider, 2008).

Brachytherapy means "short" or "close" therapy. The radiation source comes into direct, continuous contact with the tumor tissues for a specific time period. This method provides a high dose of radiation in tumor tissues and a very limited dose in surrounding normal tissues.

Brachytherapy uses radioactive isotopes either in solid form or within body fluids. Isotopes can be delivered to the tumor tissues in several ways. *With all types of brachytherapy, the radiation source is within the patient. Therefore the patient emits radiation for a period of time and is a hazard to others* (Waring & Gosselin, 2010). When the isotopes used are unsealed and suspended in a fluid, they are given by the oral or IV routes or instilled within body cavities. An example of brachytherapy with soluble isotopes is the ingestion or injection of the radionuclide iodine-131 (^{131}I) (an iodine base with a half-life of 8.05 days) to treat some thyroid cancers. The iodine concentrates in the thyroid gland and destroys the thyroid cancer cells. *When the isotopes are unsealed, they enter body fluids and eventually are eliminated in waste products, which are radioactive and should not be directly touched by other people. After the isotope is completely eliminated from the body, neither the patient nor the body wastes are radioactive.*

Solid or sealed radiation sources are implanted within or near the tumor. These sources can be temporary or permanent. Most implants emit continuous, low-energy radiation to tumor tissues. Some devices (e.g., seeds or needles) can be placed into the tissues and stay in place by themselves. Some devices are so small and the half-life of the isotope so short that the device is permanently left in place (most often for prostate cancer) and, over time, completely loses its radioactivity. Other devices are removed and reused in other patients. Some sources must be held in place during therapy using special applicators. *While the solid implants are in place, the patient emits radiation but excreta are not radioactive and do not pose a hazard to anyone.*

Traditional implants deliver "low-dose rates" (LDRs) of radiation continuously and patients are hospitalized for

CHART 24-1 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE**Care of the Patient with Sealed Implants of Radioactive Sources**

- Assign the patient to a private room with a private bath.
- Place a “Caution: Radioactive Material” sign on the door of the patient’s room.
- If portable lead shields are used, place them between the patient and the door.
- Keep the door to the patient’s room closed as much as possible.
- Wear a dosimeter film badge at all times while caring for patients with radioactive implants. The badge offers no protection but measures a person’s exposure to radiation. Each person caring for the patient should have a separate dosimeter to calculate his or her specific radiation exposure.
- Wear a lead apron while providing care. Always keep the front of the apron facing the source of radiation (do not turn your back toward the patient).
- Pregnant nurses should not care for these patients; do not allow pregnant women or children younger than 16 years to visit.
- Limit each visitor to one-half hour per day. Be sure visitors stay at least 6 feet from the source.
- Never touch the radioactive source with bare hands. In the rare instance that it is dislodged, use a long-handled forceps to retrieve it. Deposit the radioactive source in the lead container kept in the patient’s room.
- Save all dressings and bed linens in the patient’s room until after the radioactive source is removed. After the source is removed, dispose of dressings and linens in the usual manner. Other equipment can be removed from the room at any time without special precautions and does not pose a hazard to other people.

several days. “High-dose rate” (HDR) implant radiation is another delivery type. The patient comes into the radiation therapy department several times a week, and a stronger radiation implant is placed for only an hour or so each time. The patient goes home between treatments and is radioactive only when the implant is in place (Waring & Gosselin, 2010). [Chart 24-1](#) lists the best practices for care of the patient with sealed implant radiation sources and for the safety of the personnel providing the care.

Side Effects of Radiation Therapy

The immediate and long-term side effects of all types of radiation are limited to the tissues exposed to the radiation. Therefore the side effects vary according to the site (Ruppert, 2011). Skin changes and hair loss are local but are often permanent depending on the total absorbed dose.

Altered taste sensations and fatigue are two common systemic side effects noted by patients receiving teletherapy, regardless of the radiation site. Taste changes are thought to be caused by metabolites released from dead and dying cells. Many patients develop an aversion to the taste of red meats. Fatigue may be related to the increased energy demands needed to repair damaged cells. Regardless of the cause, radiation-induced fatigue can be debilitating and may last for months (Kuchinski et al., 2009).

Radiation damage to normal tissues during cancer therapy can start inflammatory responses that lead to tissue fibrosis and scarring. These effects may appear years after radiation treatment. For example, women who receive HDR therapy for uterine cancer may develop radiation-induced changes in

CHART 24-2 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT**Skin Protection During Radiation Therapy**

- Wash the irradiated area gently each day with either water or a mild soap and water as prescribed by your radiologist.
- Use your hand rather than a washcloth to be gentler.
- Rinse soap thoroughly from your skin.
- If ink or dye markings are present to identify exactly where the beam of radiation is to be focused, take care not to remove them.
- Dry the irradiated area with patting motions rather than rubbing motions; use a clean, soft towel or cloth.
- Use only powders, ointments, lotions, or creams on your skin at the radiation site that are prescribed by the radiation oncology department.
- Wear soft clothing over the skin at the radiation site.
- Avoid wearing belts, buckles, straps, or any type of clothing that binds or rubs the skin at the radiation site.
- Avoid exposure of the irradiated area to the sun.
 - Protect this area by wearing clothing over it.
 - Try to go outdoors in the early morning or evening to avoid the more intense sun rays.
 - When outdoors, stay under awnings, umbrellas, and other forms of shade during the times when the sun’s rays are most intense (10 AM to 7 PM).
- Avoid heat exposure.

the colon (which also was irradiated) years later, resulting in constipation and obstruction.

PATIENT-CENTERED COLLABORATIVE CARE

Most patients are anxious about radiation and look to the nurse to explain the purpose and side effects of radiation therapy. Accurate, objective information about radiation therapy helps patients cope with the treatment and continue to participate in normal activities.

Skin in the path of radiation becomes very dry and may break down. Teaching patients about skin care needs during radiation therapy is a priority nursing intervention. [Chart 24-2](#) lists skin care and other precautions needed with external radiation therapy. Instruct the patient to not remove any temporary ink markings when cleaning the skin until the entire course of radiation therapy is completed. At one time, patients were told to avoid using lotions or other skin care products within 4 hours of the radiation therapy; however, this practice is not evidence-based and is now controversial (Bieck, Phillips, & Steele-Moses, 2010). Teach patients to follow the radiation-oncology department’s policy regarding the use and timing of skin care products. Use of skin care products designed to manage or protect the skin from radiation damage does reduce the degree of skin problems that develop during a full course of radiation therapy (Gosselin et al., 2010) (see the Evidence-Based Practice box on p. 414).

! NURSING SAFETY PRIORITY**Action Alert**

Skin in the radiation path is more sensitive to sunburn and damage. Advise against direct skin exposure to the sun during treatment and for at least 1 year after completing radiation therapy.

EVIDENCE-BASED PRACTICE

Do Skin Care Products Reduce Radiation Skin Effects?

Gosselin, T., Schneider, S., Plambeck, M., & Rowe, K. (2010). A prospective randomized, placebo-controlled skin care study in women diagnosed with breast cancer undergoing radiation therapy. *Oncology Nursing Forum*, 37(5), 619-626.

Breast cancer is a common cancer among women and is often treated with external beam radiation. The radiation therapy, administered daily for 6 to 7 weeks, can cause skin reactions. At times, patients are told not to use skin care products in the area of irradiation during the treatment period. This study sought to (1) identify the incidence of radiation-induced skin reactions among women undergoing external beam radiation therapy for breast cancer; and (2) compare the effectiveness of three skin care products versus placebo in reducing radiation-induced skin reactions.

A convenience sample of 208 adult women undergoing teletherapy for breast cancer were recruited into the study. Each subject was randomly assigned to one of four groups and asked to use a skin care product on the irradiated area twice daily throughout the radiation therapy period (placebo, product 1, product 2, product 3). The groups and the researchers were blinded to which products were assigned to which groups. The women kept a home journal to describe the skin site and the features of the assigned skin care product. Skin condition was assessed weekly using the Radiation Therapy Oncology Group (RTOG) acute radiation morbidity scoring criteria. Although this tool has no published validity and reliability, it has been used for 25 years as a standard of practice in radiation oncology. The inter-rater reliability for this tool among data collectors in this study was 0.96.

Of the 208 subjects completing the study, 95% experienced a skin reaction, usually by the 4th week of treatment. Although subjects using all skin care products had a slightly reduced skin reaction compared with those in the placebo-control group, the difference did not reach statistical significance.

Level of Evidence: 2

The study method was prospective, randomized, double-blind, and placebo-controlled. The large number of subjects, the random assignment, and double-blinding of the groups added strength to the study, as did objective skin-scoring using an established tool. The statistical evaluation methods were appropriate for the design, and power was adequate.

Commentary: Implications for Practice and Research

The study is important for many reasons. First, it established the incidence of radiation skin reactions for a large group of subjects all receiving radiation to the same tissue area, at the same dosage levels, for the same time period. The study also demonstrated that weekly skin assessment by radiation oncology nurses is a feasible and desirable care intervention. Second, it established that the physical benefits of three different skin care products often prescribed for use during radiation therapy were not statistically significant and had minimal clinical benefit. In fact, the product the women rated as most satisfactory (for ease of use and lifestyle fit) was the product with the poorest performance in protection against radiation skin reactions. Nurses in radiation oncology departments are often the professionals who are asked how to manage the associated skin problems. Some of the recommended products are available by prescription only and have significant cost. Thus nurses can inform patients that use of any skin care product does not prevent radiation skin reactions and that no product is superior to another. Therefore patients should decide what product to use based on ease of use, availability, and cost.

The study defined important areas for future nursing research. Issues include which patient characteristics increase the risk for radiation skin reactions, what are the reliability and validity of the RTOG acute radiation morbidity scoring criteria tool, and did weekly skin assessments by radiation oncology nurses identify problems earlier or increase patient satisfaction with therapy.

The normal tissues most sensitive to external radiation are bone marrow cells, skin, mucous membranes, hair follicles, and germ cells (ova and sperm). When possible, these tissues are shielded from radiation during therapy. At times, they are in the radiation path and cannot be protected from exposure. Some changes caused by radiation are permanent. The long-term problems vary with the location and dose of radiation received. For example, radiation to the throat and upper chest can cause difficulty in swallowing. Combined with taste alteration, this problem can lead to reduced nutrition. A registered dietitian is part of the radiation oncology team (Gosselin et al., 2008). Head and neck radiation may damage the salivary glands and cause dry mouth (**xerostomia**), which increases the patient's lifelong risk for tooth decay. Bone exposed to radiation therapy is less dense and breaks more easily. Teach about the symptoms that might be expected from the location and dose of radiation (see [Table 24-1](#) for the location of this information for different cancer types).

**NCLEX EXAMINATION CHALLENGE****Health Promotion and Maintenance**

Which precaution is most important for the nurse to teach a client receiving radiation therapy for head and neck cancer?

- A. Avoid eating red meat during treatment.
- B. Pace your leisure activities to prevent fatigue.
- C. See your dentist twice yearly for the rest of your life.
- D. Avoid using headphones or headsets until your hair grows back.

CHEMOTHERAPY**Overview**

Chemotherapy, the treatment of cancer with chemical agents, is used to cure and to increase survival time. It has some selectivity for killing cancer cells over normal cells. This killing effect on cancer cells is related to the ability of chemotherapy to damage DNA and interfere with cell division. Tumors with rapid growth are most sensitive to chemotherapy.

As described in [Chapter 23](#), cancer cells can separate from the original tumor, spread to new areas, and establish new cancers at distant sites (**metastasis**). Patients with metastatic cancer will die unless treatment eliminates the metastatic cancer cells along with the original cancer cells. Chemotherapy is useful in treating cancer because its effects are systemic, providing the opportunity to kill metastatic cancer cells that may have escaped local treatment. Chemotherapy used along with surgery or radiation is termed **adjuvant** therapy.

Drugs used for chemotherapy usually are given systemically and exert their cell-damaging (**cytotoxic**) effects against healthy cells as well as cancer cells. The normal cells most affected by chemotherapy are those that divide rapidly, including skin, hair, intestinal tissues, spermatocytes, and blood-forming cells. These drugs are classified by the specific types of action they exert in the cancer cell. [Table 24-2](#) lists categories, drugs, and their potential to induce nausea and vomiting (emetogenic) or to damage surrounding tissue.

Chemotherapy Drug Categories

Alkylating agents cross-link DNA, making the two DNA strands bind tightly together. This tight binding prevents proper DNA and ribonucleic acid (RNA) synthesis, which inhibit cell division.

TABLE 24-2 CATEGORIES OF CHEMOTHERAPEUTIC DRUGS

DRUG	EMETOGENIC POTENTIAL	TISSUE DAMAGE POTENTIAL
Antimetabolites		
Azacitidine (Vidaza)	High	Irritant
Capecitabine (Xeloda)	Low	N/A (oral drug)
Cladribine (Leustatin)	Moderate	Bruising
Clofarabine (Clofar)	Low—Moderate	Irritant
Cytarabine (Cytosar, ara-C)	Moderate	Irritant
Decitabine (Dacogen)	Moderate	Irritant
Floxuridine (FUDR)	High	Bruising
5-Fluorouracil (Adrucil, Efudex, Fluoroplex)	Moderate	Irritant
Fludarabine (Fludara, FLAMP)	Low	Bruising
Gemcitabine (Gemzar)	Moderate	Bruising
6-Mercaptopurine (Purinethol)	Low	N/A (oral drug)
Methotrexate (MTX, Mexate)	Low—Moderate	Bruising
Nelarabine (Arranon)	Moderate	Irritant
Pemetrexed (Alimta)	Moderate—High	Bruising
Pentostatin (Nipent)	Low—Moderate	Irritant
6-Thioguanine (Tabloid)	Moderate—High	N/A (oral drug)
Antitumor Antibiotics		
Bleomycin (Blenoxane)	Moderate	Irritant
Dactinomycin (Cosmegen)	High	Vesicant
Daunorubicin (Cerubidine, Daunomycin)	High	Vesicant
Doxorubicin (Adriamycin, Rubex)	High	Vesicant
Doxorubicin liposomal (Doxil)	High	Vesicant
Epirubicin (Ellence)	High	Vesicant
Idarubicin (Idamycin)	Moderate—High	Vesicant
Mitomycin C (Mutamycin)	Moderate	Vesicant
Mitoxantrone (Novantrone)	Low	Irritant
Valrubicin (Valstar)	N/A	N/A (intravesicular drug)
Antimitotics		
Cabazitaxel (Jevtana)	Moderate	Irritant
Docetaxel (Taxotere)	Moderate	Bruising
Etoposide (VP-16, VePesid)	Low	Irritant
Eribulin mesylate (Halaven)	Low—Moderate	Irritant
Paclitaxel (Taxol)	Moderate	Irritant & potential vesicant
Teniposide (Vumon)	Moderate	Vesicant
Vinblastine (Velban, Velbe, Velsar)	Low—Moderate	Vesicant
Vincristine (Oncovin)	Low	Vesicant
Vinorelbine (Navelbine)	Moderate	Vesicant
Alkylating Agents		
Altretamine (Hexalen)	Moderate	N/A (oral drug)
Bendamustine (Treanda)	Moderate	Vesicant
Busulfan (Busulfex)	High	Bruising
Carboplatin (Paraplatin)	High	Irritant
Carmustine (BiCNU; Gliadel)	High	Irritant
Chlorambucil (Leukeran)	High	N/A (oral drug)
Cisplatin (Platinol)	High	Irritant
Cyclophosphamide (Cytoxan, Procytox)	High	Bruising
Dacarbazine (DTIC)	Moderate—High	Irritant
Estramustine (Emcyt, Estracyte)	Moderate	Vesicant
Ifosfamide (Ifex)	High	Bruising
Lomustine (CCNU, CeeNU)	High	N/A (oral drug)
Mechlorethamine (Mustargen)	High	Vesicant

Continued

TABLE 24-2 CATEGORIES OF CHEMOTHERAPEUTIC DRUGS—cont'd

DRUG	EMETOGENIC POTENTIAL	TISSUE DAMAGE POTENTIAL
Melphalan (Alkeran) (available in oral or IV form)	High	Vesicant (IV drug)
Oxaliplatin (Eloxatin)	Moderate—High	Vesicant
Streptozocin (Zanosar)	High	Bruising
Temozolomide (Temodar)	Moderate—High	N/A (oral drug)
Thiotepa (Thioplex)	Low	Bruising
Topoisomerase Inhibitors		
Irinotecan (Camptosar)	Moderate	Irritant
Topotecan (Hycamtin)	Moderate	Irritant
Miscellaneous Agents		
Arsenic trioxide (Trisenox)	Moderate	Not known
Asparaginase (Elspar)	Low	Vesicant
Hydroxyurea (Droxia, Hydrea)	Low	N/A (oral drug)
Ixabepilone (Ixempra)	Low—Moderate	Irritant
Pegaspargase (Oncaspar)	Low	Bruising
Procarbazine (Matulane, Natulan 🍁)	High	N/A (oral drug)
Vorinostat (Zolinza)	Moderate	N/A (oral drug)

Data from www.fda.gov/cder/index.html; and www.mdconsult.com/php/82925233-2/homepage.

Antimetabolites are similar to normal metabolites needed for vital cell processes. Most cell reactions require metabolites in order to begin or continue the reaction. Antimetabolites closely resemble normal metabolites and are “counterfeit” metabolites that fool cancer cells into using the antimetabolites in cellular reactions. Because antimetabolites cannot function as proper metabolites, their presence impairs cell division.

Antimitotic agents interfere with the formation and actions of microtubules so cells cannot complete mitosis during cell division. As a result, the cancer cell either does not divide at all or divides only once, resulting in two daughter cells that cannot continue to divide.

Antitumor antibiotics damage the cell’s DNA and interrupt DNA or RNA synthesis. Exactly how the interruptions occur varies with each agent.

Topoisomerase inhibitors disrupt an enzyme (topoisomerase) needed for DNA synthesis and cell division. The enzyme nicks and straightens the DNA helix, allowing the DNA to be copied, and then reattaches the DNA together. Topoisomerase inhibitors prevent proper DNA maintenance, causing DNA breakage and cell death.

Miscellaneous chemotherapy drugs are those with mechanisms of action that are either unknown or do not fit those of other drug categories.

Combination Chemotherapy

Successful cancer chemotherapy involves giving more than one specific anticancer drug in a timed manner. This technique is called *combination chemotherapy*. Using more than one drug is more effective in killing cancer cells than using only a single drug. However, the side effects and damage caused to normal tissues also increase with combination chemotherapy.

The selection of drugs is based on known tumor sensitivity to the drugs and the degree of side effects expected. For example, most chemotherapy drugs suppress bone marrow activity and immune function to some degree, but some

agents cause more bone marrow suppression than others. There is also variation in the timing of drug-induced suppression and neutropenia.

The time when bone marrow activity and white blood cell counts are at their lowest levels after chemotherapy is the **nadir**. It occurs at different times for different drugs. To reduce immunosuppression, combination chemotherapy avoids using drugs with nadirs that occur at or near the same time.

GENETIC/GENOMIC CONSIDERATIONS

A newer approach to chemotherapy selection is checking the patient’s genetic profile to determine the likelihood of experiencing dangerous side effects. This process, known as *pharmacogenomics*, allows a more individualized approach to chemotherapy selection and side effect management. In addition, checking the genetic profile of the tumor can determine its sensitivity to various chemotherapy and targeted therapy agents. This increasingly common practice individualizes cancer therapy and improves therapy outcomes (Huang & Ratain, 2009).

Treatment Issues

Dosages for most chemotherapy drugs are calculated according to the type of cancer and the patient’s size. Usually, calculations are based on milligrams per square meter of total body surface area (TBSA), which considers both the patient’s height and weight.

Chemotherapy drugs are given on a regular basis and are timed to maximize cancer cell kill and minimize damage to normal cells. The schedule may vary somewhat to accommodate a patient’s response to therapy, but chemotherapy is usually scheduled every 3 to 4 weeks for a specified number of times (on average, 4 to 12 times). Newer protocols of giving higher doses of chemotherapy more often, called **dose-dense chemotherapy**, are often used for aggressive cancer treatment, especially for breast cancer. This dose-dense chemotherapy also results in more intense side effects than traditional dosing schedules.

Most chemotherapy drugs are given IV, although other routes may be used. For specific cancer types, the chemotherapy may be infused or instilled into a body cavity. The *intrathecal* route delivers drugs into the spinal canal, and the *intraventricular* route delivers drugs directly into the ventricles of the brain. *Intraperitoneal* instillations place the drugs within the abdominal cavity, most often for ovarian cancer (Karius, 2010). Drugs for bladder cancer can be instilled directly into the bladder (*intravesicular* route). For a few cancer types, *intra-arterial* infusions may be used to deliver a higher dose locally. This technique is not common and is used mostly for bone cancers and, on a limited basis, for head and neck cancer. The techniques and care needs for different routes are described with the specific cancer type most commonly associated with the specific administration route.

The IV route is the most preferred route for chemotherapy. The standard of care designated by the Oncology Nursing Society (ONS) and supported by the American Society of Clinical Oncologists (ASCO) for safe administration of IV chemotherapy is that administration of these drugs requires special education (Polovich et al., 2009). *Special education for competency does not mean that only an advanced practice nurse can perform this function; however, it does mean that the person should be a registered nurse who has completed an approved chemotherapy course. Responsibility for monitoring the patient during chemotherapy administration, however, rests with all nurses providing patient care.*

A serious complication of IV infusion is **extravasation**, which occurs when drug leaks into the surrounding tissues (also called *infiltration*). When the drugs given are **vesicants** (chemicals that damage tissue on direct contact), the results of extravasation can include pain, infection, and tissue loss (Fig. 24-3). Surgical intervention is sometimes needed for severe tissue damage. See Table 24-2 for a listing of known vesicant and irritant chemotherapy drugs.

FIG. 24-3 Appearance of tissue damage and loss after chemotherapy extravasation.

The most important nursing intervention for extravasation is prevention. Small extravasations resolve without extensive treatment if less than 0.5 mL of the drug has leaked into the tissues. If a larger amount has leaked, extensive tissue damage occurs and surgery may be needed. *Close monitoring of the access site is critical during chemotherapy administration to prevent leakage of larger volumes.* Management depends on the specific drug. With some drugs, cold compresses to the area are prescribed; for other agents, warm compresses are used. Antidotes or chemoprotective agents may be injected into the site of extravasation (Hadaway, 2009). Coordinate with the oncologist and pharmacist to determine the specific antidote needed for the extravasated drug. Chart 24-3 outlines documentation of an extravasation event.

Most chemotherapy drugs, even oral drugs, are absorbed through the skin and mucous membranes. As a result, the health care workers who prepare or give these drugs (especially nurses and pharmacists) are at risk for absorbing them. Even at low doses, long-term exposure to chemotherapy drugs can affect health. Anyone preparing, giving, or disposing of chemotherapy drugs or handling excreta from patients within 48 hours of receiving IV chemotherapy must use extreme caution and wear personal protective equipment.

CHART 24-3 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Documentation of Extravasation

- Document the date and time when extravasation was suspected or identified.
- Document the date and time when the infusion was started.
- Record the time when the infusion was stopped.
- Document the exact contents of the infusion fluid and the volume of fluid infused.
- Document the estimated amount of fluid extravasated.
- Diagram the exact insertion site, and indicate whether this is a venous access device, an implanted port, or a tunneled catheter.
- Document the method of administration (pump, controller, etc.; rate of infusion).
- Document the needle type and size.
- Indicate on the diagram the location and number of venipuncture attempts.
- Record the time between the extravasation and the last documented full blood return.
- Identify all agents administered in the previous 24 hours through this site (list agent administered, dosage and volume, and order of administration).
- Take and record the patient's vital signs.
- Ask and record the patient's subjective sensations and symptoms.
- Record all observations of the site, including size, color, and texture.
- Take a photograph of the site.
- Document the administration of neutralizing or antidote agents.
- Document the application of compresses and their temperature.
- Document other nursing interventions.
- Record the patient's responses to nursing interventions.
- Document the prescribing physician notification (including the time).
- Document the written and oral instructions given to the patient about follow-up care.
- Document any consultation request.
- Sign the documentation.

Data modified from Polovich, M., Whitford, J., & Olsen, M. (Eds.). (2009). *Chemotherapy and biotherapy guidelines and recommendations for practice* (3rd ed.). Pittsburgh: ONS Publishing.

(PPE). Such equipment includes eye protection, masks, double gloves or “chemo” gloves, and gown. The Occupational Safety and Health Administration (OSHA) and the Oncology Nursing Society (ONS) have established these practice guidelines and protective standards (Polovich et al., 2009).

About two dozen anticancer drugs are available currently as oral agents (Table 24-3). This number is expected to double within the next 10 years. Only a few are actually oral formulations of classic chemotherapy agents; more are classified as specific types of targeted therapy agents (Moody & Jackowski, 2010). Oral drugs are more convenient for the patient, and they can be taken at home. However, there are many problems with oral anticancer drugs. One of the biggest problems is the perception by patients and non-oncology nurses that these drugs are less toxic than those given intravenously (Simchowicz et al., 2010; Simmons, 2010), which is **not** true. *Oral anticancer drugs are just as toxic to the person taking the drug and the person handling the drug as are standard chemotherapy drugs.* Also, because the responsibility for administration of these drugs often shifts from

the oncology clinic to the home or to non-oncology acute care settings, issues of protection, correct administration, adherence, and recognition and management of side effects are major concerns. Patients require much education and support to self-manage this therapy. Not all patients are willing or able to accept the responsibility of self-management, and this must be considered during patient selection for oral chemotherapy.

Because these oral agents can be absorbed through skin and mucous membranes and exert toxic effects, the professional who handles and administers them needs to use PPE in the same way as during IV chemotherapy administration. This becomes a more critical issue when non-oncology nurses are administering the drugs. The ONS practice guidelines stress nurse education for competence to administer these drugs. All nurses administering these drugs must know the indications for drug use, dosage ranges, side effects and adverse effects, schedules, and specific precautions. In addition, these oral agents must not be crushed, split, broken, or chewed. These drugs are biohazardous and must be discarded in accordance with agency policy.

TABLE 24-3 CURRENT ORAL CHEMOTHERAPEUTIC DRUGS

AGENT	DRUG CATEGORY	CANCER TYPE	AGENT	DRUG CATEGORY	CANCER TYPE
Altretamine (Hexalen)	Alkylating agent	Ovarian cancer	Lenalidomide (Revlimid)	Angiogenesis inhibitor	Multiple myeloma; Myelodysplastic syndrome
Capecitabine (Xeloda)	Antimetabolite	Breast cancer Colorectal cancer	Lomustine (CCNU, CeeNU)	Alkylating agent	Hodgkin's lymphoma Malignant glioma
Chlorambucil (Leukeran)	Alkylating agent	Chronic lymphocytic leukemia; Hodgkin's lymphoma Non-Hodgkin's lymphoma	Melphalan (Alkeran)	Alkylating agent	Multiple myeloma Ovarian cancer
Dasatinib (Sprycel)	Tyrosine kinase inhibitor	Chronic myelogenous leukemia; acute myelogenous leukemia that is Philadelphia chromosome positive	Mercaptopurine (Purinethol)	Antimetabolite	Acute lymphocytic leukemia
Erlotinib (Tarceva)	Epidermal growth factor receptor inhibitor	Non-small cell lung cancer Pancreatic cancer	Nilotinib (Tasigna)	Tyrosine kinase inhibitor	Chronic myelogenous leukemia that is Philadelphia chromosome positive
Everolimus (Afinitor)	Angiogenesis inhibitor	Advanced renal cell carcinoma	Pazopanib (Votrient)	Multikinase inhibitor	Advanced renal cell carcinoma
Gefitinib (Iressa)	Epidermal growth factor receptor inhibitor	Non-small cell lung cancer	Procarbazine (Matulane, Natulan )	Miscellaneous agent	Hodgkin's lymphoma
Hydroxyurea (Droxia, Hydrea)	Miscellaneous agent	Chronic myelogenous leukemia Head and neck cancer Melanoma Ovarian cancer Sickle cell disease	Sorafenib (Nexavar)	Multikinase inhibitor	Advanced renal cell carcinoma; hepatocellular carcinoma
Imatinib (Gleevec)	Tyrosine kinase inhibitor	Chronic myelogenous leukemia that is Philadelphia chromosome positive Gastrointestinal stromal tumors Myelodysplastic syndrome	Sunitinib (Sutent)	Multikinase inhibitor	Advanced renal cell carcinoma; gastrointestinal stromal tumor
Lapatinib (Tykerb)	Tyrosine kinase inhibitor	Breast cancer	Temozolomide (Temodar)	Alkylating agent	Brain tumors (primary)
			Thioguanine (Tabloid)	Antimetabolite	Acute myelogenous leukemia
			Topotecan (Hycamtin)	Topoisomerase inhibitor	Small cell lung cancer
			Vorinostat (Zolinza)	Histone inhibitor	Cutaneous T-cell lymphoma

Adherence to defined oral chemotherapy schedules and dosages is more of a problem than with IV administration. Studies have shown that even highly motivated patients with cancer consider that skipping doses or reducing doses of oral drugs has only a minor impact (Moore, 2010; Simchowitz et al., 2010; Winkeljohn, 2010). Disrupting the schedule or reducing dosages has a negative impact on therapy outcomes and leads to drug resistance among cancer cells, disease progression, and reduced survival.

Side Effects of Chemotherapy

Temporary and permanent physical damage can occur to normal tissues from oral or IV chemotherapy because it is systemic and exerts its effects on all cells. Known problems include hemorrhagic cystitis, cardiac muscle damage, and loss of bone density. For some cancer drugs, agents that protect specific healthy cells (cytoprotectants) are administered ahead of or with chemotherapy drugs to decrease the impact of chemotherapy on normal tissues. These protective agents have little effect on cancer cells but do protect some normal tissues.

Serious short-term side effects occur with aggressive chemotherapy. The side effects on the hematopoietic (blood-producing) system can be life threatening and are the most common reason for changing the dosage or schedule. The suppressive effects on the blood-forming cells of bone marrow cause **anemia** (decreased numbers of red blood cells and hemoglobin), **neutropenia** (decreased numbers of white blood cells leading to immunosuppression), and **thrombocytopenia** (decreased numbers of platelets). Common distressing side effects include nausea and vomiting, **alopecia** (hair loss), **mucositis** (open sores on mucous membranes), many skin changes, anxiety, sleep disturbance, altered bowel elimination, and changes in cognitive function. These side effects are referred to as *cancer therapy symptom distress*.

Drug therapy often is used to reduce symptom distress for some of these side effects. For other problems, such as alopecia, the side effect cannot be prevented but the patient can be helped to reduce his or her distress from its presence. General nonpharmacologic nursing interventions for many types of symptom distress include distraction, massage, guided imagery, reiki, aromatherapy, and other forms of complementary therapy.

Psychosocial issues can occur during chemotherapy administration. For many chemotherapy regimens, drugs are given over a period ranging from 2 hours to as long as 8 hours. During this time, the patient is confined to a treatment area and is constantly reminded of his or her disease and treatment, which is unpleasant. Distraction methods such as virtual reality, guided imagery, reading, watching television, and talking with visitors may help reduce the sense of unpleasantness.

PATIENT-CENTERED COLLABORATIVE CARE

The priority care issues during chemotherapy are protecting the patient from the life-threatening side effects and managing the distressing symptoms that occur with therapy. For some patients, the symptoms are so unpleasant that they stop treatment.

Bone Marrow Suppression

In addition to killing cancer cells, chemotherapy also destroys circulating blood cells and reduces replacement of these cells by suppressing bone marrow function, also known as *myelosuppression*. The numbers of all circulating leukocytes, erythrocytes, and platelets are decreased. Reduced leukocyte numbers, especially reduced neutrophils (**neutropenia**), greatly increase the risk for infection. Decreased erythrocytes and platelets cause hypoxia, fatigue, and an increased tendency to bleed.

Infection risk results from neutropenia, placing the patient at extreme risk for sepsis. *This critical problem is the major dose-limiting side effect of cancer chemotherapy and can lead to death during treatment* (O'Leary, 2010). Most chemotherapy drugs cause myelosuppression to some degree and decrease the patient's protective responses to organism invasion. The severity of the risk is related to drug dosage. Impairment is temporary, and protection recovers within weeks after therapy completion. However, the seriousness of potential infectious complications makes this problem a major treatment concern. The most common infections are fungal, bacterial, and some residual viral breakthrough. *Most infections during neutropenia result from overgrowth of the patient's own normal flora.*

Infection risk can be managed with the use of biological response modifiers (BRMs) and growth factors to stimulate bone marrow production of immune system cells. Although not appropriate for all types of cancer, this supportive treatment can reduce the risk for infection during chemotherapy (O'Leary, 2010; Quirion, 2009). This treatment is discussed in the Immunotherapy section on p. 427. Actual infections are treated with anti-infective drugs, such as antibiotic, anti-fungal, and antiviral drugs. Just like for any other infection, anti-infective therapy is specific for the organism(s) causing the infection.

CONSIDERATIONS FOR OLDER ADULTS

Older adults are at even greater risk for chemotherapy-induced neutropenia because of age-related changes in bone marrow function. Using growth factors, such as filgrastim (Neupogen) and pegfilgrastim (Neulasta), before neutropenia occurs rather than later can reduce the severity of neutropenia and the risk for infectious complications (Flores & Ershler, 2010).

! NURSING SAFETY PRIORITY

Action Alert

The priority nursing interventions for the patient with neutropenia are protecting him or her from infection within the health care system and teaching the patient and family how to reduce infection in the home. Total patient assessment, including skin and mucous membrane inspection, lung sounds, mouth assessment, and close inspection of venous access device insertion sites, should be performed every 8 hours by a registered nurse for hospitalized patients.

Explain to the patient the importance of reporting any change in skin and mucous membranes or other health status. Instruct him or her to report any pimple, sore, rash, or open skin area. Also teach him or her to report a cough, burning on urination, pain around the venous access site, or new drainage from any body area. Good handwashing before

contact with the patient is essential infection prevention. Use aseptic technique with any invasive procedure. **Chart 24-4** lists the best practices to prevent infection in patients with neutropenia.

When delegating any nursing care activity to unlicensed assistive personnel (UAP) with supervision, teach them the importance of protecting the neutropenic patient from infection. Stress the ways that cross-contamination can occur and how to avoid this source of infection. Also ensure that UAP understand that even when the neutropenic patient is very tired and does not feel well, certain aspects of personal hygiene cannot be deferred. *Teach the importance of mouth care and washing of the axillary and perianal regions at least every 12 hours.*

Monitoring for manifestations of infection is critical for the hospitalized patient with neutropenia. The reduced numbers of neutrophils and other WBCs can limit the presence of common infection manifestations. Often the patient with neutropenia does not develop a high fever or have purulent drainage even when a severe infection is present. Hospital units specializing in care of neutropenic patients often have standard protocols that nurses initiate as soon as infection is suspected, *before a physician examines the patient*, because treatment delay can result in sepsis and death. These

CHART 24-4 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Care of the Patient with Myelosuppression and Neutropenia

- Place the patient in a private room whenever possible.
- Use good handwashing technique or use alcohol-based hand rubs before touching the patient or any of the patient's belongings.
- Ensure that the patient's room and bathroom are cleaned at least once each day.
- Do not use supplies from common areas for patients with myelosuppression and neutropenia. For example, keep a dedicated box of disposable gloves in his or her room and do not share this box with any other patient. Provide single-use food products, individually wrapped gauze, and other individually wrapped items.
- Limit the number of health care personnel entering the patient's room.
- Monitor vital signs every 4 hours, including temperature.
- Inspect the patient's mouth at least every 8 hours.
- Inspect the patient's skin and mucous membranes (especially the anal area) for the presence of fissures and abscesses at least every 8 hours.
- Inspect open areas, such as IV sites, every 4 hours for manifestations of infection.
- Change wound dressings daily.
- Obtain specimens of all suspicious areas for culture (as specified by the agency), and promptly notify the physician.
- Assist the patient in coughing and deep-breathing exercises.
- Encourage activity at a level appropriate for the patient's current health status.
- Change IV tubing daily, or according to unit protocol.
- Keep frequently used equipment in the room for use with this patient only (e.g., blood pressure cuff, stethoscope, thermometer).
- Limit visitors to healthy adults.
- Use strict aseptic technique for all invasive procedures.
- Monitor the white blood cell count, especially the absolute neutrophil count (ANC), daily.
- Avoid the use of indwelling urinary catheters.
- Keep fresh flowers and potted plants out of the patient's room.
- Teach the patient to avoid eating raw fruits and vegetables; undercooked meat, eggs, and fish; pepper; and paprika.

protocols specify what types of cultures to obtain (e.g., blood, urine, sputum, central line, wound), what diagnostic tests to obtain (e.g., chest x-ray), and what antibiotics to start immediately.

! NURSING SAFETY PRIORITY

Critical Rescue

Consider any temperature elevation in a patient with neutropenia a sign of infection. Report it to the health care provider immediately, and implement standard infection protocols.

Many patients remain at home during periods of neutropenia and are at continuing risk for infection. The focus remains on keeping the patient's own normal flora under control and preventing transmission of organisms from other people to him or her. *At no time is the patient an infection hazard to other people; however, other people can be an infection hazard to the patient.* Teach patients and families actions to reduce the risk for infection (**Chart 24-5**).

CHART 24-5 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Prevention of Infection

During the times your white blood cell counts are low:

- Avoid crowds and other large gatherings of people who might be ill.
- Do not share personal toilet articles, such as toothbrushes, toothpaste, washcloths, or deodorant sticks, with others.
- If possible, bathe daily, using an antimicrobial soap. If total bathing is not possible, wash the armpits, groin, genitals, and anal area twice a day with an antimicrobial soap.
- Clean your toothbrush at least weekly by either running it through the dishwasher or rinsing it in liquid laundry bleach (and then rinsing the bleach out with hot running water).
- Wash your hands thoroughly with an antimicrobial soap before you eat and drink, after touching a pet, after shaking hands with anyone, as soon as you come home from any outing, and after using the toilet.
- Avoid eating salads; raw fruits and vegetables; undercooked meat, fish, and eggs; and pepper and paprika.
- Wash dishes between use with hot, sudsy water, or use a dishwasher.
- Do not drink water, milk, juice, or other cold liquids that have been standing at room temperature for longer than an hour.
- Do not reuse cups and glasses without washing.
- Do not change pet litter boxes.
- Take your temperature at least once a day and whenever you do not feel well.
- Report any of these signs or symptoms of infection to your physician immediately:
 - Temperature greater than 100° F.
 - Persistent cough (with or without sputum)
 - Pus or foul-smelling drainage from any open skin area or normal body opening
 - Presence of a boil or abscess
 - Urine that is cloudy or foul smelling or that causes burning on urination
- Take all prescribed drugs.
- Wear clean disposable gloves underneath gardening gloves when working in the garden or with houseplants.
- Wear a condom (if you are a man) when having sex. If you are a woman having sex with a male partner, ensure that he wears a condom.

Anemia and thrombocytopenia also result from the bone marrow suppression caused by some chemotherapy drugs. Anemia causes patients to feel fatigued, and some tissues are hypoxic. Thrombocytopenia increases the risk for excessive bleeding. When the platelet count is less than 50,000/mm³, small trauma can lead to prolonged bleeding. With a count lower than 20,000 platelets/mm³, spontaneous and uncontrollable bleeding may occur. Both anemia and thrombocytopenia may require transfusion therapy (Miller, 2010).

The use of growth factors to stimulate marrow production of red blood cells and platelets is common. Erythropoiesis-stimulating agents (ESAs) such as darbepoetin alfa (Aranesp) and epoetin alfa (Epogen and Procrit) can prevent or improve anemia associated with chemotherapy and can reduce the need for transfusion therapy. These drugs increase the production of many blood cell types, not just erythrocytes, increasing the patient's risk for hypertension, blood clots, strokes, and heart attacks, especially among older adults (Miller, 2010). Also, certain types of cancer cells grow faster in the presence of these ESAs, such as head and neck cancer cells, leukemias, and some lymphomas. Dosing is based on individual patient hemoglobin levels to ensure that just enough red blood cells are produced to avoid the need for transfusion but not to bring hemoglobin or hematocrit levels up to normal.

Growth factor therapy for thrombocytopenia is the use of oprelvekin (Neumega). This modified version of interleukin-11 (IL-11) increases the production of platelets. The drug causes fluid retention and increases the risk for heart failure and pulmonary edema. Other side effects include conjunctival bleeding, hypotension, and tachycardia. Teach patients to weigh themselves daily and keep a record. Remind them to immediately report sudden weight gain or dyspnea to the health care provider.

The priority for nursing care for the patient with thrombocytopenia is to provide a safe hospital environment. Chart 24-6 lists the best practices for bleeding precautions during hospitalization. Teach UAP the importance of using bleeding precautions and the need to report any evidence of bleeding immediately.

Teach patients with thrombocytopenia and their families to avoid injury and excessive bleeding when discharge occurs before the platelet count has returned to normal. Chart 24-7 reviews precautions to teach patients to prevent bleeding and what to do if bleeding occurs.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client receiving high-dose chemotherapy who has bone marrow suppression has been receiving daily injections of epoetin alfa (Procrit). Which assessment finding indicates to the nurse that today's dose should be held and the health care provider notified?

- Hematocrit of 28%
- Total white blood cell count of 6200 cells/mm³
- Blood pressure change from 130/90 mm Hg to 148/98 mm Hg
- Temperature change from 99° F (37.2° C) to 100° F (37.8° C)

Chemotherapy-Induced Nausea and Vomiting

Chemotherapy-induced nausea and vomiting (CINV) arises from a variety of GI and neural mechanisms. Most chemotherapy drugs are **emetogenic** (vomiting inducing) to some degree, depending on the dose. Most drugs induce nausea

and vomiting when the drug is given and for 1 to 2 days afterward. Some drugs, such as cisplatin (Platinol), induce delayed nausea and vomiting that can continue as long as 5 to 7 days after receiving it. Patients who have CINV during one round of chemotherapy may begin to have the same symptoms before the next round as a result of sheer anticipation. Once considered the single most distressing side effect of chemotherapy, CINV often can be well controlled with appropriate antiemetic therapy.

Drug Therapy. Many antiemetics are available to relieve nausea and vomiting. These drugs vary in the side effects they produce and how well they control CINV. One or more antiemetics are usually given before, during, and after chemotherapy. Drugs commonly used short-term to control CINV are listed in Chart 24-8. *Patient response to antiemetic therapy is variable, and the drug combinations are individualized for best effect.*

NURSING SAFETY PRIORITY

Drug Alert

Do not confuse the antiemetic drug Anzemet (dolasetron) with the diabetes drug Avandamet (a combination of metformin and rosiglitazone). The drugs have similar sounding names but totally different actions.

Regardless of which drug or drugs are being used to prevent or reduce CINV, they are most effective when used aggressively and on a scheduled basis (Hawkins & Grunberg,

CHART 24-6 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Prevention of Injury for the Patient with Thrombocytopenia

- Handle the patient gently.
- Use and teach UAP to use a lift sheet when moving and positioning the patient in bed.
- Avoid IM injections and venipunctures.
- When injections or venipunctures are necessary, use the smallest-gauge needle for the task.
- Apply firm pressure to the needle stick site for 10 minutes or until the site no longer oozes blood.
- Apply ice to areas of trauma.
- Test all urine and stool for the presence of occult blood.
- Observe IV sites every 4 hours for bleeding.
- Instruct patients to notify nursing personnel immediately if any trauma occurs and if bleeding or bruising is noticed.
- Avoid trauma to rectal tissues:
 - Do not administer enemas.
 - If suppositories are prescribed, lubricate liberally and administer with caution.
- Measure the patient's abdominal girth daily.
- Instruct the patient and UAP to use an electric shaver rather than a razor.
- When providing mouth care or supervising others in providing mouth care:
 - Use a soft-bristled toothbrush or tooth sponges.
 - Do not use water pressure gum cleaners.
 - Make certain that dentures fit and do not rub.
- Instruct the patient not to blow the nose or insert objects into the nose.
- Instruct UAP and the patient that the patient should wear shoes with firm soles whenever ambulating.
- Keep pathways and walkways clear and uncluttered.

CHART 24-7 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Preventing Injury or Bleeding

During the time your platelet count is low:

- Use an electric shaver.
- Use a soft-bristled toothbrush.
- Do not have dental work performed without consulting your cancer health care provider.
- Do not take aspirin or any aspirin-containing products. Read the label to be sure that the product does not contain aspirin or salicylates.
- Do not participate in contact sports or any activity likely to result in your being bumped, scratched, or scraped.
- If you are bumped, apply ice to the site for at least 1 hour.
- Avoid hard foods that would scrape the inside of your mouth.
- Eat warm, cool, or cold foods to avoid burning your mouth.
- Check your skin and mouth daily for bruises, swelling, or areas with small reddish purple marks that may indicate bleeding.
- Notify your cancer health care provider if you:
 - Are injured and persistent bleeding results
 - Have excessive menstrual bleeding
 - See blood in your urine or bowel movement
- Avoid anal intercourse.
- Take a stool softener to prevent straining during a bowel movement.
- Do not use enemas or rectal suppositories.
- Avoid bending over at the waist.
- Do not wear clothing or shoes that are tight or that rub.
- Avoid blowing your nose or placing objects in your nose. If you must blow your nose, do so gently without blocking either nasal passage.
- Avoid playing musical instruments that raise the pressure inside your head, such as brass wind instruments and woodwinds or reed instruments.

2009). Drug therapy for CINV works best when given before the nausea and vomiting are out of control. *Thus the nursing priority is to coordinate with the patient and health care provider to ensure adequate control of CINV. Ensure that antiemetics are given before chemotherapy.* When patients are receiving dose-dense chemotherapy, the intensity of CINV also increases and greater antiemetic therapy is needed. Teach patients to continue the prescribed therapy, even when CINV appears controlled. *When the patient stops taking the drug(s), teach him or her to start retaking the drug at the first sign of nausea to prevent it from becoming uncontrollable.*

CONSIDERATIONS FOR OLDER ADULTS

Older patients may receive lower doses of chemotherapy because it was thought that they would not be able to tolerate the side effects of chemotherapy-induced nausea and vomiting (CINV). Studies have shown that older patients do not have greater CINV than younger patients, and their chemotherapy regimens should not be altered on this basis alone. However, the older adult can become dehydrated more quickly if CINV is not controlled. Teach older adults to be proactive with taking their prescribed antiemetics and to contact their health care provider if the CINV either does not resolve within 12 hours or becomes worse (Cope & Reb, 2006).

Complementary and Alternative Therapies. Complementary and alternative therapies may assist the patient with

CINV to achieve comfort through nonpharmacologic means along with antiemetics. Music, progressive muscle relaxation, guided imagery, acupressure, distraction, or drinking Concord grape juice before meals may help reduce or relieve nausea and vomiting. Assess patients for vomiting, dehydration, and electrolyte imbalances.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

Which action is most important for the nurse to implement to prevent nausea and vomiting in a client who is prescribed to receive the first round of IV chemotherapy?

- Keep the client NPO during the time chemotherapy is infusing.
- Administer antiemetic drugs before administering chemotherapy.
- Ensure that the chemotherapy is infused over a 4- to 6-hour period.
- Assess the client for manifestations of dehydration hourly during the infusion period.

Mucositis

Mucositis (sores in mucous membranes) often develops in the entire GI tract, especially in the mouth (**stomatitis**). Normally, the lining of the GI tract undergoes rapid cell division and quickly replaces cells. Chemotherapy kills mucous membrane cells more rapidly than they are replaced, resulting in sores. Mouth sores are painful and interfere with eating and general quality of life. **Chart 24-9** lists the patient education for self-management of mucositis.

Frequent mouth assessment and oral hygiene are key in managing stomatitis and mucositis. Stress the importance of good and frequent oral hygiene, including teeth cleaning and mouth rinsing. Because most patients with mucositis also have myelosuppression (bone marrow suppression) and are at risk for bleeding, they must take care to avoid traumatizing the oral mucosa. Instruct them to use a soft-bristled toothbrush or disposable mouth sponges. New recommendations include gentle flossing once daily (Harris et al., 2008). Encourage them to rinse the mouth with plain water or saline every hour while awake. Teach them to avoid mouthwashes that contain alcohol or other drying agents that may further irritate the mucosa.

Oral hygiene equipment must be kept clean. Remind patients not to share toothbrushes. Toothbrushes can be cleaned weekly by using a home dishwasher or by rinsing them with a concentrated solution of liquid bleach or hydrogen peroxide and then rinsing with hot water.

Many compounds are available for pain relief from stomatitis or mucositis as “swish and spit” mixtures that contain a local anesthetic combined with anti-inflammatory agents. Remind the patient that these mixtures are not to be swallowed.

Alopecia

Alopecia, hair loss, may occur as whole-body hair loss or may be as mild as only a thinning of the scalp hair. Reassure patients that hair loss is temporary. Hair regrowth usually begins about 1 month after completion of chemotherapy; however, the new hair may differ from the original hair in color, texture, and thickness. No known treatment prevents alopecia. *The priority nursing interventions for the patient with alopecia are to teach the patient to prevent injury to the scalp and to assist him or her in coping with this body image change.*

CHART 24-8 COMMON EXAMPLES OF DRUG THERAPY

Antiemetic Drugs for Chemotherapy-Induced Nausea and Vomiting

DRUG/USUAL DOSAGE	PHYSIOLOGIC PURPOSE	NURSING INTERVENTIONS	RATIONALE
Serotonin Antagonists			
Ondansetron (Zofran) 8 mg IV or orally every 8 hr	Prevent CINV by blocking the 5-HT3 receptors in the brain (chemotrigger zone) and in the intestines. This action prevents serotonin from binding to the receptors and activating the nausea and vomiting centers.	Teach patient to change positions slowly to avoid falls.	These drugs may induce bradycardia, hypotension, and vertigo.
Granisetron (Kytril) 1 mg IV or orally every 12 hr		Assess the patient for headache.	Headache is a common side effect of drugs from this class.
Granisetron transdermal (Sancuso) 1 patch per day starting 24 to 48 hrs before chemotherapy administration and continuing for up to 7 days after chemotherapy administration			
Dolasetron (Anzemet) 100 mg IV or orally 30 minutes before chemotherapy administration			
Palonosetron (Aloxi) 0.25 mg IV as a single dose 30 minutes before chemotherapy administration			
Neurokinin Receptor Antagonists			
Aprepitant (Emend)	Reduce CINV by blocking the substance P neurokinin receptor. When used together with a serotonin antagonist and a corticosteroid, both acute and delayed nausea and vomiting are controlled.	Teach patients who are also taking warfarin (Coumadin) to have their INRs checked before and after the 3 days of this therapy.	This drug interferes with the effectiveness of warfarin.
3-day oral regimen:			
Day 1, 125 mg 1 hour before chemotherapy administration			
Days 2 and 3, 80 mg in the morning (no chemotherapy these days)		Teach women who are using oral contraceptives to use an additional form of birth control while on this drug.	The drug reduces the effectiveness of oral contraceptives, increasing the risk for an unplanned pregnancy.
Corticosteroids			
Dexamethasone (Decadron) 5-10 mg IV or orally daily	Reduce CINV by decreasing swelling in the brain's chemotrigger zone.	Teach patients to reduce salt intake to about 4 g daily.	Drug causes fluid retention and hypertension.
Prokinetic Agents			
Metoclopramide (Reglan) 20-40 mg IM or IV twice or three times daily	Reduce CINV by blocking dopamine receptors in the brain's chemotrigger zone.	Teach the patient to avoid driving or operating heavy machinery.	Increased drowsiness is common.
Benzodiazepines			
Lorazepam (Ativan) 1-3 mg orally or IV twice or three times daily	Reduce CINV by enhancing cholinergic effects and by decreasing the person's awareness.	Teach the patient and family that the patient should avoid driving, operating heavy machinery, making legal decisions, and going up and down staircases unassisted.	The drug induces amnesia and profound drowsiness.

CINV, Chemotherapy-induced nausea and vomiting; INR, international normalized ratio.

One practice that patients have used to preserve hair is the application of an ice cap during and for a few hours after chemotherapy administration. This practice limits exposure of the hair follicles to chemotherapy, and less hair loss results. However, this practice also may allow circulating cancer cells to escape exposure to chemotherapy, increasing the risk for cancer recurrence. Thus this practice is not recommended by professional oncology organizations.

The hairless scalp is at risk for injury. Teach the patient to avoid direct sunlight on the scalp by wearing a hat or other head covering. Sunscreen use is essential to prevent sunburn even with minimal sun exposure (many chemotherapy drugs increase sun sensitivity), regardless of skin darkness. This skin can be damaged by helmets, headphones, headsets, and other items that rub the head. Teach the patient to wear some head covering underneath these items. Head coverings also are

needed during cold weather to reduce body heat loss and prevent hypothermia.

Assist patients in selecting a type of head covering that suits their income and lifestyle. Having very short hair or a shaved head now is common and socially acceptable for men, and many men choose not to wear a wig during chemotherapy. Cutting the hair very short before chemotherapy begins allows a better wig fit.

Suggest that patients purchase a wig before therapy begins and have their hairdresser shape the wig to mimic their usual hairstyle so there is less change in appearance. High-quality wigs are expensive but can look very much like the patient's own hair. Many local units of the American Cancer Society offer the loan of wigs that other patients have used and then donated to be lent to others with cancer. Patients also can disguise hair loss with caps, scarves, and turbans. Patients in

CHART 24-9 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Mouth Care for Patients with Mucositis

- Examine your mouth (including the roof, under the tongue, and between the teeth and cheek) every 4 hours for fissures, blisters, sores, or drainage.
- If sores or drainage is present, see your health care provider to have these areas cultured.
- Brush the teeth and tongue with a soft-bristled brush or sponges every 8 hours and before meals.
- Rinse the mouth with a solution of one-half peroxide and one-half normal saline every 12 hours.
- Avoid the use of mouthwashes that contain alcohol or glycerin.
- Rinse your mouth four times daily with a bland rinse.
- Drink 2 or more liters of water per day if another health problem does not require limiting fluid intake.
- Take antimicrobial drugs as prescribed.
- Use topical analgesic drugs as prescribed or as needed.
- “Swish and spit” room-temperature tap water or normal saline as needed.
- Apply a water-based moisturizer to your lips after each episode of mouth care and as needed.
- Use prescribed “artificial saliva” or mouth moisturizers as needed.
- Avoid using tobacco or drinking alcoholic beverages.
- Avoid spicy, salty, acidic, dry, rough, or hard food.
- Cool liquids to prevent burns or irritation.
- If you wear dentures, use them only during meals. When not in place, soak dentures in an antimicrobial solution. Rinse thoroughly before placing them in your mouth.

control of their appearance may improve their quality of life during cancer therapy (Borsellino & Young, 2011).

Changes in Cognitive Function

Some patients receiving chemotherapy have reported changes in cognitive function, most commonly reduced ability to concentrate, memory loss, and difficulty learning new information during treatment and for months to years after treatment (Evens & Eschiti, 2009). Although most types of chemotherapy drugs do not cross the blood-brain barrier and were thought not to affect any part of brain function, the drugs can induce inflammation and general biochemical changes that could reduce cognitive function, at least temporarily.

This problem, termed “chemo brain,” is reported most often in women undergoing chemotherapy for breast cancer, although it is not limited either to women or to breast cancer treatment. The fact that it is reported more in this population reflects the issues that breast cancer is very common, it is often treated with high-dose chemotherapy, and most patients with breast cancer survive a long time after therapy.

Comparisons of brain structure and cognitive function before, during, and after high-dose chemotherapy show some anatomic changes in brain white matter and gray matter. These changes are not usually present at 3 years after completion of therapy. It is not known why all patients receiving high-dose chemotherapy do not develop the problem; however, genetic differences in cytokine release and disruption of the blood-brain barrier may be partly responsible (Evens & Eschiti, 2009; Myers et al., 2008). Not only is the exact cause of this side effect unclear, so are the personal risk factors.

The priority for nursing care is to support the patient who reports this side effect. Listen to the patient’s concerns, and tell

him or her that other patients have also reported such problems. Providing absolute reassurance is difficult because only a few studies using appropriate research methods have examined this issue; however, early results indicate that recovery is likely with time. A common sense approach includes that patients should be warned against participating in other behaviors that could alter cognitive functioning, such as excessive alcohol intake, recreational drug use, and activities that increase the risk for head injury.

Chemotherapy-Induced Peripheral Neuropathy

Chemotherapy-induced peripheral neuropathy (CIPN) is the loss of sensory or motor function of peripheral nerves associated with exposure to certain anticancer drugs (Donovan, 2009; Tofthagen, 2010). Although most commonly seen in patients with long-term diabetes, patients undergoing chemotherapy with nerve-damaging drugs (especially the antimitotics and platinum-based drugs) often have rapid onset of severe CIPN (Visovsky et al., 2008). The degree of CIPN is related to the dosage of the nerve-damaging drugs; higher doses lead to greater neuropathy. The results of CIPN on function are widespread, with the most common problems including loss of sensation in the hands and feet, orthostatic hypotension, erectile dysfunction, neuropathic pain, loss of taste discrimination, and severe constipation (Visovsky et al., 2008). CIPN is a long-term consequence and may be permanent in some people. No known interventions prevent CIPN.

The priority for nursing care of patients experiencing CIPN is teaching them to prevent injury. Loss of sensation increases the patient’s risk for injury because he or she may not be aware of excessive heat, cold, or pressure. The risk for injury to the feet is very high. Falls are more likely because the patient cannot feel changes in terrain and because of orthostatic hypotension. **Chart 24-10** lists teaching priorities for the patient with CIPN.

Some issues, such as erectile dysfunction, may be helped with devices or drug therapy (see **Chapter 75** for options for erectile dysfunction). Other issues are not correctable and often affect many aspects of quality of life. The loss of sensation in the hands may make some activities that require very fine motor skills impossible. For other activities, such as piano-playing, the person may have to watch his or her hands to know just where the keys are and may not be able to control how hard a key is struck. Assess the patient’s ability to cope with these changes. Coordinate with an occupational therapist to help the patient adjust for sensory deficits in performing activities.

HORMONAL MANIPULATION

Overview

Hormones are naturally occurring chemicals secreted by endocrine (ductless) glands and picked up by capillaries. Once in the bloodstream, hormones circulate to all body areas but exert their effects only on their specific target tissues. Some hormones make hormone-sensitive tumors grow more rapidly. Thus decreasing the amount of these hormones to hormone-sensitive tumors can slow the cancer growth rate.

Hormonal manipulation can help control some types of cancer for many years but does not cure the disease. If a tumor depends on hormone A for growth and a large quantity of hormone B (similar to A) is given to the patient,

CHART 24-10 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Chemotherapy-Induced Peripheral Neuropathy

- Protect feet and other body areas where sensation is reduced (e.g., do not walk around in bare feet or stocking feet; always wear shoes with a protective sole).
- Be sure shoes are long enough and wide enough to prevent creating sores or blisters.
- Buy shoes in the afternoon or evening to accommodate any size change needed for foot swelling.
- Provide a long break-in period for new shoes; do not wear new shoes for longer than 2 hours at a time.
- Avoid pointed-toe shoes and shoes with heels higher than 2 inches.
- Inspect your feet daily (with a mirror) for open areas or redness.
- Avoid extremes of temperature; wear warm clothing in the winter, especially over hands, feet, and ears.
- Test water temperature with a thermometer when washing dishes or bathing. Use warm water rather than hot water (less than 105° F).
- Use potholders when cooking.
- Use gloves when washing dishes or gardening.
- Do not eat foods that are “steaming hot”; allow them to cool before placing them in your mouth.
- Eat foods that are high in fiber (e.g., fruit, whole grain cereals, vegetables).
- Drink two to three liters of fluid (nonalcoholic) daily unless your health care provider has told you to restrict fluid intake.
- Get up from a lying or sitting position slowly. If you feel dizzy, sit back down until the dizziness fades before standing; then stand in place for a few seconds before walking or using the stairs.
- Look at your feet and the floor or ground where you are walking to assess how the ground, floor, or step changes to prevent tripping or falling.
- Avoid using area rugs, especially those that slide easily.
- Use handrails when going up or down steps.

hormone B will interfere with the tumor’s uptake of hormone A or will limit the amount produced. As a result, tumor growth is slowed and survival time increases. Table 24-4 lists drugs used in hormonal manipulation for cancer therapy.

Some drugs are hormone antagonists that compete with natural hormones at the receptors. When hormone antagonists are given, they bind to the specific hormone receptor on or in the tumor cell and prevent the needed hormone from binding to the receptor. If a tumor needs a certain hormone to grow and the hormone can enter or activate the cell only through a receptor, hormone antagonists can slow tumor growth.

The hormone inhibitors are another class of drugs used for hormonal therapy. These drugs inhibit the production of specific hormones in the normal hormone-producing organs. For example, the aromatase inhibitor anastrozole (Arimidex) prevents the production of estrogen in the adrenal gland and reduces the blood level of estrogen, which results in slower growth of some breast cancers.

Side Effects of Hormonal Manipulation

Androgens and the antiestrogen receptor drugs cause masculinizing effects in women. Chest and facial hair may develop, menstrual periods stop, and breast tissue shrinks. Patients may have some fluid retention. For men and women receiving androgens, acne may develop, hypercalcemia is common, and liver dysfunction may occur with prolonged therapy. Women

TABLE 24-4 COMMON AGENTS USED FOR HORMONAL MANIPULATION OF CANCER

TYPE OF AGENT	EXAMPLE
Hormone Agonists	
Androgen	Fluoxymesterone (Halotestin) Testolactone (Teslac)
Estrogen	Chlorotrianisene (Tace) Conjugated equine estrogen (Premarin) Diethylstilbestrol (DES, Stilphostrol) Ethinyl estradiol (Estinyl)
Progestin	Medroxyprogesterone (Amen, Provera) Megestrol (Megace)
Luteinizing hormone–releasing hormone (LHRH)	Leuprolide (Eligard, Lupron, Viadur) Goserelin (Zoladex)
Hormone Antagonists	
Antiandrogens	Bicalutamide (Casodex) Flutamide (Eulexin)
Antiestrogens	Fulvestrant (Faslodex) Tamoxifen (Nolvadex) Toremifene (Fareston)
Hormone Inhibitors	
	Aminoglutethimide (Cytadren, Elipten) Anastrozole (Arimidex) Exemestane (Aromasin) Letrozole (Femara)

receiving estrogens or progestins have irregular menses, fluid retention, and breast tenderness. All patients who take estrogen or progestins are at increased risk for venous thromboembolism.

Feminine manifestations appear in men who take estrogens, progestins, or antiandrogen receptor drugs. Facial hair thins or disappears, facial skin is smoother, body fat is redistributed, and **gynecomastia** (breast development in men) can occur. Bone loss is common, which increases the risk for osteoporosis and pathologic bone fractures (Abarado & Mahon, 2010). Testicular and penile atrophy also occurs to some degree. Although sexual function may continue, achieving and maintaining an erection are difficult. Teach patients and families about expected side effects. Encourage them to express their feelings about body changes. Refer them for counseling, if needed.

PHOTODYNAMIC THERAPY

Overview

Photodynamic therapy (PDT) is the selective destruction of cancer cells through a chemical reaction triggered by types of laser light. It can be used to destroy some cancers, reduce the size of tumors and then allow more complete tumor removal by surgery, and shrink tumors in airways or the esophagus to relieve obstruction. PDT for cancer therapy is used most often for non-melanoma skin cancers, ocular tumors, GI tumors, and lung cancers located in the airways.

An agent that sensitizes cells to light is injected IV along with a dye. These agents enter all cells but leave normal cells more rapidly than cancer cells. Usually, within 48 to 72 hours,

most of the drug has collected in high concentrations in cancer cells. At this time, a laser light is focused on the tumor. The light activates a chemical reaction within those cells retaining the sensitizing drug that induces irreversible cell damage. Some cells die and slough immediately; others continue to slough for several days. Some lesions require only one exposure to the laser, and others must be re-exposed several days after the first treatment.

PATIENT-CENTERED COLLABORATIVE CARE

The priorities for nursing care of the patient receiving PDT are teaching the patient and family to prevent complications and coordinating changes in the care environment for protection of the patient (Collins & Garner, 2007). The patient has general sensitivity to light for up to 12 weeks after the photosensitizing drug is injected. The most intense period of light sensitivity is the 48 hours after injection and before the laser treatment. During this time, the patient is at high risk for sunburn and eye pain or damage.

Teaching must begin before the patient comes for the injection. Specific instructions are listed in Chart 24-11. Instruct the patient to bring clothing, hat, and eye protection to wear on the way home from the injection. Clothing should include gloves, shirts or blouses with long sleeves and high collars, long pants, and socks, to prevent burns from exposure to direct or indirect sunlight (including light through windows) and other intense light sources. Stress that the skin and eyes will remain sensitive for 30 to 90 days, even among people with very dark skin. Thus the patient will need to use protective measures and be homebound for 1 to 3 months.

When the patient returns for the laser light therapy, the process may occur on an outpatient basis, or for airway lesions, the patient may require several days as an inpatient in an intensive care unit. The nurse coordinates with all other members of the health care team in ensuring that the environment is safe for the patient. Lighting of all types is kept to a minimum. Even the use of a penlight or the sensor on a pulse oximeter can lead to burns for the patient who has been injected with a photosensitizer. Turn down the light intensity of the readouts on electronic monitoring equipment to as low as possible and ensure that it is not facing the patient. When the patient is transported, reducing hallway lighting and avoiding windows are essential. An especially important member of the team to consult is the pharmacist. Any drug the patient is prescribed must be considered for its photosensitizing properties. For example, certain antibiotics (tetracycline and erythromycin) increase photosensitivity as do many antihypertensive drugs. When these drugs are taken by the patient receiving PDT, the intensity of the photosensitivity is increased and the patient's risk for harm also is increased.

IMMUNOTHERAPY: BIOLOGICAL RESPONSE MODIFIERS

Overview

Biological response modifiers (BRMs) modify the patient's biologic responses to tumor cells. The BRMs used as cancer therapy are cytokines, which are small protein hormones made by white blood cells.

CHART 24-11 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Photodynamic Therapy

Before Photosensitization

- Bring protective clothing (e.g., shirts with long sleeves and high collars, long pants or skirt, gloves, socks, wide-brimmed hat) and UV-protective sunglasses with you when you come to be injected with the photosensitizing agent.
- If possible, have someone else drive you home so that you can place a sheet or light blanket over yourself.
- Plan to avoid leaving your home during daylight hours for anywhere from 1 to 3 months.
- Cover all windows with light-blocking shades or heavy drapes/curtains.
- Replace high-wattage light bulbs with lower-wattage ones, and use as few as possible.

After Photosensitization

- Remember that the photosensitizing effects last from 1 to 3 months.
- Continue to wear all protective clothing, avoid sunlight in any form, and avoid high-wattage indoor lights.
- Drink plenty of water to prevent becoming dehydrated.
- Do not take any newly prescribed or over-the-counter drugs without contacting the physician who performed the photodynamic therapy. Some drugs make the light sensitivity even worse; others interact with the photosensitizing drug.
- When you do start to re-expose yourself to sunlight and other bright lights, do so slowly. Start out exposing only about 1 inch of your skin to sunlight at a time.
 - Start out with only 10 minutes, and increase the time only by about 5 minutes each day.
- Remember that sunscreen will not prevent severe sunburn during this time.
- If you experience pain or blistering, notify the photodynamic therapy health care team.
- Continue to wear dark glasses, even indoors, until you no longer have eye pain when in a normally lighted environment.
- When you no longer are photosensitive, see an ophthalmologist to check whether your retina has any damage.

UV, Ultraviolet.

Some cytokines enhance immune function, which plays an important role in cancer prevention (see [Chapters 19 and 23](#)). Cytokines and other BRMs work by stimulating the immune system to recognize cancer cells and take actions to eliminate or destroy them. Some BRMs stimulate faster recovery of bone marrow function after treatment-induced suppression.

BRMs as Cancer Therapy

Two common types of BRMs used as cancer therapy are the interleukins and interferons. Some agents can stimulate specific immune system cells to attack and destroy cancer cells; other agents block cancer cell access to an essential function or nutrient.

Interleukins (ILs) are a group of 37 known substances the body makes to help regulate inflammation and immune protection. Some are now synthesized as drugs. ILs help different immune system cells recognize and destroy abnormal body cells. In particular, IL-1, IL-2, and IL-6 appear to “charge up” the immune system and enhance attacks on cancer cells by macrophages, natural killer (NK) cells, and tumor-infiltrating lymphocytes.

TABLE 24-5 COMMON BIOLOGICAL RESPONSE MODIFIERS USED AS SUPPORTIVE CANCER THERAPY

AGENT	CELL TYPE AFFECTED	INDICATIONS
Sargramostim (Leukine, Prokine)	All granulocytes Neutrophils Eosinophils Monocytes Macrophages	Chemotherapy-induced leukopenia
Filgrastim (Neupogen) Pegfilgrastim (Neulasta)	Neutrophils	Chemotherapy-induced neutropenia
Epoetin alfa (Epogen, Procrit) Darbepoetin alfa (Aranesp)	Erythrocytes	Chemotherapy-induced anemia Chemotherapy-induced fatigue Anemia induced by renal failure
Oprelvekin (Neumega)	Platelets	Chemotherapy-induced thrombocytopenia
Sipuleucel-T (Provenge) (product is a vaccine)	T-cells; antigen-processing cells (macrophages)	Hormone-refractory prostate cancer

Interferons (INFs) are cell-produced proteins that have been effective to some degree in the treatment of melanoma, hairy cell leukemia, renal cell carcinoma, ovarian cancer, and cutaneous T-cell lymphoma. They assist in cancer therapy by:

- Slowing tumor cell division
- Stimulating the growth and activation of NK cells
- Inducing cancer cells to resume a more normal appearance and function
- Inhibiting the expression of oncogenes

One drug classified as a BRM that has a different action is thalidomide (Thalomid), which reduces the level of tumor angiogenesis factor (TAF). TAF is needed to maintain blood supply to the tumor. When TAF is reduced, the tumor is poorly nourished and cancer cells die. This drug is approved for treatment of multiple myeloma.

BRMs as Supportive Therapy

BRMs used for supportive therapy during cancer treatment are the colony-stimulating factors or “growth factors” (Table 24-5). These factors induce more rapid recovery of the bone marrow after suppression by chemotherapy. This effect has two benefits. First, when bone marrow suppression is shortened or less severe, patients are less at risk for life-threatening infections, anemia, and bleeding. Second, because the growth factors allow more rapid bone marrow recovery, patients can receive their chemotherapy on time and may even be able to tolerate higher doses, improving the curative outcome of chemotherapy.

Side Effects of Biological Response Modifier Therapy

Patients receiving interleukins have generalized and often severe inflammatory reactions. Fluid shifts and capillary leak are widespread with edema forming in most tissues. Tissue

swelling affects the function of all organs and can be life threatening. Patients receiving high-dose BRM therapy should receive care in an intensive care or monitoring unit. These effects occur during the period of acute drug infusion and resolve after therapy completion.

Many BRMs and growth factors induce symptoms of mild inflammation during and immediately after receiving the drug, including fever, chills, rigors, and flu-like general malaise. Problems are worse when higher doses are given, but they seem to become less severe over time. Fever is treated with acetaminophen. Patients with severe rigors are managed with meperidine (Demerol).

Interferon therapy causes peripheral neuropathy similar to that found in patients who have long-standing diabetes mellitus. Some of the problems resulting from the neuropathy include decreased sensory perception, visual disturbances, decreased hearing, unsteady balance and gait, and orthostatic hypotension. It is not known whether the neuropathy is temporary or permanent. (See the [Chemotherapy-Induced Peripheral Neuropathy](#) section on p. 424.)

Skin dryness, itching, and peeling occur with many types of BRM therapy. The skin problems are more severe with higher doses and when more than one type of BRM is used at the same time. Reactions are temporary but cause much discomfort and distress. Advise patients to apply moisturizers (unscented) to the skin and to use mild soap to clean the skin. Involved areas should be protected from the sun with clothing or the use of sunscreen agents. Teach patients to avoid swimming and to not use topical steroid creams on affected areas.

TARGETED THERAPY

Overview

As discussed in Chapter 23, normal cells have tightly controlled regulation over when and to what extent a cell divides; cancer cells have escaped this tight control. External events can indicate to a cell that cell division is needed. However, these external events must be communicated to the cell's nucleus to activate the genes that promote cell division (oncogenes) and turn off the genes that normally suppress cell division (suppressor genes). The key to communicating the need for cell division is the presence and activation of signal transduction pathways. Fig. 24-4 shows a segment of a cell with one signal transduction pathway. When this pathway is activated at the cell surface by binding growth factors to their receptors, having certain drugs interact with the cell's plasma membrane, binding of certain adhesion proteins, changing movement of calcium and sodium across the membrane, or other cell-to-cell interactions, the first result is an increase in the cell's production of a family of enzymes known as *tyrosine kinases* (TKs). With increased TKs present, the pro-cell division signal activates many substances, known as *transcription factors*, within the pathway. When the pro-cell division transcription factors reach the cell's nucleus, oncogenes are activated, suppressor genes are inactivated, and a variety of proteins are produced to make cell division occur.

When cell division is not needed, external signals, such as growth factor inhibitors and the surrounding of a cell plasma membrane with other cells, send signals that inhibit activation of TKs and the signal transduction pathway. As a result,

FIG. 24-4 Pro-cell division signal transduction pathway.

few transcriptions are produced, suppressor genes are expressed, and oncogenes are suppressed. The proteins needed for cell division are not produced, and cell division does not occur.

Overall, cancer cells have more active signal transduction pathways and transcription factors that ultimately lead to excessive division of the cancer cells. Targeted therapies take advantage of differences in one or more parts of the signal transduction pathway to block it. Often these parts are overexpressed in cancer cells. Agents used as targeted therapies can disrupt the pathway and slow or stop cell division. They may work by blocking a growth factor receptor, by preventing the activation of tyrosine kinases, by limiting the production of transcription factors, and by other mechanisms that are not yet fully understood. Regardless of how a targeted therapy works, it will work only with those cancer cells that have the actual target. The result is that the signal for turning on cell division genes (oncogenes) does not get through to the cell's nucleus (Fig. 24-5) (Byar & Workman, 2012).

Drugs for targeted therapy have been approved as treatment for certain cancers. These drugs are classified based on the main mechanism of action, and some have more than one action (Table 24-6). *It is important to remember that these drugs will not work unless the cancer cell overexpresses the actual target substance. Thus not all patients with the same cancer type would benefit from the use of targeted therapy.* Each person's cancer cells are evaluated to determine whether the cells have enough of a target to be affected by targeted therapy.

Tyrosine Kinase Inhibitors

Drugs with the main action of inhibiting activation of tyrosine kinases are **tyrosine kinase inhibitors (TKIs)**. There are many different TKs. Some are unique to the cell type; others may be present only in cancer cells that express a specific gene

mutation. As a result, the different TKI drugs are effective in disrupting the growth of some cancer cell types and not others. An example of a TKI is imatinib mesylate (Gleevec). This drug binds to the energy site of one specific tyrosine kinase and prevents its activation. The drug is most useful in cancers that overexpress the *ABL1* oncogene, such as Philadelphia chromosome–positive chronic myeloid leukemia and metastatic gastrointestinal stromal tumors (GISTs).

Side effects common to most TKIs include fluid retention, electrolyte imbalances, and bone marrow suppression. This suppression can be severe enough to cause neutropenia, anemia, and thrombocytopenia. The problems associated with bone marrow suppression are increased when the patient also receives traditional chemotherapy with drugs that suppress bone marrow.

Epidermal Growth Factor/Receptor Inhibitors

The epidermal growth factor/receptor inhibitors (EGFRIs) block epidermal growth factor from binding to its cell surface receptor. As shown in Fig. 24-5, when this receptor is blocked, it cannot activate tyrosine kinase. As a result, the signal transduction pathway for promotion of cell division is inhibited.

An example of an EGFR drug is trastuzumab (Herceptin), which binds the excessive amounts of a certain type of EGFR produced by some breast cancer, ovarian, and colon cancer cells in response to the activation of the *HER2/neu* gene. Binding this receptor prevents cancer cell division and increases the sensitivity to chemotherapy and immune system actions.

The most common side effects of EGFRIs include a variety of skin reactions. These may be as mild as a rash or result in excessive skin peeling and fissures. Trastuzumab has been available longer than the other EGFRIs and has been found to have adverse effects on the heart (Frankel, 2010). It is not known if the cardiac effects also are common to other EGFRIs.

FIG. 24-5 Sites of action for targeted therapies that inhibit a signal transduction pathway and greatly reduce cell division.

TABLE 24-6 EXAMPLES OF TARGETED THERAPY AGENTS

CLASSIFICATION	AGENT
Tyrosine kinase inhibitors	Dasatinib (Sprycel) Imatinib mesylate (Gleevec) Lapatinib (Tykerb) Nilotinib (Tasigna)
Epidermal growth factor receptor inhibitors (EGFRIs)	Cetuximab (Erbix) Erlotinib (Tarceva) Gefitinib (Iressa) Panitumumab (Vectibix) Trastuzumab (Herceptin)
Vascular endothelial growth factor receptor inhibitors (VEGFRIs)	Bevacizumab (Avastin)
Multikinase inhibitors	Sorafenib (Nexavar) Sunitinib (Sutent) Pazopanib (Votrient)
Proteasome inhibitors	Bortezomib (Velcade)
Angiogenesis inhibitors	Everolimus (Afinitor) Lenalidomide (Revlimid) Temsolimus (Torisel)
Monoclonal antibodies	Alemtuzumab (Campath) Ibritumomab tiuxetin (Zevalin) Rituximab (Rituxan) ¹³¹ I tositumomab (Bexxar)

Vascular Endothelial Growth Factor/Receptor Inhibitors

The currently approved drug in the vascular endothelial growth factor/receptor inhibitor class is bevacizumab (Avastin). It binds to vascular endothelial growth factor

(VEGF) and prevents the binding of VEGF with its receptors on the surfaces of endothelial cells present in blood vessels. This inhibits formation of new blood vessels with a tumor. As a result, tumor cells are poorly nourished and metastasis is inhibited. This drug is used with standard chemotherapy for many cancers that overexpress the receptor.

The most common side effects are hypertension and impaired wound healing. In addition, bone marrow suppression with neutropenia and thrombocytopenia also occur, especially when the drug is used in combination with chemotherapy drugs that cause bone marrow suppression.

Multikinase Inhibitors

The multikinase inhibitors (MKIs) are drugs that inhibit the activity of specific kinases in cancer cells and in tumor blood vessels. An example of an MKI is sunitinib (Sutent). These drugs are most effective in preventing the activation of tyrosine kinases that have a specific gene mutation found most often in some renal cell carcinomas, GI stromal tumors, and pancreatic, colon, and non-small cell lung cancer cells.

A common side effect of this class of drugs is hypertension. Others include nausea and vomiting, diarrhea, constipation, mucositis, and mild neutropenia and thrombocytopenia.

Proteasome Inhibitors

Proteasome inhibitors work by preventing the formation of a large complex of proteins (a proteasome) in cells. The proteasome helps regulate the expression of genes that promote cell division and prevent cell death. With only limited amounts of proteasome present, the cell is less likely to divide and more likely to respond to signals for cell death. An example of a proteasome inhibitor is bortezomib (Velcade). Proteasomes

are present in normal and cancer cells, but cancer cells are much more sensitive to the effects of proteasome inhibition than are normal cells.

The most common side effects of bortezomib are nausea, vomiting, anorexia, abdominal pain, bowel changes, and decreased taste sensation. Peripheral neuropathy is also common. Other side effects include headache, rash, pruritus, back and bone pain, and muscle aches.

Angiogenesis Inhibitors

Angiogenesis inhibitors target a specific protein kinase known as the *mammalian target of rapamycin (mTOR)*. An example of an angiogenesis inhibitor is temsirolimus (Torisel). When the drug binds to an intracellular protein, a protein-drug complex forms that inhibits the activity of mTOR. When mTOR is inhibited, the concentrations of vascular endothelial growth factor (VEGF) are greatly reduced and many pro-cell division signal transduction pathways are disrupted. This drug is especially useful in suppressing the growth of renal cell carcinomas.

Hypersensitivity reactions to these drugs are common and so is hyperglycemia. Bone marrow suppression is moderate to severe with anemia, neutropenia, and thrombocytopenia. Other general side effects include headache, nausea and vomiting, back pain, muscle and joint pain, mucositis, diarrhea, and skin problems.

Monoclonal Antibodies

Monoclonal antibodies bind to their target antigens, which are often specific cell surface membrane proteins. Binding prevents the protein from performing its functions. Some cancer cells express cell membrane surface proteins that are unique to cancer cells and have a role in cancer cell division. So, by binding these proteins, monoclonal antibodies prevent cell division. Some monoclonal antibodies actually make tumor cells more sensitive to chemotherapy and increase the effectiveness of immune system attacks on the cancer cells. The most well known monoclonal antibody in use as a targeted therapy is rituximab (Rituxan). It binds to the protein CD20, which is often overexpressed on the surface of non-Hodgkin's lymphoma cell membranes. This protein activates an early step of the cell cycle division process. Binding CD20 with rituximab prevents it from stimulating cell division in the non-Hodgkin's lymphoma cells.

Allergic reactions are an issue in patients receiving monoclonal antibodies. Most of these antibodies were developed in mice and express some mouse proteins. Now many of these antibodies have been "humanized," reducing the risk for allergic reactions.

The monoclonal antibodies to EGFR bind to those specific receptors when the receptors are on normal tissue. Thus side effects occur in those tissues that normally express EGFR, such as the skin, mucous membranes, and lining of the GI tract (Eaby, 2008).

ONCOLOGIC EMERGENCIES

Cancer is a chronic disease. However, a number of complications from the cancer and its treatment can occur. Early diagnosis and immediate intervention of these emergency conditions are essential to avoid life-threatening situations. The role of the nurse is to implement interventions to

prevent and detect these complications early for immediate treatment.

SEPSIS AND DISSEMINATED INTRAVASCULAR COAGULATION

Pathophysiology

Sepsis, or *septicemia*, is a condition in which organisms enter the bloodstream (bloodstream infection [BSI]) and can result in septic shock, a life-threatening condition. Patients with cancer are at risk for infection and sepsis because their white blood cell counts are often low and immune function is impaired. Chapter 39 describes the pathophysiology of sepsis and septic shock.

Disseminated intravascular coagulation (DIC) is a problem with the blood-clotting process. DIC is triggered by many severe illnesses, including cancer. In patients with cancer, DIC often is caused by gram-negative sepsis, by the release of thrombin or thromboplastin (clotting factors) from cancer cells, or by blood transfusions.

Extensive, abnormal clotting occurs throughout the small blood vessels of patients with DIC. This widespread clotting uses up the existing clotting factors and platelets. This process is followed by extensive bleeding. Bleeding from many sites is the most common problem and ranges from minimal to fatal hemorrhage. Clots block blood vessels and decrease blood flow to major body organs and result in pain, stroke-like manifestations, dyspnea, tachycardia, reduced kidney function, and bowel necrosis.

PATIENT-CENTERED COLLABORATIVE CARE

DIC is a life-threatening problem and has a high mortality rate even when proper therapies are instituted. *Thus the best management of sepsis and DIC is prevention. Identify patients at greatest risk for sepsis and DIC. Practice strict adherence to aseptic technique during invasive procedures and during contact with nonintact skin and mucous membranes. Teach patients and families the early manifestations of infection and when to seek assistance.*

When sepsis is present and DIC is likely, management focuses on reducing the infection and halting the DIC process. IV antibiotic therapy is initiated. During the early phase of DIC, anticoagulants (especially heparin) are given to limit clotting and prevent the rapid consumption of circulating clotting factors. Clotting factors are given when DIC has progressed and hemorrhage is the primary problem. See Chapter 39 for a more detailed discussion of the management of DIC.

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE

Pathophysiology

In healthy people, antidiuretic hormone (ADH) is secreted by the posterior pituitary gland only when more fluid (water) is needed in the body, such as when plasma volume is decreased. Certain conditions induce ADH secretion when not needed by the body.

Cancer is a common cause of the syndrome of inappropriate antidiuretic hormone (SIADH), especially small cell lung

cancer, but SIADH may occur with other cancers, especially when tumors are present in the brain. Some tumors make and secrete ADH, whereas others stimulate the brain to secrete ADH. Drugs often used in patients with cancer also can cause SIADH (e.g., morphine sulfate, cyclophosphamide).

In SIADH, water is reabsorbed to excess by the kidney and put into systemic circulation. The retained water dilutes blood serum sodium levels. Mild manifestations include weakness, muscle cramps, loss of appetite, and fatigue. Serum sodium levels range from 115 to 120 mEq/L or lower (normal range is 135 to 145 mEq/L). With greater fluid retention, weight gain, nervous system changes, personality changes, confusion, and extreme muscle weakness occur. As the sodium level drops toward 110 mEq/L, seizures, coma, and death may follow depending on how rapidly the sodium value is lowered.

PATIENT-CENTERED COLLABORATIVE CARE

SIADH is managed by treating the condition and the cause. Nursing priorities focus on patient safety, restoring normal fluid balance, and providing supportive care. Management includes fluid restriction, increased sodium intake, and drug therapy. One drug, demeclocycline (Declomycin), works in opposition to ADH. Immediate cancer therapy with radiation or chemotherapy can cause enough tumor regression that ADH production returns to normal.

Patient safety includes preventing fluid overload from becoming worse, leading to pulmonary edema and heart failure. The older adult and those with coexisting cardiac problems, kidney problems, lung problems, or liver problems are at greater risk for complications.

Monitor for increasing fluid overload (bounding pulse, increasing neck vein distention, presence of crackles in lungs, increasing peripheral edema, reduced urine output) at least every 2 hours. *Pulmonary edema can occur very quickly and can lead to death.* Notify the health care provider of any change that indicates the fluid overload from SIADH either is not responding to therapy or is becoming worse. See [Chapter 65](#) for a detailed discussion of SIADH management.

SPINAL CORD COMPRESSION

Pathophysiology

Spinal cord compression (SCC) and damage occur either when a tumor directly enters the spinal cord or when the vertebrae collapse from tumor degradation of the bone. Tumors may begin in the spinal cord but more often spread from the lung, prostate, breast, and colon. SCC may cause back pain before nerve deficits occur. Neurologic problems are specific to the level of spinal compression and can lead to paralysis, which is usually permanent.

PATIENT-CENTERED COLLABORATIVE CARE

Early recognition and treatment of spinal cord compression are key to a positive outcome. Assess for neurologic changes, including back pain, muscle weakness or a sensation of heaviness in the arms or legs, numbness or tingling in the hands

or feet, inability to distinguish hot and cold, and an unsteady gait. Depending on how low the compression occurs, constipation, incontinence, and difficulty starting or stopping urination also may be present. Consider the possibility of SCC with new onset of any of these problems. Teach patients and families the manifestations of early SCC, and instruct them to seek help as soon as problems occur.

Treatment is often palliative with high-dose corticosteroids given first to reduce swelling around the spinal cord and relieve symptoms. High-dose radiation may be used to reduce the size of the tumor in the area and relieve compression. Surgery may be performed to remove the tumor and rearrange the bony tissue so less pressure is placed on the spinal cord. External back or neck braces may be used to reduce the weight borne by the spinal column and to reduce pressure on the spinal cord or spinal nerves.

HYPERCALCEMIA

Pathophysiology

Hypercalcemia (increased serum calcium level) occurs most often in patients with bone metastasis. Cancer in bone causes release of calcium into the bloodstream. Some cancers, especially in the lung, head and neck, kidney, or lymph nodes, secrete parathyroid hormone, causing bone to release calcium. Decreased mobility and dehydration worsen hypercalcemia.

Early manifestations include fatigue, loss of appetite, nausea, vomiting, constipation, and increased urine output. More serious problems include severe muscle weakness, loss of deep tendon reflexes, paralytic ileus, dehydration, and electrocardiographic (ECG) changes. Symptom severity depends on how high the calcium level is and how quickly it rose (see [Chapter 13](#)).

PATIENT-CENTERED COLLABORATIVE CARE

Cancer-induced hypercalcemia develops slowly for many patients, which allows the body time to adapt to this electrolyte change. As a result, symptoms of hypercalcemia may not be evident until the serum calcium level is greatly elevated.

Oral hydration may be enough to reduce calcium levels and relieve symptoms. Normal saline is used when parenteral hydration is needed. Many drugs, such as oral glucocorticoids, calcitonin, diphosphonate, gallium nitrate, and mithramycin, lower serum calcium, but only temporarily. When cancer-induced hypercalcemia is life threatening or occurs with kidney disease, dialysis can temporarily reduce serum calcium levels.

SUPERIOR VENA CAVA SYNDROME

Pathophysiology

Superior vena cava (SVC) syndrome occurs when the SVC is compressed or obstructed by tumor growth or by clots in the vessel ([Fig. 24-6](#)). SVC compression is painful and life threatening and occurs most often in patients with lymphomas, lung cancer, and breast cancer.

The manifestations result from the blockage of venous return from the head, neck, and upper trunk. Early manifestations occur when the patient arises after a night's sleep and

include edema of the face, especially around the eyes, and tightness of the shirt or blouse collar. As the compression worsens, the patient develops engorged blood vessels and erythema of the upper body (Fig. 24-7), edema in the arms and hands, dyspnea, and epistaxis. Late manifestations include hemorrhage, cyanosis, mental status changes, decreased cardiac output, and hypotension. Death results if compression is not relieved.

PATIENT-CENTERED COLLABORATIVE CARE

SVC syndrome is a late-stage manifestation; the tumor is usually widespread. High-dose radiation therapy to the upper chest area may be used to provide temporary relief. Surgery is rarely performed for this condition. A metal stent can be placed in the vena cava in an interventional radiation

department to relieve swelling. Follow-up angioplasty can keep this stent open for a longer period.

TUMOR LYSIS SYNDROME

Pathophysiology

In tumor lysis syndrome (TLS), large numbers of tumor cells are destroyed rapidly. Their intracellular contents, including potassium and purines (DNA components), are released into the bloodstream faster than the body can eliminate them (Fig. 24-8) (King, 2008; McGraw, 2008). Unlike other oncologic emergencies, TLS is a positive sign that cancer treatment is effective.

Severe or untreated TLS can cause tissue damage and death. Serum potassium levels can increase to the point of hyperkalemia, causing cardiac dysfunction (see Chapter 13). The large amounts of purines form uric acid, causing hyperuricemia. These uric acid crystals precipitate in the kidney,

FIG. 24-6 Compression of the superior vena cava by lymph nodes and tumors in superior vena cava syndrome.

FIG. 24-7 Appearance of the face, neck, upper arms, and chest in a patient with superior vena cava syndrome.

FIG. 24-8 Pathology of tumor lysis syndrome.

blocking kidney tubules and leading to acute kidney injury (AKI).

TLS is usually seen in patients receiving radiation or chemotherapy for cancers that are very sensitive to these therapies, including leukemia, lymphoma, small cell lung cancer, and multiple myeloma.

PATIENT-CENTERED COLLABORATIVE CARE

Hydration prevents and manages TLS. Hydration dilutes the serum potassium level and increases the kidney filtration and flow rates. These actions prevent the precipitation of uric acid crystals, increase the excretion of potassium, and flush any kidney precipitate.

With tumors known to be very sensitive to cancer therapy, instruct patients to drink at least 3000 mL (5000 mL is more desirable) of fluid the day before, the day of, and for 3 days after treatment. Some fluids should be alkaline (sodium bicarbonate) to help prevent uric acid precipitation. Stress the importance of keeping fluid intake consistent throughout the 24-hour day, and help patients draw up a schedule of fluid intake.

Because some patients have nausea and vomiting after cancer therapy and may not feel like drinking fluids, stress the importance of following the antiemetic regimen. Instruct patients to contact the cancer clinic immediately if nausea

prevents adequate fluid intake so parenteral fluids can be started.

Management becomes more aggressive for patients who become hyperkalemic or hyperuricemic. In addition to fluids, diuretics (especially osmotic types) are given to increase urine flow through the kidney. These agents are used cautiously to avoid dehydration. Drugs that promote purine excretion, such as allopurinol (Aloprim, Zyloprim), rasburicase (Elitek), or febuxostat (Uloric), are given. To reduce serum potassium levels for mild to moderate hyperkalemia, sodium polystyrene sulfonate can be given orally or as a retention enema. For more severe hyperkalemia, IV infusions containing glucose and insulin may be given. Patients who have severe hyperkalemia and hyperuricemia may need dialysis.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client being treated for advanced breast cancer with chemotherapy reports that she must be allergic to one of her drugs because her entire face is swollen. What assessment does the nurse perform?

- A. Asks whether the client has other known allergies
- B. Checks the capillary refill on fingernails bilaterally
- C. Examines the client's neck and chest for edema and engorged veins
- D. Compares blood pressure measured in the right arm with that in the left arm

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use aseptic technique during care for open skin areas or any invasive procedure.
- Perform good handwashing before providing any care to patients with neutropenia.
- Use bleeding precautions for any patient with thrombocytopenia (see [Chart 24-6](#)).
- Position shields properly when patients in inpatient settings are receiving brachytherapy.
- Use appropriate personal protection equipment (gowns, gloves, masks, eye protection) when mixing or administering IV or oral chemotherapeutic drugs and when handling the excreta of a patient receiving chemotherapy.

Health Promotion and Maintenance

- Teach patients receiving radiation therapy how to care for the skin in the radiation path (see [Chart 24-2](#)).
- Teach the patient and family about the manifestations of infection and when to seek medical advice.
- Teach patients at risk for bleeding the precautions to avoid injury (see [Chart 24-7](#)).

Psychosocial Integrity

- Allow the patient the opportunity to express concerns regarding the diagnosis of cancer or the treatment regimen.
- Encourage the patient to verbalize feelings about changes in appearance resulting from cancer therapy.
- Explain all procedures, restrictions, drugs, and follow-up care to the patient and family.
- Encourage patients to use strategies to improve their appearance when alopecia occurs.
- Refer patients and family members to local cancer resources and support groups.

Physiological Integrity

- Assess the venous access device at least every 30 to 60 minutes during chemotherapy administration.
- Assess the patient receiving chemotherapy for infection at least every 8 hours.
- Inspect the oral mucosa of patients with neutropenia at least every 8 hours.
- Report any temperature over 100° F (37.8° C) in a patient with neutropenia.
- Instruct the patient and family in the manifestations of complications and when to seek assistance.

CHAPTER

25

Care of Patients with Infection

Concept Map Creator

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Explain the Centers for Disease Control and Prevention (CDC) hand hygiene recommendations for health care workers.
2. Describe infection control methods, such as hand hygiene and Transmission-Based Precautions.
3. Apply current principles of infection prevention and control.

Health Promotion and Maintenance

4. Specify health teaching for patients, families, and staff about infection control measures.

Psychosocial Integrity

5. Plan ways to help patients cope with Transmission-Based Precautions.

Physiological Integrity

6. Identify patients most at risk for infection, including older adults.
7. Provide information to patient and family about drug therapy for infections.
8. Identify common clinical manifestations of infectious diseases.
9. Interpret laboratory test findings related to infections and infectious diseases.
10. Evaluate nursing interventions for management of the patient with an infection.
11. Explain why multidrug-resistant organisms are increasing.
12. Identify common emerging diseases and their basic clinical management.

The human body has many *protective* systems that promote homeostasis. Physiologic mechanisms are the structural and functional defenses that protect people from stressors such as infection. When these mechanisms fail to work properly or are overcome with microbes, infection can result.

Infections and infectious diseases have been the major cause of millions of deaths worldwide for centuries. Today, threats of bioterrorism have been added to the concerns about multidrug-resistant and emerging infections. Global travel and migration have increased exposure to a wider variety of infectious agents than in the past. For example, severe acute respiratory syndrome (SARS), monkeypox, and Avian influenza (“bird flu”) have appeared for the first time in the United States during the past decade. However, humans have not gotten any of these diseases yet.

Advancing technology and invasive procedures also introduce microorganisms into the body, often resulting in infection, even though in other environments these microorganisms are harmless. This chapter provides an overview of infection and general principles for prevention and management. Specific infections and their management are described elsewhere in this text.

OVERVIEW OF THE INFECTIOUS PROCESS

A **pathogen** is any microorganism (also called an *agent*) capable of producing disease. Infections can be **communicable** (transmitted from person to person [e.g., influenza]) or not communicable (e.g., peritonitis). Microorganisms with differing levels of **pathogenicity** (ability to cause disease)

surround everyone. **Virulence** is a term for pathogenicity. However, virulence is related more to the frequency with which a pathogen causes disease (degree of communicability) and its ability to invade and damage a host. It can also indicate the severity of the disease.

Many microorganisms live in or on the human host without causing disease. Some microbes are beneficial. Each body location harbors its own characteristic bacteria, or **normal flora**. Normal flora often functions to compete with and prevent infection from unfamiliar agents attempting to invade a body site. In some instances, microorganisms that are often pathogenic may be present in the tissues of the host and yet not cause symptomatic disease because of normal flora; this process is called **colonization**.

In the United States, the Centers for Disease Control and Prevention (CDC) collects information about the occurrence and nature of infections and infectious diseases. It then recommends guidelines to health care agencies for infection control and prevention. Certain diseases, such as tuberculosis, must be reported to health departments and the CDC. The infection control practitioner (ICP) for each health care agency is responsible for tracking infections (**surveillance**) and ensuring compliance with federal and local requirements.

Transmission of Infectious Agents

Transmission of infection in health care requires three factors:

- Reservoir (or source) of infectious agents
- Susceptible host with a portal of entry
- Mode of transmission

Reservoirs (sources of infectious agents) are numerous. Animate reservoirs include people, animals, and insects. Inanimate reservoirs include soil, water, other environmental sources, and medical equipment (e.g., IV solutions, urine collection devices). The host's body can be a reservoir; pathogens colonize skin and body substances (e.g., feces, sputum, saliva, wound drainage). A person with an active infection or an asymptomatic **carrier** (one who harbors an infectious agent without active disease) is a reservoir. Examples of *community* reservoirs include sewage, stagnant or contaminated water, and improperly handled foods.

Bacteria like *Neisseria meningitidis* can exist in the respiratory tract while causing no illness. If the bacteria invade the bloodstream or cerebrospinal fluid, they become extremely pathogenic. Another example is *Enterococcus*, which lives as normal flora in the GI system, where it is nonpathogenic and assists in the digestive process. If it enters the bloodstream, *Enterococcus* can cause disease.

Continued multiplication of a pathogen is sometimes accompanied by toxin production. **Toxins** are protein molecules released by bacteria to affect host cells at a distant site. **Exotoxins** are produced and released by certain bacteria into the surrounding environment. Botulism, tetanus, diphtheria, and *Escherichia coli* 0157:H7–related systemic diseases are attributed to exotoxins. **Endotoxins** are produced in the cell walls of certain bacteria and released only with cell lysis. For example, typhoid and meningococcal diseases are caused by endotoxins.

Host factors influence the development of infection (Table 25-1). Host defenses provide the body with an efficient system for *protection* against pathogens. Breakdown of these defense mechanisms may increase the **susceptibility** (risk) of the host for infection.

TABLE 25-1 HOST FACTORS THAT INFLUENCE THE DEVELOPMENT OF INFECTION

HOST FACTOR	INCREASED RISK FOR INFECTION
Natural immunity	Congenital or acquired immune deficiencies
Normal flora	Alteration of normal flora by antibiotic therapy
Age	Infants and older adults
Hormonal factors	Diabetes mellitus, corticosteroid therapy, and adrenal insufficiency
Phagocytosis	Defective phagocytic function, circulatory disturbances, and neutropenia
Skin/mucous membranes/normal excretory secretions	Break in skin or mucous membrane integrity; interference with flow of urine, tears, or saliva; interference with cough reflex or ciliary action; changes in gastric secretions
Nutrition	Malnutrition or dehydration
Environmental factors	Tobacco and alcohol consumption and inhalation of toxic chemicals
Medical interventions	Invasive therapy, chemotherapy, radiation therapy, and steroid therapy; surgery

The patient's *immune status* plays a large role in determining risk for infection. Congenital abnormalities, as well as acquired health problems (e.g., renal failure, steroid dependence, cancer, acquired immune deficiency syndrome [AIDS]), can result in numerous immunologic deficiencies. Depression of the immune system may make the host more susceptible to infection or cripple the ability to combat organisms that have gained entry.

Immunity is resistance to infection; it is usually associated with the presence of antibodies or cells that act on specific microorganisms. **Passive immunity** is of short duration (days or months) and either natural by transplacental transfer from the mother or artificial by injection of antibodies (e.g., immunoglobulin). **Active immunity** lasts for years and is natural by infection or artificial by stimulation of the body's immune defenses (e.g., vaccination). Chapter 19 discusses the immune system and immunity in detail.

Environmental factors can also influence patients' immune status and thus their susceptibility to or ability to fight infection. Examples include alcohol consumption, nicotine use, inhalation of bone marrow–suppressing toxic chemicals, and certain vitamin deficiencies. Malnutrition, especially protein-calorie malnutrition, places patients at increased risk for infection. Diseases such as diabetes mellitus also predispose a patient to infection. *Older adults have decreased immune systems, as well as other physiologic changes that make them very susceptible to infection* (Chart 25-1).

Medical and surgical interventions may impair normal immune response. Steroid therapy, chemotherapy, and anti-rejection drugs increase the risk for infection. Medical devices (e.g., intravascular or urinary catheters, endotracheal tubes, synthetic implants) may also interfere with normal host defense mechanisms. Surgery, trauma, radiation therapy, and burns result in nonintact skin. *The body's skin is one of the best barriers or defenses against infection*. When this barrier is broken, infection often results.

Microorganisms may enter the body in a variety of ways, including the respiratory tract, GI tract, genitourinary tract, skin and mucous membranes, and bloodstream.

CHART 25-1 NURSING FOCUS ON THE OLDER ADULT

Factors That May Increase Risk for Infection in the Older Patient

FACTOR	AGING-ASSOCIATED CHANGES OR CONDITIONS
• Immune system	• Decreased antibody production, lymphocytes, and fever response
• Integumentary system	• Thinning skin, decreased subcutaneous tissue, decreased vascularity, slower wound healing
• Respiratory system	• Decreased cough and gag reflexes
• Gastrointestinal system	• Decreased gastric acid and intestinal motility
• Chronic illness	• Diabetes mellitus, chronic obstructive pulmonary disease, neurologic impairments
• Functional/cognitive impairments	• Immobility, incontinence, dementia
• Invasive devices	• Urinary catheters, feeding tubes, IV devices, tracheostomy tubes
• Institutionalization	• Increased person-to-person contact and transmission

Pathogens may enter the body through the *respiratory tract*. Microbes in droplets are sprayed into the air when people with infected oral or nasal tissues talk, cough, or sneeze. A susceptible host then inhales droplets, and pathogens localize in the lungs or are distributed via the lymphatic system or bloodstream to other areas of the body. Microorganisms that enter the body by the respiratory tract and produce distant infection include influenza virus, *Mycobacterium tuberculosis*, and *Streptococcus pneumoniae*.

Other pathogens enter the body through the GI tract. Some stay there and produce disease (e.g., *Shigella* causing self-limited disease). Others invade the GI tract to produce local and distant infection (e.g., *Salmonella enteritidis*). Some produce limited GI symptoms, causing systemic infection (e.g., *Salmonella typhi*) or profound involvement of other organs (e.g., hepatitis A virus). Millions of foodborne illness cases occur each year in the United States. This type of illness results in many hospitalizations and deaths.

Microorganisms also enter through the genitourinary tract. *Urinary tract infection (UTI)* is one of the most common *health care–associated infections (HAIs)*. More than half of patients in adult intensive care units (ICUs) have urinary catheters in place. Indwelling urinary catheters are a primary cause of UTIs. *The use of invasive catheters has decreased in long-term care settings because older adults are very susceptible to infections.*

Although intact skin is the best barrier to prevent most infections, some pathogens such as *Treponema pallidum* can enter the body through intact skin or mucous membranes. Most enter through breaks in these normally effective surface barriers. Sometimes a medical procedure creates a break in cutaneous or mucocutaneous barriers, as in catheter-acquired *bacteremia* (bacteria in the bloodstream) and surgical-site infections (SSIs). *Fragile skin of older patients*

and of those receiving prolonged steroid therapy increases infection risk.

Microorganisms can gain direct access to the *bloodstream*, especially when invasive devices or tubes are used. The incidence of bloodstream infections (BSIs) continues to increase in hospitals throughout the United States. Central venous catheters (CVCs) are a primary cause of these infections (see [Chapter 15](#) for more discussion of CVC-related BSIs). In the community setting, biting insects can inject organisms into the bloodstream, causing infection (e.g., Lyme disease, West Nile viral encephalitis).

For infection to be *transmitted* from an infected source to a susceptible host, a transport mechanism is required. Microorganisms are transmitted by several routes:

- Contact transmission (indirect and direct)
- Droplet transmission
- Airborne transmission

Contact transmission is the usual mode of transmission of most infections. Many infections are spread by direct or indirect contact. With *direct contact*, the source and host have physical contact. Microorganisms are transferred directly from skin to skin or from mucous membrane to mucous membrane. Often called *person-to-person transmission*, direct contact is best illustrated by the spread of the “common cold.”

Indirect contact transmission involves the transfer of microorganisms from a source to a host by passive transfer from a contaminated object. Contaminated articles or hands may be sources of infection. For example, patient-care devices like glucometers and electronic thermometers may transmit pathogens if they are contaminated with blood or body fluids. Uniforms, laboratory coats, and isolation gowns used as part of personal protective equipment may be contaminated as well.

Indirect transmission may involve contact with infected secretions or *droplets*. Droplets are produced when a person talks or sneezes; the droplets travel short distances. Susceptible hosts may acquire infection by contact with droplets deposited on the nasal, oral, or conjunctival membranes. Therefore the CDC recommends that staff stay at least 3 feet (1 m) away from a patient with droplet infection (Siegel et al., 2007). An example of droplet-spread infection is influenza. Unlike airborne droplet nuclei, discussed later, droplets do not stay suspended in the air.

Airborne transmission occurs when small airborne particles containing pathogens leave the infected source and enter a susceptible host. These pathogens can be suspended in the air for a prolonged time. The particles carrying pathogens are usually contained in droplet nuclei or dust; they are usually propelled from the respiratory tract by coughing or sneezing. A susceptible person then inhales the particles directly into the respiratory tract. For example, tuberculosis is spread via airborne transmission.

Preventing the spread of microbes that are transmitted by the airborne route requires the use of special air handling and ventilation systems in an airborne infection isolation room (AIIR). *M. tuberculosis* and the varicella-zoster virus (chickenpox) are examples of airborne agents that require one of these systems. In addition to the AIIR, respiratory protection using certified N95 or higher level respirator masks is recommended for health care personnel entering the patient’s room (Siegel et al., 2007). The N95 rating means that at least 95% of the inhaled air is filtered.

Other sources of infectious agents include the environment, such as contaminated food, water, or vectors. Vectors are insects that carry pathogens between two or more hosts, such as the deer tick that causes Lyme disease.

The *portal of exit* completes the chain of infection. Exit of the microbe from the host often occurs through the portal of entry. An organism, such as *M. tuberculosis*, enters the respiratory tract and then exits the same tract as the infected host coughs. Some organisms can exit from the infected host by several routes. For example, varicella-zoster virus can spread through direct contact with infective fluid in vesicles and by airborne transmission.

Physiologic Defenses for Infection

Strong and intact host defenses can prevent microbes from entering the body or can destroy a pathogen that has entered. Impaired host defenses may be unable to defend against microbial invasion, allowing entry of organisms that can destroy cells and cause infection. Common defense mechanisms include:

- Body tissues
- Phagocytosis
- Inflammation
- Immune systems

Intact skin forms the first and most important physical barrier to the entry of microorganisms. In addition to providing a mechanical barrier, the skin's slightly acidic pH (resulting from breakdown of lipids into fatty acids), together with normal skin flora, creates an unfriendly environment for many bacteria.

Mucous membranes' mucociliary action provides some mechanical protection against pathogenic invasion. More important, however, mucous membranes are bathed in secretions that inactivate many microorganisms. **Lysozymes**, which dissolve the cell walls of some bacteria, are present in large quantities in many body secretions, particularly in tears and nasal mucus.

Other body systems provide natural barriers to infection. For instance, the healthy respiratory tract clears about 90% of all inhaled material by upper airway filtration, humidification, mucociliary transport, and coughing. Peristaltic action mechanically empties the GI tract of pathogenic organisms. Stomach acid, intestinal secretions, pancreatic enzymes, and bile, together with the competition from normal bowel flora, provide an environment that protects the GI tract from invasion by harmful organisms. In the genitourinary tract, the flushing action of urine eliminates pathogenic organisms. The low pH of urine also maintains a sterile environment, although some microorganisms, such as *E. coli*, thrive in an acid medium.

Phagocytosis occurs when a foreign substance evades the first-line mechanical barriers and enters the body. Various leukocyte types function differently in the immune reaction, but neutrophils bear primary responsibility for phagocytosis. This process of engulfing, ingesting, killing, and disposing of an invading organism is an essential mechanism in host defense. Phagocytic dysfunction dramatically increases a patient's risk for infection.

Inflammation is another important nonspecific defense mechanism for preventing the spread of infection. It occurs when tissue becomes damaged. Damaged cells release enzymes, and polymorphonuclear (PMN) leukocytes

(neutrophils) are attracted to the infected site from the bloodstream. One important substance, histamine, increases the permeability of the capillaries in inflamed tissues, thus allowing fluid, proteins, and white blood cells to enter an inflamed area. Other enzymes activate fibrinogen, which causes leaked fluid to clot and prevents its flow away from the damaged site into unaffected tissue, essentially "walling off" the inflamed tissue. The process of phagocytosis disposes of the invading microorganism and often dead tissue. If inflammation is caused by infection, the end products of inflammation form pus, which is then absorbed or exits the body through a break in the skin. Chapter 19 discusses the process of inflammation in more detail.

Specific defense responses to specific microorganisms are provided by the antibody- and cell-mediated immune systems. The **antibody-mediated immune system** produces antibodies directed against certain pathogens. These antibodies inactivate or destroy invading microorganisms as well as protect against future infection from that microorganism. Resistance to other microorganisms is mediated by the action of specifically sensitized T-lymphocytes and is called **cell-mediated immunity**. The components of the immune system work both independently and together to protect against infection. Chapter 19 describes the function of the immune system in detail.

HEALTH PROMOTION AND MAINTENANCE

Infection Control in Inpatient Health Care Agencies

Infections occur most often in high-risk patients, such as older adults and those who have inadequate immune systems (immunocompromised). Implement interventions to prevent infection and detect signs and symptoms as early as possible. Chart 25-2 summarizes nursing interventions for infection prevention and control.

Infection acquired in the inpatient health care setting (not present or incubating at admission) is termed a **health care-associated infection (HAI)**. When occurring in a hospital setting, they are sometimes referred to as *hospital-acquired infections*, but the former term is more accurate. HAIs can be **endogenous** (from a patient's flora) or **exogenous** (from

CHART 25-2 BEST PRACTICES FOR PATIENT SAFETY AND QUALITY CARE

The Patient at Risk for Infection

- Assess patients for risk for infections.
- Monitor for signs and symptoms of infection.
- Monitor laboratory tests results, such as cultures and white blood cell (WBC) count and differential.
- Screen all visitors for infections or infectious disease.
- Inspect skin and mucous membranes for redness, heat, pain, swelling, and drainage.
- Promote sufficient nutritional intake, especially protein for healing.
- Encourage fluid intake to treat fever.
- Teach the patient and family the signs and symptoms of infections and when to report them to the health care provider.
- Teach the patient and family how to avoid infections in health care agencies and the community.

outside the patient, often from the hands of health care workers, tubes, or implants). Therefore use of the less popular term *nosocomial infection* does not imply that an infection was caused by health care (or poor health care delivery) but only that it occurred while receiving health care. HAIs, including surgical-site infections (SSIs), occur in 1 in 20 inpatients yearly, causing increased health care costs and many deaths (see discussion of SSIs in [Chapter 18](#)). These infections tend to occur most often because health care workers do not follow basic infection control principles, especially aseptic technique and injection practices (Siegel et al., 2007).

Infection control within a health care facility is designed to reduce the risk for HAIs and thus reduce morbidity and mortality, as recommended in The Joint Commission's National Patient Safety Goals (NPSGs). This expected outcome is consistent with the desire for health care facilities to create a *culture of safety* within their environments (see [Chapter 1](#)). Infection control and prevention is a collaborative effort and includes:

- Facility- and department-specific infection control policies and procedures
- Surveillance and analysis
- Patient and staff education
- Community and interdisciplinary collaboration
- Product evaluation with an emphasis on quality and cost savings
- Bioengineering for designing health care facilities that help control the spread of infections

The infection control program of a hospital is usually coordinated and implemented by a health care professional certified in infection control (CIC) who has clinical and administrative experience. The Centers for Disease Control and Prevention (CDC) recommends one person with CIC credentials for every 100 occupied acute care beds. Long-term care facilities may not have a practitioner who is dedicated to infection control. However, every facility must designate a health care professional to be responsible for coordinating and implementing an infection prevention and control program.

Long-term care facilities are unique in that they have a large group of older adults who are together in one setting for weeks to years. Nursing homes, in particular, are required to provide a homelike environment in which residents can move and interact freely. Therefore infection control in these settings can be challenging. As a result, many infectious outbreaks have occurred, such as pneumonia, *Clostridium difficile*, and multidrug-resistant organisms (discussed in the Multidrug-Resistant Organism Infections and Colonizations section on pp. 440-443).

Infection Control in Community-Based Settings

Ambulatory and home health care are the fastest growing segments of the health care system. Infection remains the most common cause of death for dialysis patients. Data on infections in other ambulatory settings are lacking because the CDC has only recently recommended surveillance systems and prevention guidelines. Little information is available about acquired infections in home health settings because data are not systematically collected, surveillance programs are not established, and best practices for infection prevention and control do not exist.

CHART 25-3 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Hand Hygiene

- When hands are visibly soiled or contaminated with proteinaceous material or are visibly soiled with blood or other body fluids, wash hands with soap and water.
- If hands are not visibly soiled, use an alcohol-based hand rub (ABHR) for decontaminating hands or wash hands with soap and water.
- Use either ABHR or wash with soap and water (decontaminate hands) before having direct contact with patients.
- Decontaminate hands before donning sterile gloves to perform a procedure, such as inserting an invasive device (e.g., indwelling urinary catheter).
- Decontaminate hands after contact with a patient's intact skin (e.g., taking a pulse) or with body fluids or excretions/secretions.
- Decontaminate hands after removing gloves.
- Decontaminate hands after contact with inanimate objects (including medical equipment) in the immediate vicinity of the patient.

Methods of Infection Control

All health care workers who come in contact with patients or care areas are involved in some aspect of the infection control program of the agency. According to the CDC, infections can be prevented or controlled in at least five major ways:

- Hand hygiene
- Personal protective equipment (PPE) (also called *barriers*)
- Adequate staffing
- Disinfection/sterilization
- Patient placement and transport

Health care workers' hands are the primary way in which infection is transmitted from patient to patient or staff to patient.

Hand hygiene refers to both handwashing and alcohol-based hand rubs (ABHRs) ("hand sanitizers"). There is a lack of rigorous evidence linking which specific hand hygiene recommendations best prevent health care-associated infections (HAIs) (Backman et al., 2008).

In 2002, the CDC released a document entitled "CDC Hand Hygiene Recommendations." These recommendations are summarized in [Chart 25-3](#). *Handwashing is still an important part of hand hygiene, but it is recognized that in some health care settings, sinks may not be readily available.* Despite years of education, health care workers often find it difficult to leave the patient care setting to wash their hands and do not perform hand hygiene on a consistent basis.

Effective **handwashing** includes wetting, soaping, lathering, applying friction under running water for at least 15 seconds, rinsing, and adequate drying. *Friction is essential to remove skin oils and to disperse transient bacteria and soil from hand surfaces.* Performing adequate handwashing takes time that health care workers (HCWs) may not feel they have. Handwashing can also cause dry skin, and therefore hand moisturizers are essential to maintain good hand health and hygiene.

Alcohol-based hand rubs (ABHRs) allow care providers to spend less time seeking out sinks and more time delivering care. However, these hand rubs have their limitations.

The CDC recommends using antiseptic solutions such as chlorhexidine, povidone-iodine, or parachlorometaxylenol (PCMX) for handwashing in caring for patients who are at

FIG. 25-1 A, Nurse in personal protective equipment (PPE) caring for a patient in a private room. B, N95 respirator mask.

! NURSING SAFETY PRIORITY

Action Alert

If your hands are visibly dirty or soiled or feel sticky or if you have just toileted, *wash your hands instead of using ABHRs*. Keep in mind that ABHRs are also ineffective against spore-forming organisms such as *Clostridium difficile*, a common cause of health care–associated diarrhea, especially in older adults. Do not use an ABHR before inserting eye drops, ointments, or contact lenses because alcohol can irritate the patient’s eyes, causing burning and redness. The Joint Commission’s National Patient Safety Goals require that health care agencies monitor handwashing practices and the use of ABHRs to make sure that HCWs are performing hand hygiene on a regular basis.

high risk for infection (e.g., those who are immunocompromised). The use of these solutions is also recommended after caring for patients who are infected with multidrug-resistant or other virulent organisms.

The CDC guidelines (Centers for Disease Control and Prevention [CDC], 2002) also address the issue of artificial fingernails, which have been linked to a number of outbreaks due to poor fingernail health and hygiene. *The guidelines recommend that artificial fingernails and extenders not be worn while caring for patients at high risk for infections, such as those in ICUs or operating suites. Most health care agencies have banned artificial nails for all health care workers providing direct patient care and require that natural nails be short and without nail polish.*

Personal protective equipment (PPE) refers to the use of gloves, isolation gowns, face protection (masks, goggles, face shields), and respirators with N95 or higher filtration (Fig. 25-1).

! NURSING SAFETY PRIORITY

Action Alert

Remember that gloves are an essential part of infection control and should always be worn as part of Standard Precautions. Either handwashing or use of alcohol-based hand rubs should be done before donning and after removing gloves. The combination of hand hygiene and wearing gloves is the most effective strategy for preventing infection transmission!

Most health care settings in the United States and Canada have switched from latex to non-latex gloves. The U.S. National Institute for Occupational Safety and Health (NIOSH) issued a public warning about potential allergic reactions to those exposed to latex in gloves and other medical products. Reactions include rashes, nasal or eye symptoms, asthma, and (rarely) shock. People with **latex allergy** usually have an allergy to foods such as bananas, kiwis, and avocados. Health care workers (HCWs) have not been as strict with wearing gloves as they should because of poor fit or skin dryness, irritation, and dermatitis. One possible solution to dry skin is the use of aloe vera–coated gloves or moisturizers such as Eucerin or AmLactin products.

Adequate staffing of nurses is an essential method for preventing infection (Stone et al., 2008). In addition to a ratio of one infection control practitioner (ICP) to 100 occupied acute care beds, nurse staffing is critical. The CDC recommends that two methods to ensure adequate infection control (IC) be implemented (Siegel et al., 2007). First, an *infection control nurse liaison* should be designated on every unit of an inpatient facility. This nurse is responsible for implementing new IC policies, increasing staff IC compliance through education, and collaborating with the facility’s ICP to monitor for infections. Second, bedside nurse staffing should consist of full-time nurses assigned regularly to the unit rather than float, pool, or agency nurses. Studies have found that infection rates increase when float, pool, or agency nurses are substituted for full-time, regular staff (Siegel et al., 2007).

Sterilization and disinfection have helped invasive procedures become much more common and safe. **Sterilization** means destroying all living organisms and bacterial spores. All items that invade human tissue where bacteria are not commonly found should be sterilized. **Disinfection** does not kill spores and only ensures a reduction in the level of disease-causing organisms. High-level disinfection is adequate when an item is going inside the body where the patient has resident bacteria or normal flora (e.g., GI and respiratory tracts). As with sterilization, no high-level disinfection can occur without first cleaning the item. This can be especially difficult with items that have narrow lumens in which organic debris can become trapped and is not easily visible. For example,

endoscopes have been especially challenging to clean and have been linked to a number of infectious outbreaks.

Patient placement has been used as a way to reduce the spread of infection. Some studies have suggested that private patient rooms help decrease infections. However, the CDC has not mandated that all patients, even those with infections, have a private room. *The CDC does recommend that private rooms always be used for patients on Airborne Precautions and those in a protective environment (PE).* A PE is architecturally designed and structured to prevent infection from occurring in patients who are at extremely high risk, such as those having stem cell therapy. The CDC also prefers private rooms for patients who are on Contact and Droplet Precautions (Siegel et al., 2007). Many hospitals are increasing their number of private rooms, and some are becoming totally private-room facilities. Large health care systems often have biomedical engineers to assist in designing the best environment to reduce the spread of infection, including ventilation systems and physical layout.

Cohorting is another method of patient placement. **Cohorting** is the practice of grouping patients who are colonized or infected with the same pathogen. This method has been used the most with patients who have an outbreak of a multidrug-resistant organism like methicillin-resistant *Staphylococcus aureus* (MRSA). It is particularly effective in long-term care settings.

Infection control principles for *patient transport* include limiting movement to other areas of the facility, using appropriate barriers like covering infected wounds, and notifying other departments or agencies who are receiving the patient about the necessary precautions (Siegel et al., 2007). Complete and accurate hand-off communication between agencies is also very important to prevent the spread of infection, according to The Joint Commission's NPSGs.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

Which statement by the nursing assistant indicates a need for further teaching by the nurse regarding infection control?

- A. "I will wash my hands after direct client care."
- B. "I will wear gloves when emptying the Foley bag."
- C. "I don't need to wash my hands if I wear gloves."
- D. "I will use a hand sanitizer when I can't wash my hands."

CENTERS FOR DISEASE CONTROL AND PREVENTION TRANSMISSION-BASED GUIDELINES

The 2007 guidelines from the CDC focus on transmission mechanisms and the precautions needed to prevent the spread of infection. Included in these guidelines are Standard Precautions and Transmission-Based Precautions, including Airborne, Droplet, and Contact Precautions (Tables 25-2 and 25-3).

Standard Precautions

Standard Precautions reflect that all body excretions, secretions, and moist membranes and tissues, excluding perspiration, are potentially infectious. The protective measures from the previous Universal Precautions and Body Substance Isolation were combined to better protect health care workers.

In 2007, the CDC added two new requirements to these precautions, both of which protect patients (Siegel et al., 2007).

Respiratory hygiene/cough etiquette (RH/CE) is now required because of the widespread SARS outbreaks in 2003. This requirement is directed at patients and visitors with signs of respiratory illness, such as sinus or chest congestion, cough, or rhinorrhea ("runny nose"). The elements for RH/CE include:

- Patient, staff, and visitor education
- Posted signs
- Hand hygiene
- Covering the nose and mouth with a tissue and prompt tissue disposal or using surgical masks (or sneezing/coughing into a shirt sleeve rather than the hand)
- Separation from the person with respiratory infection by more than 3 feet (1 m)

The other requirement is *safe injection practices*. These include using a sterile, single-use disposable needle and syringe for each injection and preventing contamination of injection equipment and medication (Siegel et al., 2007).

Transmission-Based Precautions

Transmission-Based Precautions may also be referred to as *Isolation Precautions*. But, the word *isolation* implies that the patient is physically separated from everyone, which is not always the case.

Airborne Precautions are used for patients known or suspected to have infections transmitted by the airborne transmission route. These infections are caused by organisms that can be suspended in air for prolonged periods. Negative airflow rooms are required to prevent airborne spread of microbes. Enclosed booths with high-efficiency particulate air (HEPA) filtration or ultraviolet light may be used for sputum induction procedures. Tuberculosis, measles (rubeola), and chickenpox (varicella) are examples of airborne diseases.

Droplet Precautions are used for patients known or suspected to have infections transmitted by the droplet transmission route. Such infections are caused by organisms in droplets that may travel 3 feet but are not suspended for long periods. Examples of infectious conditions requiring Droplet Precautions include influenza, mumps, pertussis, and meningitis caused by either *N. meningitidis* or *Haemophilus influenzae* type B.

Contact Precautions are used for patients known or suspected to have infections transmitted by direct contact or contact with items in the environment. Patients with significant multidrug-resistant organism (MDRO) infection or colonization, such as methicillin-resistant *Staphylococcus aureus* (MRSA) or vancomycin-resistant *Enterococcus* (VRE), are placed on Contact Precautions. Other infections requiring Contact Precautions include pediculosis (lice), scabies, respiratory syncytial virus (RSV), and *C. difficile*.

MULTIDRUG-RESISTANT ORGANISM INFECTIONS AND COLONIZATIONS

Antibiotics have been available for many years. Unfortunately, these drugs were commonly prescribed for conditions that did not need them or were given at higher doses and for longer periods of time than were necessary. As a result, a

TABLE 25-2 RECOMMENDATIONS FOR APPLICATION OF STANDARD PRECAUTIONS FOR THE CARE OF ALL PATIENTS IN ALL HEALTH CARE SETTINGS

COMPONENT	RECOMMENDATIONS	COMPONENT	RECOMMENDATIONS
Hand hygiene	After touching blood, body fluids, secretions, excretions, contaminated items; immediately after removing gloves; between patient contacts	Needles and other sharps	Do not recap, bend, break, or hand-manipulate used needles; if recapping is required, use a one-handed scoop technique only; use safety features when available; place used sharps in puncture-resistant container
Personal protective equipment (PPE)		Patient resuscitation	Use mouthpiece, resuscitation bag, other ventilation devices to prevent contact with mouth and oral secretions
Gloves	For touching blood, body fluids, secretions, excretions, contaminated items; for touching mucous membranes and nonintact skin	Patient placement	Prioritize for single-patient room if patient is at increased risk for transmission, is likely to contaminate the environment, does not maintain appropriate hygiene, or is at increased risk for acquiring infection or developing adverse outcome following infection
Gown	During procedures and patient-care activities when contact of clothing/exposed skin with blood/body fluids, secretions, and excretions is anticipated	Respiratory hygiene/cough etiquette (source containment of infectious respiratory secretions in symptomatic patients, beginning at initial point of encounter [e.g., triage and reception areas in emergency departments and physician offices])	Instruct symptomatic persons to cover mouth/nose when sneezing/coughing; use tissues and dispose in no-touch receptacle; observe hand hygiene after soiling of hands with respiratory secretions; wear surgical mask if tolerated or maintain spatial separation, >3 feet if possible
Mask, eye protection (goggles), face shield*	During procedures and patient-care activities likely to generate splashes or sprays of blood, body fluids, secretions, especially suctioning, endotracheal intubation		
Soiled patient-care equipment	Handle in a manner that prevents transfer of microorganisms to others and to the environment; wear gloves if visibly contaminated; perform hand hygiene		
Environmental control	Develop procedures for routine care, cleaning, and disinfection of environmental surfaces, especially frequently touched surfaces in patient-care areas		
Textiles and laundry	Handle in a manner that prevents transfer of microorganisms to others and to the environment		

*During aerosol-generating procedures on patients with suspected or proven infections transmitted by respiratory aerosols (e.g., SARS), wear a fit-tested N95 or higher respirator in addition to gloves, gown, and face/eye protection.
SARS, Severe acute respiratory syndrome.

number of microorganisms have become resistant to certain antibiotics; that is, drugs that were once useful no longer control these infectious agents (multidrug-resistant organisms [MDROs]). For this reason, a culture of safety related to infection control has been mandated by the CDC, the Institute for Healthcare Improvement (IHI), and The Joint Commission: Standard Precautions must be strictly followed today in all health care settings to prevent more of these difficult and deadly infections.

One of the newest discoveries to explain the increase in health care–acquired infections (HCAIs), especially the rise in drug-resistant infections, is the formation of biofilms. A **biofilm**, also called *glycocalyx*, is a complex group of microorganisms that functions within a “slimy” gel coating on medical devices such as urinary catheters, orthopedic implants, and enteral feeding tubes; on parts of the body like the teeth (plaque) and tonsils; and in chronic wounds. These reservoirs become sources of infection for which antibiotics and disinfection are not effective. Antibiotic therapy may increase the growth of microbes within biofilms (Childs, 2008).

Biofilms are extremely difficult to treat, and mechanical disruption strategies are the mainstay of management and research (Ramage et al., 2010). Many studies have been and continue to be conducted on biofilms that cause the most common HCAIs, such as catheter-associated urinary tract

infections (CAUTIs) and wound infections. Many specific biofilms have been identified, and methods to remove or disrupt them are being researched.

Patients with *indwelling urinary catheters* are at high risk for pyelonephritis and septicemia. Current evidence shows that urease-producing bacteria, especially *Proteus mirabilis*, cause crystalline biofilms that create a crust that can block the catheter (Stickler & Feneley, 2010). The use of antimicrobial catheters, either silver-alloy or antimicrobial-coated, is recommended for short-term urinary catheter use (less than 3 weeks) to decrease encrustation (Parker et al., 2009). Little evidence is available to demonstrate methods to reduce CAUTIs in long-term indwelling catheters except for frequent catheter changes. In postoperative patients, Palese et al. (2010) found that the regular use of ultrasound bladder scanners reduces urinary tract infections by preventing the inappropriate use of urinary catheters. Nurses can use this information to provide the most current assessment interventions for reducing CAUTIs.

Traditional débridement alone is not successful to prevent or manage *chronic wound* infections, often caused by *Staphylococcus aureus*. A systematic review by Lo et al. (2008) found that silver-releasing dressings were very effective. Biofilms can be disrupted by using dry gauze to mechanically disrupt them after débridement (Hurlow & Bowler, 2009). Antibacterial enzymes may also be used.

TABLE 25-3 TRANSMISSION-BASED INFECTION CONTROL PRECAUTIONS

PRECAUTIONS (IN ADDITION TO STANDARD PRECAUTIONS)	EXAMPLES OF DISEASES IN CATEGORY
Airborne Precautions 1. Private room required with monitored negative airflow (with appropriate number of air exchanges and air discharge to outside or through HEPA filter); keep door(s) closed 2. Special respiratory protection: - N95* respirator for known or suspected TB - Susceptible persons not to enter room of patient with known or suspected measles or varicella unless immune caregivers are not available - Susceptible persons who must enter room must wear N95 HEPA filter 3. Transport: patient to leave room only for essential clinical reasons, wearing surgical mask	Diseases that are known or suspected to be transmitted by air: - Measles (rubeola) <i>Mycobacterium tuberculosis</i>, including multidrug-resistant TB (MDRTB) - Varicella (chickenpox)†; disseminated zoster (shingles)†
Droplet Precautions 1. Private room preferred: if not available, may cohort with patient with same active infection with same microorganisms if no other infection present; maintain distance of at least 3 feet from other patients if private room not available 2. Mask: required when working within 3 feet of patient 3. Transport: as above	Diseases that are known or suspected to be transmitted by droplets: - Diphtheria (pharyngeal) - Streptococcal pharyngitis - Pneumonia - Influenza - Rubella - Invasive disease (meningitis, pneumonia, sepsis) caused by <i>Haemophilus influenzae</i> type B or <i>Neisseria meningitidis</i> - Mumps - Pertussis
Contact Precautions 1. Private room preferred: if not available, may cohort with patient with same active infection with same microorganisms if no other infection present 2. Wear gloves when entering room 3. Wash hands with antimicrobial soap before leaving patient's room 4. Wear gown to prevent contact with patient or contaminated items or if patient has uncontrolled body fluids; remove gown before leaving room 5. Transport: patient to leave room only for essential clinical reasons; during transport, use needed precautions to prevent disease transmission 6. Dedicated equipment for this patient only (or disinfect after use before taking from room)	Diseases that are known or suspected to be transmitted by direct contact: <i>Clostridium difficile</i> - Colonization or infection caused by multidrug-resistant organisms (e.g., MRSA, VRE) - Pediculosis - Respiratory syncytial virus - Scabies - Viral hemorrhagic infections (e.g., Ebola)

HEPA, High-efficiency particulate air; MRSA, methicillin-resistant *Staphylococcus aureus*; TB, tuberculosis; VRE, vancomycin-resistant *Enterococcus*.

*Before use: training and fit testing required for personnel.

†Add Contact Precautions for draining lesions.

Methicillin-Resistant *Staphylococcus aureus* (MRSA)

Staphylococcus aureus (*S. aureus*) is a common bacterium found on the skin and perineum and in the nose of many people. It is usually not infectious when in these areas because the number of bacteria is controlled by good hygiene measures. However, when skin or mucous membranes are not intact, minor infections, like boils or conjunctivitis, may occur. If the organism enters into deep wounds, surgical incisions, the lungs, or bloodstream, more serious infections occur that require strong antibiotics like methicillin.

Within the past 40 years, more and more *S. aureus* infections have not responded to methicillin or other penicillin-based drug. Known as MRSA, these infections are one of the fastest growing and most common in health care today. In its *5 Million Lives Campaign*, the IHI included reducing MRSA infections as one of its six new goals (see Chapter 1). The CDC estimates that 130,000 cases occur in hospitals each year, which lead to over 5,500 deaths. This type of infection is called *health care-associated MRSA*, or HA-MRSA. Patients who have HA-MRSA have increased hospital stays at a very high cost. To add to this problem, about 25% of patients may

be colonized with the organism, sometimes referred to as a “super bug.” Health care staff members may also colonize.

MRSA is spread by direct contact and invades hospitalized patients through indwelling urinary catheters, vascular access devices, and endotracheal tubes. It is susceptible to only a few antibiotics, such as vancomycin (Lyphocin, Vancocin) and linezolid (Zyvox). Patients who develop HA-MRSA pneumonia, abscesses, or bacteremia (bloodstream infection [BSI]) can quickly progress to sepsis and death.

! NURSING SAFETY PRIORITY

Action Alert

Patients most at risk for HA-MRSA are older adults and those who are immunosuppressed, have a long history of antibiotic therapy, or have invasive tubes or lines. ICU patients are especially at risk. Assess your patients for risk, and look for possible manifestations. Those who are colonized are not symptomatic.

Although controversial, some health care facilities have a MRSA-surveillance program in which each patient's nose is swabbed and cultured for MRSA. Staff may also be cultured.

All patients with HA-MRSA infection or colonization should be placed on Contact Precautions.

Community-associated MRSA, or CA-MRSA, causes infections in healthy, nonhospitalized people, especially those living in college housing and prisons. It is easily transmitted among family members and can cause serious skin and soft-tissue infections, including abscesses, boils, and blisters. The best way to decrease the incidence of this growing problem is health teaching, including:

- Performing frequent hand hygiene, including using hand sanitizers
- Avoiding close contact with people who have infectious wounds
- Avoiding large crowds
- Avoiding contaminated surfaces
- Using good overall hygiene

Minocycline (Minocin, Apo-Minocycline 🍁) and doxycycline (Doryx, Apo-Doxy 🍁) are usually effective in treating CA-MRSA.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

A client is admitted with a catheter-associated methicillin-resistant *Staphylococcus aureus* (MRSA) infection. Which personal protective equipment is appropriate when providing client care? **Select all that apply.**

- A. Mask
- B. Gloves
- C. Shoe covers
- D. Goggles
- E. Gown

Vancomycin-Resistant *Enterococcus* (VRE)

Enterococci are bacteria that live in the intestinal tract and are important for digestion. When they move to another area of the body, such as during surgery, they can cause an infection, usually treatable with vancomycin. However, in recent years, over a fourth of these infections have been resistant to the drug and VRE results. Risk factors for this infection include prolonged hospital stays, severe illness, abdominal surgery, enteral nutrition, and immunosuppression. Patients with VRE infections are placed on Contact Precautions.

Unfortunately, VRE can live on almost any surface for days or weeks and still be able to cause an infection. Contamination of toilet seats, door handles, and other objects is very likely for a lengthy period.

Other Multidrug-Resistant Organisms

Although MRSA and VRE have been publicized and extensively studied, a number of other MDROs are emerging. Examples include multidrug-resistant tuberculosis, pneumonia, and gonorrhea, all of which are discussed elsewhere in this text. Two other infections, vancomycin-intermediate *S. aureus* (VISA) and vancomycin-resistant *S. aureus* (VRSA), have recently appeared. VISA and VRSA share some of the same characteristics, including prior MRSA infection, prior and prolonged vancomycin therapy, and renal disease needing dialysis. Several drugs have been effective for these two infections, such as linezolid (Zyvox) and quinupristin-dalfopristin (Synercid).

OCCUPATIONAL EXPOSURE TO SOURCES OF INFECTION

The **Occupational Safety and Health Administration (OSHA)** is a federal agency that protects workers from injury or illness at their place of employment. Unlike the voluntary guidelines developed by the CDC, OSHA regulations are law. Employers can be fined or disciplined for noncompliance with OSHA regulations. The regulation for prevention of exposure to bloodborne pathogens, such as hepatitis B and hepatitis C or the human immune deficiency virus (HIV), is one example of an OSHA regulation.

Reduction of skin and soft tissue injuries (e.g., needle sticks) is essential to reduce bloodborne pathogen transmission to health care personnel. *OSHA mandates that sharp objects (“sharps”) and needles be handled with care.* Many contaminated sharp-object exposures involve nurses. Needleless devices have helped decrease these exposures, especially when caring for patients receiving infusion therapy (see Chapter 15).

Other infection control concerns that nurses and other HCWs have are the possibilities of pandemic influenza, plague, or biologic agent exposure. A large outbreak of one of the MDROs is also worrisome, especially if no drug is sensitive enough for successful management. Nurses fear that they will accidentally bring the infectious agent to their homes and families.

NURSING SAFETY PRIORITY

Action Alert

To help prevent the transmission of an MDRO, wear scrubs and change clothes before leaving work. Keep work clothes separate from personal clothes. Take a shower when you get home, if possible, to rid your body of any unwanted pathogens. Be careful not to contaminate equipment that is commonly used, such as your stethoscope or scissors.

PROBLEMS FROM INADEQUATE ANTIMICROBIAL THERAPY

Inadequate antimicrobial therapy may range from an incorrect choice of drug to poor patient adherence. Some infections relapse in a subtle fashion. Drug regimen **noncompliance** (deliberate failure to take the drug) or **nonadherence** (accidental failure to take the drug) prevents contact of harmful microorganisms with sufficient concentrations of the drug and contributes to resistant-organism development.

Some diseases such as tuberculosis (TB) have legal sanctions that require that a patient complete treatment. Patients who are at risk for noncompliance or nonadherence with an anti-TB drug regimen may be placed on *directly observed therapy (DOT)*. This means that a health care worker must observe and validate patient compliance with the drug regimen. DOT has been very effective at reducing the spread of multidrug-resistant TB.

Serious complications of infection may also result from incomplete or inadequate antibiotic therapy. Local infections that could be cured without complications, such as cellulitis and pneumonia, may progress to abscess formation if appropriate drug therapy is not continued. Although drug therapy

does not always prevent abscess, early therapy may prevent or limit the size of an abscess.

In addition to abscess formation, inadequate therapy may not prevent systemic spread. If the infection is not resolved or if it is treated with drugs that are ineffective for the offending microorganism, the pathogen may enter the bloodstream (septicemia or bloodstream infection [BSI]). Inadequately treated local infections may also lead to BSI with leukocytosis (increased white blood cell count). In severe or advanced cases, leukopenia (decreased white blood cell count) and life-threatening disseminated intravascular coagulation (DIC) may occur. After pathogens invade the bloodstream, no site is protected from invasion.

BSI may progress to **septic shock**, more accurately called *sepsis-induced distributive shock*. In septic shock, insufficient cardiac output is compounded by hypovolemia. Inadequate blood supply to vital organs leads to hypoxia (lack of oxygen) and organ failure. [Chapter 39](#) describes this type of shock and its management in detail.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

The patient's age, history of tobacco or alcohol use, current illness or disease (e.g., diabetes), past and current drug use (e.g., steroids), and poor nutritional status may place him or her at increased risk for infection. Ask the patient about previous vaccinations or immunizations, including the dates of administration.

Determine whether the patient has been exposed to infectious agents. A history of recent exposure to someone with similar clinical symptoms or to contaminated food or water, as well as the time of exposure, assists in identifying a possible source of infection. This information helps determine the incubation period for the disease and thus provides a clue to its cause.

Contact with animals, including pets, may increase exposure to infection. Question the patient about recent animal contact at home or work or in leisure activities (e.g., hiking). Insect bites should be documented.

Obtain a travel history. Travel to areas both within and outside the patient's home country may expose a susceptible person to infectious organisms not encountered in the local community.

A thorough sexual history may reveal behavior associated with an increased risk for sexually transmitted diseases. Obtain a history of IV drug use and a transfusion history to assess the patient's risk for hepatitis B, hepatitis C, and HIV infections.

Identifying the type and location of symptoms may point to affected organ systems. The onset order of symptoms gives clues to the specific problem. Gathering a history of past infection or colonization with multidrug-resistant organisms will help determine which precautions are needed.

Physical Assessment/Clinical Manifestations

Disorders caused by pathogens vary depending on the infection cause and site. Common clinical manifestations are associated with specific sites of infection. Carefully inspect the

skin for symptoms of *local* infection at any site (*pain, swelling, heat, redness, pus*). Wounds can easily become infected because the integrity of the skin is broken.

Fever (generally a temperature above 101° F [38.3° C]), chills, and malaise are primary indicators of a systemic infection. Fever may accompany other noninfectious disorders, and infection can be present without fever. The older adult, whose normal temperature may be 1° to 2° lower than the normal temperature in younger adults, may have a fever at 99° F (37.2° C). In most patients with an infection, fever (**hyperthermia**) is a normal immune response that can help destroy the pathogen. Assess the patient for these signs and symptoms, and carefully ask about their history and pattern.

Lymphadenopathy (enlarged lymph nodes), pharyngitis, and GI disturbance (usually diarrhea or vomiting) are often associated with infection. To detect enlargement, palpate the cervical, axillary, and other lymph nodes; examine the throat for redness. Ask about changes in stool and if the patient has had any nausea or vomiting.

Psychosocial Assessment

The patient with an infectious disease often has psychosocial concerns. Delay in diagnosis because of the need to await clinical test results produces anxiety. Assess the patient's and family's level of understanding about various diagnostic procedures and the time required to obtain test results. Plan education on infection risk reduction at a time when they are ready to learn.

Feelings of malaise and fatigue often accompany infection. Assess the patient's current level of activity and the impact of these symptoms on family, occupational, and recreational activities.

The potential spread of infection to others is an additional stress associated with the diagnosis of infection. The patient may curtail family and social interactions for fear of spreading the illness. Determine the patient's and family's understanding of the infection, the mode of transmission, and mechanisms that may limit or prevent transmission. Special precautions, although sometimes necessary for preventing transmission of the organism, can be emotionally difficult for the patient and family.

A number of transmissible infectious diseases, especially those identified with social stigmas (e.g., IV drug abuse), are associated with labeling. The patient may feel socially isolated or have guilt related to behavior that increased the risk for infection. Observe carefully for the patient's reaction to labels and how these feelings further affect socialization.

Laboratory Assessment

The definitive diagnosis of an infectious disease requires identification of a microorganism in the tissues of an infected patient. Direct examination of blood, body fluids, and tissues under a microscope may not yield a definitive identification. However, laboratory assessment usually provides helpful information about organisms, such as shape, motility, and reaction to staining agents. Even when direct microscopy does not provide a conclusive specific diagnosis, often enough information is obtained for starting appropriate antimicrobial therapy.

*The best procedure for identifying a microorganism is **culture**, or isolation of the pathogen by cultivation in tissue cultures or artificial media. Specimens for culture can be*

obtained from almost any body fluid or tissue. The health care provider usually decides when and where the specimen for culture is taken.

Proper collection and handling of specimens for culture, using Standard Precautions, are essential for obtaining accurate results. Specimens collected must be appropriate for the suspected infection. Be sure that the specimen is of adequate quantity and is freshly obtained and placed in a sterile container to preserve the specimen and microorganism. Label the specimen properly, including the date and time it was collected. Follow your agency's policy if you have any questions about how to perform a culture.

After isolation of a microorganism in culture, antibiotic **sensitivity** testing is performed to determine the effects of various drugs on that particular microorganism. An agent that is killed by acceptable levels of an antibiotic, for example, is considered sensitive to that drug. An organism that is not killed by tolerable levels of an antibiotic is considered resistant to that drug. Preliminary results are usually available in 24 to 48 hours, but the final results generally take 72 hours. *Antibiotic therapy should not begin until after the culture specimen is obtained.*

Newer rapid cultures or assays are beginning to be used in ambulatory care settings to provide quicker assessments of infections. The most popular is the rapid antigen detection test for group A streptococci to rule out “strep throat” in patients who present with pharyngitis (sore, inflamed throat). Other examples of newer tests are those for tuberculosis (TB) and influenza (“flu”), discussed in [Chapter 33](#).

A *white blood cell (WBC) count with differential* is often done for the patient with a suspected infection. Five types of leukocytes (white blood cells) are measured as part of the results:

- Neutrophils
- Lymphocytes
- Monocytes
- Eosinophils
- Basophils

In most active infections, especially those caused by bacteria, the total leukocyte count is elevated. Various infections are characterized by changes in the percentages of the different types of leukocytes. The differential count usually shows an increased number of immature neutrophils, or a **shift to the left** (“left shift”). A few infectious diseases, however, such as malaria and infectious mononucleosis, are associated with neutropenia (decreased neutrophils). See [Chapter 19](#) for further discussion.

The *erythrocyte sedimentation rate (ESR)* measures the rate at which red blood cells fall through plasma. This rate is most significantly affected by an increased number of acute-phase reactants, which occurs with inflammation. Thus an elevated ESR (>20 mm/hr) indicates inflammation or infection somewhere in the body. Chronic infection, especially osteomyelitis, and chronic abscesses are commonly associated with an elevated ESR. The ESR is chronically elevated with inflammatory arthritis and other connective tissue diseases as well (see [Chapter 20](#)). The effectiveness of therapy is often determined by a decrease in this value.

Serologic testing is performed to identify pathogens by detecting antibodies to the organism. The antibody titer tends to *increase* during the acute phase of infectious diseases such as hepatitis B. The titer *decreases* as the patient improves.

Many agencies are using DNA microassay analysis for testing genetic differences among bacteria. This test helps detect antimicrobial genes in nearly all bacteria.

Imaging Assessment

X-ray films may be obtained to determine activity or destruction by an infectious microorganism. Radiologic studies (e.g., chest films, sinus films, joint films, GI studies) are available for diagnosis of infection in a specific body site.

More sophisticated techniques for infection diagnosis include computed tomography (CT) scans and magnetic resonance imaging (MRI). Tomography is helpful in assessing for abscesses. CT scans help identify suspected osteomyelitis and fluid collections that point to possible infection. MRI scans provide a cross-sectional assessment for infection.

Another diagnostic tool for the evaluation of a patient with an infectious disease is ultrasonography. This noninvasive procedure is particularly helpful in detecting infection involving the heart valves.

Scanning techniques using radioactive substances such as gallium can determine the presence of inflammation. Inflammatory tissue is identified by its increased uptake of the injected radioactive material.

ANALYSIS

The priority problems for patients with an infection or infectious disease are:

1. Fever related to the immune response triggered by pathogenic invasion
2. Risk for feelings of isolation related to Transmission-Based Precautions

PLANNING AND IMPLEMENTATION

Managing Fever

Planning: Expected Outcomes. Patients with an infection or infectious disease are expected to have a body temperature within normal limits as a result of effective collaborative management.

Interventions. The primary concern is to provide measures to eliminate the underlying cause of fever (also known as *hyperthermia*) and to destroy the causative microorganism. In collaboration with the health care team, nurses use a variety of methods to manage fever.

Drug therapy plays a major role in patient-centered collaborative care of patients with infection. Antimicrobials, also called *anti-infective agents*, are the cornerstone of drug therapy. Antipyretics are used to decrease patient discomfort and reduce fever.

Antibiotics, antiviral agents, and antifungals are common types of *antimicrobials* that are given for infection, depending on its type. Effective antibiotics are available to treat nearly all bacterial infections, but misuse of antibiotics has contributed to the development of multidrug-resistant organisms (MDROs) discussed earlier in this chapter. A few effective antifungal agents have been developed, but these drugs generally cause more toxicity than antibacterial agents. Effective agents are available for the treatment of influenza type A virus infection and HIV, but some viruses, such as HIV, mutate rapidly. These agents have a limited duration of effectiveness.

Effective antimicrobial therapy requires delivery of an appropriate drug, sufficient dosage, proper administration route, and sufficient therapy duration. These four requirements ensure delivery of a concentration of drug sufficient to inhibit or kill infecting microorganisms. Health care providers collaborate on selecting drugs and dosing. Antimicrobials act on susceptible pathogens by:

- Inhibiting cell wall synthesis (e.g., penicillins and cephalosporins)
- Injuring the cytoplasmic membrane (e.g., antifungal agents)
- Inhibiting biosynthesis, or reproduction (e.g., erythromycin, tetracycline, and gentamicin)
- Inhibiting nucleic acid synthesis (e.g., actinomycin)

Teach the drug's actions, side effects, and toxic effects to patients and their families. Observe and report side effects and adverse events. These reactions vary according to the specific classification of the drug. Most antibiotics can cause nausea, vomiting, and rashes. Stress the importance of completing the entire course of drug therapy, even if symptoms have improved or disappeared.

! NURSING SAFETY PRIORITY

Drug Alert

Before administering an antimicrobial agent, check to see that the patient is not allergic to it (Table 25-4). Be sure to take an accurate allergy history before drug therapy begins to prevent possible life-threatening reactions, such as anaphylaxis!

Antipyretic drugs, such as acetaminophen (Tylenol, Ace-Tabs ,) are often given to reduce fever. Because these drugs mask fever, monitoring the course of the disease may be difficult. Therefore, unless the patient is very uncomfortable or if fever presents a significant risk (e.g., in the patient with heart failure, febrile seizures, or head injury), antipyretics are not always prescribed.

Teach patients that they may have waves of sweating after each dose. Sweating may be accompanied by a fall in blood pressure followed by return of fever. These unpleasant side effects of antipyretic therapy can often be alleviated by increasing fluid intake and by regular scheduling of drug administration.

TABLE 25-4 POSSIBLE ALLERGIC REACTIONS TO ANTIBIOTIC THERAPY

- Nausea and/or vomiting
- Flushing
- Wheezing
- Sneezing
- Pruritus
- Urticaria
- Rashes
- Maculopapular to exfoliative dermatitis
- Vascular eruptions
- Erythema multiforme (Stevens-Johnson syndrome)
- Angioneurotic edema
- Serum sickness (headache, fever, chills, hives, malaise, conjunctivitis)
- Anaphylaxis (laryngeal edema, bronchospasm, hypotension, vascular collapse, cardiac arrest)
- Death

Other interventions to reduce fever may include external cooling and fluid administration. Perform a thorough assessment before and after interventions are implemented.

External cooling by hypothermia blankets or ice bags or packs can be effective mechanisms for reducing a high fever. Alternative cooling methods may be used. Sponging the patient's body with tepid water or applying cool compresses to the skin and pulse points to reduce body temperature is sometimes helpful. *Teach unlicensed assistive personnel (UAP) to observe for and report shivering during any form of external cooling. Shivering may indicate that the patient is being cooled too quickly.*

The use of fans is discouraged because they can disperse airborne- or droplet-transmitted pathogens. Fans can also disturb air balance in negative pressure rooms, making them positive pressure rooms and allowing possible transmission of the agent to those outside the room.

In patients with fever, fluid volume loss is increased from rapid evaporation of body fluids and increased perspiration. As body temperature increases, fluid volume loss increases.

! NURSING SAFETY PRIORITY

Action Alert

If fluid volume loss increases, patients may be at risk for *dehydration and require additional fluids either orally or IV. Monitor carefully for signs of dehydration, such as increased thirst, decreased skin turgor, dry mucous membranes, and acute confusion, especially in older adults. Increase oral fluid intake and provide IV fluids as prescribed. Chapter 13 discusses interventions for dehydration in detail.*

Responding to Feelings of Isolation

Planning: Expected Outcomes. The patient with an infection or infectious disease who is placed on Transmission-Based Precautions is expected to cope with feelings of isolation and interact with others.

Interventions. Education is the major intervention for meeting this outcome. Teach the patient and family about the mode of transmission of infection and mechanisms that prevent spread to others. Assess coping mechanisms that the patient has used in the past. If he or she is in the hospital, collaborate with the certified hospital chaplain or social worker to help alleviate the patient's stress, anxiety, or depression.

As part of the health care team, ensure that the patient and family understand the disease process and its cause. If necessary, ensure that the patient and family can state specific ways in which precautions will be used in the home after discharge from the hospital.

Because the patient requiring precautions may feel secluded, encourage staff and family members to maintain contact with the patient. Remind them that the pathogen, not the patient, requires special precautions. Encourage family members and friends to visit and to use appropriate infection control measures. Communication by telephone or e-mail is often effective for continuing contact with loved ones. Television, Internet, and iPods or other MP3 players help bring the outside world into the life of the patient confined to the room.

In the long-term care setting, an outbreak of respiratory or GI infection usually requires limiting visitors, activities, and admissions to the facility. Nurses working in these

settings need to be familiar with federal and state regulations regarding managing infections.

Community-Based Care

Patients with infections may be cared for in the home, hospital, nursing home, or ambulatory care setting, depending on the type and severity of the infection. Infections among older adults in nursing homes are common. Residents often have meals together in a communal dining room and participate in group activities. Confused residents may not wash their hands or may enter other resident rooms. Immunizing them against respiratory infections is highly recommended because these illnesses can cause severe complications or death in older adults.

Home Care Management

The patient with an infectious disease such as osteomyelitis who is discharged from the hospital to home may require continued, long-term antibiotic therapy. Emphasize the importance of a clean home environment, especially for the patient who continues to be immunocompromised or who is uniquely susceptible to **superinfection** (i.e., reinfection or a second infection of the same kind) to reduce the chance of infection. Drugs often need to be refrigerated. Ensure that the patient has access to proper storage facilities, and teach him or her to check for signs of improper storage, such as discoloration of the drug.

Ask about the availability of handwashing facilities in the home, and check that supplies and instructions are provided as needed. Most people do not know how to wash hands correctly. Demonstrate the procedure with the patient and family, and request a repeat demonstration.

Teaching for Self-Management

Explaining the disease and making certain that the patient understands what is causing the illness are the primary purposes of health teaching. Discuss whether the pathogen causing the infection can be spread to others and the modes of transmission.

If the patient has an infectious disease that is potentially transmissible, teach the patient, family, and other home caregivers about precautions. Explain whether any special household cleaning is necessary and, if so, what those special steps include. If syringes with needles are used to administer drug therapy, explain how to dispose safely and legally of needles in the community. Clothing soiled with blood or other body fluids can be washed with bleach or disinfectant (e.g., Lysol). Recommended cleaning measures should be based on actual available equipment and facilities.

For the patient who is discharged to the home setting to complete a course of antimicrobial therapy, the importance of adherence to the planned drug regimen needs to be stressed. Explain the importance of both the timing of doses and the completion of the planned number of days of therapy. The patient (and family as appropriate) should also be taught how the agents need to be taken (e.g., before meals, with meals, without other agents) and the possible side effects. Side effects include those that are expected (e.g., gastric distress after oral administration of erythromycin), as well as more severe adverse reactions (e.g., rash, fever, other systemic signs and symptoms). Teach the patient about allergic manifestations and the need to notify a health care provider if an

adverse reaction occurs (see [Table 25-4](#)). Also discuss what to do if a drug dose is missed (e.g., doubling the dosage, waiting until the next dose time).

In the past, many patients with severe infection were hospitalized for several weeks or longer to receive IV antimicrobial therapy. Since managed care began, many patients have been discharged with an infusion device to continue drug therapy at home or in other inpatient facilities. The patient, family member, or home care nurse administers the drugs. [Chapter 15](#) describes infusion therapy.

The patient is often anxious and fearful that the infection will be transmitted to family members or friends. Teaching the patient and the family ways of preventing the spread of disease allays these fears. Pay careful attention to the patient's and family's concerns. Making concrete suggestions (e.g., "Your wife can wear gloves when changing your dressing") to address specific concerns may reduce these fears.

The patient with an infectious disease associated with lifestyle behaviors, such as sexual activity or IV drug abuse, may have guilt related to the disease. Encourage discussion of feelings associated with the illness, and assist in locating support systems that may help alleviate these feelings, such as clergy or other spiritual or cultural leaders.

Health Care Resources

In unusual instances, a patient who has been hospitalized for an infectious disease may not be able to return to the home setting immediately. In such cases, temporary placement in a skilled nursing facility (SNF) may be needed. Document care requirements, patient history of infection or colonization with multidrug-resistant organisms, medication schedules, and personal needs and preferences on transfer forms. Hand-off communication between the two facilities is required to facilitate a smooth transition from the hospital to the intermediate care setting, according to The Joint Commission's NPSGs.

Home care services are often used to teach appropriate administration of drug therapy in the patient's home. Health teaching and wound care may also be needed. These services have proved efficient, effective, psychologically supportive, and less expensive than hospitalization or SNFs.

EVALUATION: OUTCOMES

Evaluating the care of the patient with an infection or infectious disease on the basis of the identified priority problems is important. The expected outcomes include that the patient:

DECISION-MAKING CHALLENGE

Evidence-Based Practice; Quality Improvement; Informatics

The patient care coordinator of your medical unit reports a 50% increase in MRSA infections over the past 3 months. The hospital quality improvement department is seeking assistance from the unit staff to decrease this infection rate by identifying possible causes and strategies for implementation.

1. Using the PICOT format in [Chapter 7](#), develop a clinical question to address the problem.
2. How will your unit QI team begin to answer the clinical question?
3. What data sources might you use?
4. What will you do with the retrieved data?
5. How will you present your findings?

TABLE 25-5 EXAMPLES OF BIOTERRORISM AGENTS AND GENERAL CLINICAL MANAGEMENT PER THE CENTERS FOR DISEASE CONTROL AND PREVENTION

PATHOGEN OR AGENT AND DISEASE INFORMATION

Anthrax (*Bacillus anthracis*)

Cutaneous: 1-7 days after contact, exposed skin itching, progressing to papular and vesicular lesions, eschar, edema, ulceration, and sloughing. If untreated, may spread to lymph nodes and bloodstream. Fatality 5%-20%.

Inhalation: 48 hr after organism or spore inhalation, flu-like illness with possible brief improvement. 2-4 days from initial symptoms, abrupt onset of severe cardiopulmonary illness (dyspnea, tachycardia, fever, diaphoresis, thoracic edema, shock, and respiratory failure). If antibiotics delayed until onset of cardiopulmonary symptoms, mortality high. May be confused with common upper respiratory infection (URI).

Other forms: Gastrointestinal (GI), meningial, and sepsis.

Botulism (*Clostridium botulinum* and Neurotoxin)

Toxin ingestion results in dysphasia, dry mouth, drooping eyelids, and blurred or double vision. Vomiting and constipation or diarrhea may be present initially, extending to symmetric flaccid paralysis in an alert person. Acute bilateral cranial nerve impairment and descending weakness or paralysis follow.

Neurologic symptoms after 12-36 hr for foodborne botulism and in 24-72 hr after aerosol exposure. Case fatality up to 10%. Recovery may take months.

Plague (*Yersinia pestis*)

Lymphatic infection: 2-8 days after bites from fleas of an infected rodent (rarely after infected tissue or body fluid contact), onset of fever and chills, painful lymphadenopathy (or bubo—usually inguinal, axillary, or cervical lymph nodes), headache, GI symptoms, and rapidly progressive weakness. 50%-60% fatality if untreated.

Pneumonic: 1-3 days after aerosolized organism inhalation, fever and chills, productive cough, hemoptysis, rapidly progressive weakness, GI symptoms, and bronchopneumonia. Survival unlikely if not treated within 18 hr of symptom onset.

Other forms: Sepsis with coagulopathy, rarely meningitis.

Smallpox (*Variola Virus*) (*Variola Major* and *Minor*)

10-17 days after droplet or airborne virus inhalation or contact with bleeding lesions, onset of severe myalgias, headache, and high fever. 2-3 days later, a papular rash appears on face and spreads to extremities (and palms and soles). The rash quickly (simultaneously) becomes vesicular, then painful and pustular (contrasted to varicella rash that crops and concentrates more on trunk with various stages of macules to vesicles seen at one time). Patients are infectious at onset of rash until scabs separate (3 wk). Historically, variola major kills 20%.

May be confused with varicella.

Other Key Points

Assessment: Include account of symptoms, patient's incident (what, where, when, how, others exposed or ill, and officials aware).

Treatment: Antibiotic-resistance possible. Vaccine and postexposure prophylaxis are subject to change. If any of the above diseases are suspected, consult infection control practitioner for coordination with community health officials and CDC about current recommendations and specimen collection. *If bioterrorism suspected*, Federal Bureau of Investigation (FBI) will coordinate evidence collection and delivery.

Multiple exposures planning: Emergency and critical care managers must address availability and acquisition of stocks of medications, vaccines, equipment (e.g., ventilators), and communications with officials, as well as public information needs.

CLINICAL MANAGEMENT

For cutaneous and inhaled anthrax: No person-to-person spread. Contact Precautions are not needed unless patient presents directly from exposure.

Standard Precautions for:

Prescribed wound cleansing and management of lesions

Ventilator support for respiratory failure

Postmortem care

Standard Precautions: decontamination of patient is not required. No person-to-person spread.

Consider outbreak with suspicion of a single case. Consult with Centers for Disease Control and Prevention (CDC) and health departments.

Advise careful cleanup and disposal of suspected contaminated food source *after* consultation with health department about any needed laboratory sampling.

Interdisciplinary planning for nutrition and rehabilitation support during lengthy neuromuscular and respiratory recovery.

Droplet Precautions: required for pneumonic plague (until 72 hr of antibiotic therapy).

Contact Precautions until decontamination is complete:

For any suspected gross contamination. See documentation information listed under Anthrax—above.

For prescribed management of bubo(s) if incised to drain.

Community and other environmental modifications:

Apply insecticide to infested environment and pets (to kill fleas).

Reduce food and water supply for rodents.

Avoid sick or dead animals.

Standard, Contact, and Airborne Precautions for patients with vesicular rash pending diagnosis. Same for varicella and variola.

Also, avoid contact with organism while handling contaminated clothes and bedding. Wear protective attire (gloves, gown, and N95 respirator).

One case is a public health emergency—highly communicable.

Consult CDC and health departments at earliest suspicion.

Vaccine does not give reliable lifelong immunity. Previously vaccinated persons are considered susceptible. *Following exposure:* Initiate Airborne Precautions, and observe for unprotected contacts (from days 10-17). Vaccinate within 2-3 days of exposure.

- Has body temperature and other vital signs within baseline
- Adheres to drug therapy regimen
- Copes with feelings of social isolation
- Interacts with others as appropriate

Specific indicators for these outcomes are listed for each priority problem under the Planning and Implementation section (see earlier).

CRITICAL ISSUES: BIOTERRORISM AND EMERGING INFECTIONS

Current concerns related to infection and infection control are the risk for bioterrorism (Table 25-5), emerging infectious diseases, and multidrug-resistant organisms (MDROs), already discussed. As for any pathogen, strict infection control measures can prevent transmission of these microbes to you and your patients. Some of the most serious infections are briefly described here. Table 25-6 lists more emerging infections that may present as problems in the United States.

Preparation for and education about *bioterrorism* have been major focuses of the U.S. government since September 11, 2001. In some cases, vaccines are no longer given for biologic agents like smallpox. Many people in the United States have never been vaccinated, and those who had vaccinations many years ago are not guaranteed to have lifelong immunity. Anthrax, usually seen in animals, may be spread to the skin or inhaled. These infections have a high fatality rate in humans. Plague, once seen centuries ago, is one of the biggest threats because the survival rate is low. Vaccines are being researched and stockpiled by the U.S. government for some of the common biologic agents.

Pandemic infections, such as influenza, are another threat to the population. As recently as the early 1900s, the “Spanish flu” killed millions of people throughout the world. Health care workers are encouraged to have yearly influenza vaccines to prevent common strains of the virus. The federal government and health care agencies around the United States include the risk for pandemic disease in their disaster planning (see Chapter 12).

Contaminated food is another source of infection. The incidence of foodborne infections has risen in the United

States as contaminated fresh spinach, ground beef, and other foods were found to contain *E. coli* 0157:H7. Many illnesses and thousands of recent deaths in the United States have been caused by this infection. Safer food preparation practices and increased monitoring by federal agencies have resulted from demand for public safety. More information on foodborne illnesses can be found in Chapter 60.

Another pathogen, *Clostridium difficile* (*C. difficile*), is associated with antibiotic therapy use. An uncommon but virulent strain of this organism has appeared recently in the United States and Canada. *C. difficile* is spread by indirect contact with inanimate objects like medical equipment and commodes, and its toxins cause colon dysfunction and cell death from sepsis. *C. difficile*-associated disease (CDAD) is confirmed by stool culture. Patients who have three or more liquid stools per day for two or more days are suspected of having CDAD. *Older adults are the most at risk for this infection.* Metronidazole (Flagyl) and vancomycin are the drugs of choice.

TABLE 25-6 EXAMPLES OF EMERGING INFECTIOUS DISEASES IN THE UNITED STATES

Recently Emerging Diseases

- H1N1 influenza
- Severe acute respiratory syndrome (SARS)
- West Nile virus
- Avian influenza
- Hemorrhagic fevers (e.g., Ebola, Marburg)
- Monkeypox
- Bovine spongiform encephalopathy
- Chagas disease
- Vancomycin-intermediate *Staphylococcus aureus* (VISA)
- Vancomycin-resistant *Staphylococcus aureus* (VRSA)
- *Clostridium difficile* (new strain)

Older Rapidly Growing Diseases

- Methicillin-resistant *Staphylococcus aureus* (MRSA)
- Vancomycin-resistant *Enterococcus* (VRE)
- Multidrug-resistant tuberculosis
- *Clostridium difficile*

NURSING CONCEPT REVIEW

What might you NOTICE if the patient has inadequate protection as a result of infection or infectious disease?

- Flushing and sweating
- Localized skin inflammation (redness, warmth, swelling, pain)
- Open wound (draining or non-draining)
- Report of diarrhea or vomiting
- Report of sore throat
- Fatigue
- Rash
- Acute confusion (in older adults)

What should you INTERPRET and how should you RESPOND to a patient with inadequate protection as a result of infection or infectious disease?

Perform and interpret focused physical assessment findings, including:

- Vital signs
- Skin and/or wound assessment
- Lymph palpation
- Throat inspection

Respond:

- Manage fever if present.
- Take culture of drainage and send to laboratory for analysis.
- Monitor laboratory findings, including complete blood count (CBC) with white blood cell (WBC) differential.
- Place on appropriate Transmission-Based Precautions.

NURSING CONCEPT REVIEW—cont'd

- Teach patients and families about Transmission-Based Precautions and hand hygiene.
- Administer antimicrobial therapy as prescribed.
- Collaborate with the facility's infection control practitioner.
- Teach patients and families about the need to adhere to the drug therapy regimen.
- Follow CDC guidelines and The Joint Commission's National Patient Safety Goals (NPSGs).

On what should you REFLECT?

- Monitor the patient's response to drug therapy.

- Monitor the patient's vital signs for return to baseline.
- Evaluate the patient's and family's knowledge of infection, Transmission-Based Precautions, and drug therapy.
- Monitor the staff's compliance with hand hygiene and personal protective equipment (PPE).
- Evaluate the patient's and family's coping ability.
- Think about what else you might do to make the patient more comfortable.
- Decide whether you need to provide alternative or additional interventions or health teaching.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Handwashing and alcohol-based hand rubs are two methods of hand hygiene (see [Chart 25-3](#)).
- The Centers for Disease Control and Prevention (CDC) recommends a ban on artificial fingernails for health care professionals when they are caring for patients at high risk for infection.
- Infections can be prevented or controlled through hand hygiene, disinfection/sterilization, personal protective equipment (PPE), patient placement, and adequate staffing; proper hand hygiene and gloves are the most important interventions because health care workers' hands are the primary way in which disease is transmitted from patient to patient.
- Standard Precautions are used with all patients in health care settings, assuming that all body excretions and secretions are potentially infectious (see [Table 25-2](#)).
- Airborne Precautions are used for patients who have infections transmitted through the air, such as tuberculosis.
- Droplet Precautions are used for patients who have infections transmitted by droplets, such as influenza and certain types of meningitis.
- Contact Precautions are used for patients who have infections transmitted by direct contact or contact with items in the patient's environment.

Health Promotion and Maintenance

- Health teaching about clinical manifestations of infection and drug therapy is important for the patient with an infection being managed at home; some patients may need health care nursing services for IV antimicrobial therapy.
- Teach patients about antimicrobial therapy and protective measures to prevent infection transmission.
- Teach patients how to avoid community-acquired MRSA by performing frequent hand hygiene and by avoiding

crowds and direct contact with others who have infections.

Psychosocial Integrity

- Patients who have Transmission-Based Precautions may feel isolated, anxious, or depressed; they may feel neglected and dissatisfied with their care. Help patients cope with these feelings through verbalization and collaboration with the health care team.

Physiological Integrity

- Examples of multidrug-resistant organisms (MDROs) include methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant *Enterococcus* (VRE).
- A **biofilm**, also called *glycocalyx*, is a complex group of microorganisms that function within a "slimy" gel coating on medical devices, such as urinary catheters, orthopedic implants, and enteral feeding tubes; on parts of the body like the teeth (plaque) and tonsils; and in chronic wounds. Biofilms are difficult to treat, and research is examining methods to manage them to better treat.
- If infections are not treated or are inadequately treated, systemic sepsis (septicemia), septic shock, and disseminated intravascular coagulation (DIC) may result.
- A culture is the most definitive way to confirm and identify microorganisms; sensitivity testing determines which antibiotics will destroy the identified microbes.
- The differential count usually shows a shift to the left (increased number of immature neutrophils) during active infections.
- Antimicrobials and antipyretics are the most common types of drugs used when infection is accompanied by fever.
- Antipyretics are used only when the fever presents a significant risk or the patient is very uncomfortable, because antipyretics may mask the disease.
- Critical issues for the next decade include bioterrorism, emerging infectious diseases, and multidrug-resistant organisms (MDROs).

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES**Safe and Effective Care Environment**

1. Use knowledge of integumentary changes associated with aging to protect older adult patients from skin injury.
2. Modify techniques to assess skin changes in patients with darker skin.

Health Promotion and Maintenance

3. Teach all people how to protect the skin from sun exposure.
4. Teach all people to use the ABCDE method of checking lesions for manifestations of melanoma.
5. Perform health history and risk assessment for skin, hair, and nail problems.

Psychosocial Integrity

6. Teach patients and family members about what to expect during tests and procedures to assess skin function and skin disease.

7. Reassure patients who have skin changes that are variations of normal.

Physiological Integrity

8. Compare the structures and function of the epidermis, dermis, and subcutaneous tissue.
9. Use proper terminology to communicate skin assessment findings.
10. Distinguish between normal variations and abnormal skin manifestations with regard to skin color, texture, warmth, and moisture.
11. Use the ABCDE method of assessing skin lesions for cancer.

The integumentary system includes the skin, hair, and nails. The skin plays a major role in the *concept of body protection*. As shown in Fig. 26-1, the skin protects against foreign invasion by providing a first line of defense (the moat), a second line of defense (the castle wall), and even a third line of defense (the knights and soldiers). The normal flora on the surfaces of skin and mucous membranes repels some of the more harmful microorganisms. Intact skin has barrier functions, alarm functions, and even combat functions. Specialized cells called *Langerhans' cells*, present in the skin, engulf foreign substances (antigens) that invade the body when the skin is injured. These cells then alert the immune system to the presence of the invader.

The skin is the largest organ of the body and plays a major role in homeostasis. When intact, it helps regulate body temperature and maintains fluid and electrolyte balance. Changes in the skin can communicate information about a person's health and well-being (Anderson et al., 2007).

Skin as protection

FIG. 26-1 Role of the skin in the concept of body protection.

Emotional stress, systemic disease, and skin injury or disease can alter the function, appearance, and texture of the skin. Therefore examine the skin for important clues about the patient's health.

The sensory function of the skin allows the use of touch as a therapeutic intervention to provide comfort, relieve pain, and communicate caring. Because the skin has many sensory receptors, the patient can report subjective skin sensations that might indicate specific health problems.

ANATOMY AND PHYSIOLOGY REVIEW

Structure of the Skin

As shown in Fig. 26-2, the skin has three layers: subcutaneous tissue (fat), dermis, and epidermis. Each layer has unique properties that contribute to the skin's ability to maintain its complex functions.

Subcutaneous fat (adipose tissue [fat]) is the innermost layer of the skin, lying over muscle and bone. Fat cells serve as an energy reserve in the event extra calories are needed to power the body. These cells also act as heat insulators for the body. They absorb shock and protect against injury by padding internal structures. Fat distribution varies with body area, age, and gender. Many blood vessels go through the fatty layer and extend into the dermal layer, forming capillary networks that supply nutrients and remove wastes.

The *dermis (corium)* is the layer above the fat layer. It is composed of connective tissue that contains no cells. The dermis is composed of collagen and elastic fibers that are interwoven to give the skin both flexibility and strength.

Collagen, the main component of dermal tissue, is a protein formed by dermal cells called *fibroblasts*. Collagen production increases in areas of tissue injury and helps form scar tissue. Fibroblasts also produce **ground substance**, a protein lubricant that surrounds the dermal cells and fibers and contributes to the skin's normal suppleness and turgor.

FIG. 26-2 Anatomy of the skin.

The elasticity of the skin depends on both the amount and quality of the elastic fibers, which are scattered among the collagen fibers. The major component of the elastic fiber is **elastin**.

The dermis has capillaries and lymph vessels for the exchange of oxygen and heat. The dermis is also rich in sensory nerves that transmit the sensations of touch, pressure, temperature, pain, and itch.

The **epidermis** is the outermost skin layer. It is anchored to the dermis by finger-like projections of dermal tissue (**dermal papillae**). The fingers of epidermal tissue that project into the dermis are called **rete pegs**. The epidermis is less than 1 mm thick, but it is the protective barrier between the body and the environment.

The epidermis does not have its own blood supply and receives its nutrients by diffusion from the blood vessels in the dermal layer through the basement membrane. Attached to the basement membrane are the **keratinocytes**, the actual skin cells. The keratinocytes capable of cell division are the basal cells, which are located closest to the basement membrane and continuously divide to form new cells. Older keratinocytes are pushed upward and flattened to form the stratified layers of the epithelium (**malpighian layers**). When these cells reach the outermost skin layer, the **stratum corneum** (horny layer), they are no longer living cells and are shed from the skin. **Keratin**, the protein produced by keratinocytes, makes the horny layer waterproof. A keratinocyte takes about 28 to 45 days to move from the basement membrane to the skin surface.

Vitamin D is activated in the epidermis by ultraviolet (UV) light, such as sunlight. It is then distributed by the blood to the intestinal tract, where it promotes uptake of dietary calcium.

Melanocytes are pigment-producing cells found at the basement membrane. These cells give color to the skin and account for the ethnic differences in skin tone. Darker skin tones are not caused by increased numbers of melanocytes; rather, the size of the pigment granules (**melanin**) contained in each cell determines the color. The purpose of melanin is to protect the skin from damage by UV light. For this reason, people with dark skin are less likely to develop sunburn than lighter-skinned people with the same sun exposure. Freckles, birthmarks, and age spots are caused by patches of melanin within the skin. UV light stimulates the production of melanin, which protects against the harmful effects of sun exposure. Melanin production increases in areas that have endocrine changes or inflammation.

Structure of the Skin Appendages

Hair, a thick protective pelt worn by most mammals, is mainly a cosmetic feature for modern humans. Hair growth varies with race, gender, age, and genetic predisposition. Individual hairs can differ in both structure and rate of growth, depending on body location.

Hair follicles are located in the dermal layer of the skin but are actually extensions of the epidermal layer (see Fig. 26-2). Within each hair follicle, a round column of keratin forms the hair shaft. Hair keratin is tougher than skin keratin. Hair color is genetically determined by a person's rate of melanin production.

Hair growth occurs in cycles, with a growth phase followed by a resting phase. Stressors can alter the growth cycle and result in temporary hair loss. Permanent baldness, such as male pattern baldness, is inherited and is seldom influenced by personal or environmental factors.

FIG. 26-3 Anatomy of the nail.

Nails on fingers and toes have cosmetic value and are useful for grasping and scraping. Like hair follicles, the nails are extensions of the keratin-producing epidermal layers of the skin.

The white, crescent-shaped portion of the nail at the lower end of the nail plate is called the **lunula** and is the location of the nail matrix, where nail keratin is formed and nail growth begins (Fig. 26-3). Nail growth is a continuous but slow process. Fingernail replacement requires 3 to 4 months. Toenail replacement may take up to 12 months.

The **cuticle**, a layer of keratin at the nail fold, attaches the nail plate to the soft tissue of the nail fold. The nail body is translucent, and the pinkish hue reflects a rich blood supply beneath the nail surface. Nail growth and appearance are often altered during systemic disease or serious illness.

Sebaceous glands are distributed over the entire skin surface except for the palms of the hands and soles of the feet. Most of these glands are connected directly to the hair follicles (Fig. 26-4). The sebaceous glands of the eyelids, nipple areolae, and genitalia are freestanding.

Sebaceous glands produce **sebum**, a mildly bacteriostatic, fat-containing substance. Sebum lubricates the skin and reduces water loss from the skin surface.

Sweat glands of the skin are of two types: eccrine and apocrine. Eccrine sweat glands arise from the epithelial cells. They are found over the entire skin surface and are not associated with the hair follicle. The odorless, colorless, isotonic secretions of these glands are important in the regulation of body temperature. Stimulation of sweat from these glands and the resultant water evaporation can cause the body to lose as much as 10 to 12 L of fluid in a single day.

Apocrine sweat glands are in direct contact with the hair follicle. They are found mostly in the axillae, nipple areolae,

periumbilicus, and perineal body areas. The interaction of skin bacteria with the secretions of the apocrine glands causes the distinctive body odor.

Functions of the Skin

The skin is a complex organ responsible for the regulation of many body functions throughout the life span (Table 26-1) (McCance et al., 2010). In addition to the skin's protective and regulatory functions, its location on the outside of the body makes it an important way to communicate a patient's state of health and body image.

FIG. 26-4 Anatomy of the hair follicle and sebaceous and sweat glands.

Skin Changes Associated with Aging

The process of aging begins at birth. As changes in physiology progress with aging, the skin also undergoes age-related changes in both structure and function (Chart 26-1). Figs. 26-5 through 26-12 show some common age-related skin changes (Bianchi & Cameron, 2009).

Individual differences exist in how quickly and to what degree the skin ages (Helfrich et al., 2008). Although genetic background, hormonal changes, and systemic disease may change the appearance of the skin over time, chronic sun exposure is the single most important factor leading to degeneration of the skin components.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

The client reports that a previously sensitive area of skin no longer responds to temperature changes or painful stimuli. This finding indicates a functional abnormality for which skin layer?

- A. Stratum corneum
- B. Adipose layer
- C. Epidermis
- D. Dermis

ASSESSMENT METHODS

Patient History

Before examining the skin, take an accurate history from the patient so that actual and potential skin problems can be readily identified. Important data to collect include

TABLE 26-1 FUNCTIONS OF THE SKIN

EPIDERMIS	DERMIS	SUBCUTANEOUS TISSUE
Protection Keratin provides protection from injury by corrosive materials Inhibits proliferation of microorganisms because of dry external surface Mechanical strength through intercellular bonds	Provides fibroblasts for wound healing Provides mechanical strength Collagen fibers Elastic fibers Ground substance Sensory nerve endings signal skin injury and inflammation	Mechanical shock absorber Energy reserve Insulation
Homeostasis (Water Balance) Low permeability to water and electrolytes prevents systemic dehydration and electrolyte loss	Lymphatic and vascular tissues respond to inflammation, injury, and infection	No real function in water balance
Temperature Regulation Eccrine sweat glands allow dissipation of heat through evaporation of sweat secreted onto the skin surface	Cutaneous vasculature, through dilation or constriction, promotes or inhibits heat conduction from the skin surface	Fat cells act as insulators and assist in retention of body heat
Sensory Organ Transmits a variety of sensations through the neuroreceptor system	Encloses an extensive network of nerve endings for relaying sensations to the brain	Contains large pressure receptors
Vitamin Synthesis 7-Dehydrocholesterol is present in large concentrations in malpighian cells, allowing photoconversion to active vitamin D	No function	No function
Psychosocial Body image alterations occur with many epidermal diseases, such as generalized psoriasis	Body image alterations occur with many dermal diseases, such as scleroderma	Body image alterations may result from increases, decreases, and redistribution of body fat stores

CHART 26-1 NURSING FOCUS ON THE OLDER ADULT

Changes in the Integumentary System Related to Aging

PHYSICAL CHANGES	CLINICAL FINDINGS	NURSING ACTIONS
Epidermis		
Decreased thickness in epidermal layer	Increased skin transparency and fragility	Handle patients carefully to minimize friction and shear to the skin. Assess for excessive dryness or moisture. Avoid taping the skin.
Decreased epidermal mitotic activity	Delayed wound healing	Protect open areas; use moisture-retentive dressings to promote wound healing.
Decreased epidermal mitotic homeostasis	Skin hyperplasia, such as hyperkeratoses and skin cancers (especially in sun-exposed areas)	Assess non-sun-exposed areas to determine baseline skin features. Assess exposed skin areas for sun-induced changes.
Increased epidermal permeability	Increased susceptibility to irritant reactions	Teach patients how to avoid exposure to skin irritants.
Decreased number of Langerhans' cells	Decreased cutaneous inflammatory response	Do not rely on redness and swelling to indicate skin damage.
Decreased number of active melanocytes	Increased sensitivity to sun exposure	Teach patients to wear hats and protective clothing. Teach patients to avoid sun exposure from 10 AM to 4 PM and to use sunscreen when outside.
Hyperplasia of melanocytes at the dermal-epidermal junction (especially in sun-exposed areas)	Mottled hyperpigmentation and hypopigmentation (e.g., liver spots, age spots)	Teach patients to keep track of such spots, but help them to differentiate these "normal" spots from those that need evaluation for malignancy.
Decreased vitamin D production	Increased susceptibility to osteomalacia	Urge patients to take a multiple vitamin or a calcium supplement that contains vitamin D.
Flattening of the dermal-epidermal junction	Increased susceptibility to shearing forces, with resultant blisters, purpura, skin tears, and pressure-related skin problems	Avoid pulling or dragging patients. Assist patients confined to bed or chairs to change positions at least every 2 hours. Avoid or use care when removing adhesive wound dressings.
Dermis		
Decreased dermal blood flow	Increased susceptibility to dry skin (xerosis)	Teach patients to apply moisturizers when the skin is still moist and to avoid agents that promote skin dryness.
Decreased vasomotor responsiveness	Increased thermoregulatory alterations (predisposition to heat stroke and hypothermia)	Teach patients to dress for the environmental temperatures and not to rely on skin sensations to tell them they are too hot or too cold.
Decreased dermal thickness	Paper-thin, transparent skin with an increased susceptibility to trauma	Handle patients gently, and avoid the use of tape or tight dressings. Use lift sheets when positioning patients.
Degeneration of elastic fibers	Decreased tone and elasticity (wrinkles)	Use the forehead or chest to test skin turgor.
Benign proliferation of capillaries	Cherry hemangiomas	Teach patients that these are benign.
Reduced number and function of nerve endings	Alterations in sensory perception	Instruct patients to use bath thermometer and to lower the water heater temperature to prevent scalds.
Subcutaneous Layer		
Thinning of subcutaneous fat layer	Increased susceptibility to hypothermia Decreased resistance to mechanical injury (especially pressure necrosis)	Teach patients to dress warmly in cold weather and to wear hats and gloves when outdoors. Assist patients confined to bed or chairs to change positions at least every 2 hours.
Hair		
Decreased number of hair follicles and rate of growth	Increased hair thinning	Suggest wearing hats in cold weather to prevent body heat loss and when in the sun to prevent burning the scalp.
Decreased number of active melanocytes in follicle	Gradual loss of hair color (graying)	Although associated with aging, inform patients that hair color loss can occur at any age.
Nails		
Decreased rate of growth	Increased susceptibility to fungal infections	Inspect the nails (including toenails) of all older adults. Instruct patients to wear socks and to keep the feet clean, warm, and dry.

Continued

CHART 26-1 NURSING FOCUS ON THE OLDER ADULT

Changes in the Integumentary System Related to Aging—cont'd

PHYSICAL CHANGES	CLINICAL FINDINGS	NURSING ACTIONS
Decreased blood flow beneath the nail bed	Longitudinal nail ridges	Use the oral mucosa to assess for cyanosis.
Thickening of the nail	Toenails (especially) thicken and may overhang the toes	Use fingernails to assess capillary refill. Cut toenails straight across rather than on a curve. Do not use nail appearance alone to determine the presence of a fungal infection. Assess skin in contact with the nail to determine whether the thick nail is irritating it.
Glands		
Decreased sebum production despite sebaceous gland hyperplasia	Increased size of pores (especially on nose); large comedones in malar region	Teach patients not to squeeze the pores or comedones to prevent traumatizing the skin.
Decreased eccrine and apocrine gland activity	Increased susceptibility to dry skin	Urge patients to avoid deodorant soaps and to use soaps with a high fat content. Teach patients to apply moisturizers immediately after bathing when skin is moist.
	Decreased perspiration, leading to decreased cooling effect	Do not use sweat production as an indicator of hyperthermia.

FIG. 26-5 Eyelid eversion, deepening of the eye orbit, and “bags” under the eye.

FIG. 26-7 Paper-thin, transparent skin with actinic lentigo (liver spots).

FIG. 26-6 Arcus senilis of the iris.

FIG. 26-8 Wrinkles.

FIG. 26-9 Graying and thinning of the hair.

FIG. 26-12 Nail changes: longitudinal ridges and thickening.

FIG. 26-10 Xerosis (dry skin).

FIG. 26-11 Senile (cherry) angiomas.

demographic and socioeconomic information. [Chart 26-2](#) highlights specific questions to ask during a skin assessment.

Demographic data include age, race, occupation, and hobbies or recreational activities. This information can help identify causative or aggravating factors for skin problems. Age is important because many changes in the skin, hair, and nails are normal manifestations of the aging process.

Race and nationality can also be important. Some variations in the appearance of skin are normal among patients of

specific races and ethnicities but are abnormal for those of other races or ethnicities.

Information about occupation and hobbies can provide clues to chronic skin exposure to chemicals, irritants, abrasive substances, and other environmental factors that can contribute to skin problems. Also, frequent or recent travel to tropical climates may be associated with the development of skin infections or infestations.

Socioeconomic status data can help identify environmental factors that might contribute to skin disease. Recent travel may be a source of skin infections or unusual lesions.

If the patient is well tanned, ask about the amount of time spent in the sun and tanning salons and whether he or she has any skin problems from sun exposure. Use this time to teach the patient about the harmful aspects of sun exposure and how to reduce sun exposure.

Skin problems related to poor hygiene are common. Ask about living conditions, bathing practices, and the availability of running water. Teach people that keeping the skin and hair clean by bathing and shampooing regularly helps maintain the skin's health.

Information about drug use is important to obtain because prescribed drugs, over-the-counter (OTC) drugs, herbal preparations or remedies, and tobacco use can cause allergies or skin reactions or affect skin function. Ask the patient about any recent use of prescription drugs, OTC drugs (e.g., laxatives, antacids, cold remedies), and herbal preparations or remedies. Determine when each drug was started, the dose and frequency of the drug, and the time the last dose was taken. Ask the patient whether skin changes began after starting a new drug. A drug history also helps identify skin changes that result from the treatment of other health problems, such as the changes that occur with long-term steroid or anticoagulant therapy.

Allergies can develop to environmental substances and often have skin manifestations. These allergies may be well documented or have a new onset. Ask about the use of any new personal care product (e.g., shaving products, perfumes, soap, shampoo, lotion, makeup, hair gel, toothpaste), laundry detergents and softeners, and home cleaning products. Determine whether the patient wears gloves to avoid direct contact with cleaning solutions. New clothing may contain chemicals that come into contact with and irritate the skin.

CHART 26-2 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Obtaining an Accurate Nursing History of the Patient with a Skin Problem

Medical-Surgical History

- Does the patient have any current or previous medical problems?
- Has the patient undergone any recent or previous surgical procedures?

Family History

- Is there any family tendency toward chronic skin problems?
- Do any members of the immediate family have recent skin problems?

Medication History

- Is the patient allergic to any systemic or topical drug? If so, have the patient describe the reaction.
- What prescription drugs has the patient taken recently? When was the drug started? What is the dose or frequency of administration? When was the last dose taken?
- What over-the-counter drugs has the patient taken recently? When was the drug started? What is the dose or frequency of administration? When was the last dose taken?

Social History

- What is the patient's occupation?
- What recreational activities does the patient enjoy?
- Has the patient traveled recently?
- What is the patient's nutritional status?
- Does the patient use tobacco or recreational drugs, or drink alcohol?

Current Health Problem

- When did the patient first notice the skin problem?
- Where on the body did the problem begin?
- Has the problem gotten better or worse?
- Has a similar skin condition ever occurred before? If so, have the patient describe the typical course and how it was treated.
- Is the problem associated with any of the following: itching, burning, stinging, numbness, pain, fever, nausea and vomiting, diarrhea, sore throat, cold, stiff neck, new foods, new soaps or cosmetics, new clothing or bed linens, or stressful situations?
- Does anything seem to make the problem worse (e.g., sun exposure, drugs, heat or cold, menses)?
- Does anything seem to make the problem better?

Documenting the body location(s) of the skin problem can help determine its cause.

Nutrition Status

Document the patient's weight, height, body build and fat distribution, and food preferences. Poor nutrition, especially protein deficiencies, vitamin deficiencies, and obesity, can increase the patient's risk for skin lesions and delay wound healing. Fat-free diets and chronic alcoholism can lead to vitamin deficiencies and related skin changes. Some skin diseases, such as chronic urticaria and acne, may be worsened by certain foods or food additives.

Hydration influences overall skin health, and the skin reflects hydration status. Reduced fluid intake can lead to dry skin. Skin manifestations of severe fluid losses are seen as loose skin that tents when pinched together. Fluid overload with edema can stretch the skin, masking wrinkles and

allowing the formation of skin "pits" when pressure is applied to it.

Family History and Genetic Risk

Many skin problems (e.g., psoriasis, skin cancer, keloid formation, eczema) have a familial predisposition or can be inherited (Nussbaum et al., 2007). Explore any family tendency of chronic skin problems. Ask about immediate family members' current health status to identify a disease that could be transferred among family members (e.g., ringworm, scabies).

Current Health Problems

Chart 26-2 lists the best practices for obtaining a history from a patient with a skin problem. Begin by gathering information about skin changes and current skin care practices.

If a skin problem is identified, obtain more information about the specific problem, such as:

- When did the patient first notice the rash or skin change?
- Where on the body did the rash begin?
- Has the problem improved or become worse?

If a similar problem has occurred before, ask the patient to describe the course of the skin lesion and how it was treated. Try to link the problem with specific symptoms, such as itching, burning, numbness, pain, fever, sore throat, stiff neck, or nausea and vomiting. Ask him or her to identify anything that seems to make the problem better or worse.

Skin Assessment

Inspection

Skin changes may be related to specific skin diseases and may also reflect a systemic disorder. By using skin assessment skills, you are in a unique position to identify clues about a patient's overall state of health.

A thorough assessment of the skin is best performed with the patient partially or completely undressed. (Always provide privacy to maintain the patient's dignity.) Incorporate skin examination for actual or potential problems into the routine part of daily care while bathing him or her or assisting with hygiene.

Inspect the patient's skin surfaces in a well-lighted room; natural or bright fluorescent lighting enhances the visibility of subtle skin changes. Although no special equipment is needed, use a penlight to closely inspect lesions and to illuminate the mouth.

Assess each skin surface systematically, including the scalp, hair, nails, and mucous membranes. Give particular attention to the skinfold areas. The moist, warm environment of skinfolds can harbor organisms, such as yeast or bacteria. Observe and document these features:

- Obvious changes in color and vascularity
- Presence or absence of moisture
- Edema
- Skin lesions
- Skin integrity

Check the cleanliness of the various body areas to determine whether the patient's self-care activities need to be evaluated.

Skin color is affected by a number of factors, including blood flow, oxygenation, body temperature, and pigment

TABLE 26-2 COMMON ALTERATIONS IN SKIN COLOR

ALTERATION	UNDERLYING CAUSE	LOCATION	SIGNIFICANCE
White (pallor)	Decreased hemoglobin level Decreased blood flow to the skin (vasoconstriction)	Conjunctivae	Anemia
		Mucous membranes	Shock or blood loss
		Nail beds	Chronic vascular compromise
		Palms and soles	Sudden emotional upset
Yellow-orange	Genetically determined defect of the melanocyte (decreased pigmentation) Acquired patchy loss of pigmentation	Lips	Edema
		Generalized	Albinism
		Localized	Vitiligo, tinea versicolor
		Generalized	Increased hemolysis of red blood cells
Yellow-orange	Increased total serum bilirubin level (jaundice)	Mucous membranes	Liver disorders
		Sclera	
		Perioral	Increased ingestion of carotene-containing foods (carrots)
		Palms and soles	Pregnancy
Yellow-orange	Increased serum carotene level (carotenemia)	Ears and nose	Thyroid deficiency
		Absent in sclera and mucous membranes	Diabetes
		Generalized	Chronic kidney disease (uremia)
		Absent in sclera and mucous membranes	
Red (erythema)	Increased blood flow to the skin (vasodilation)	Generalized	Generalized inflammation (e.g., erythroderma)
		Localized (to area of involvement)	Localized inflammation (e.g., sunburn, cellulitis, trauma, rashes)
		Face, cheeks, nose, upper chest	Fever, increased alcohol intake
		Area of exposure	Exposure to cold
Blue	Increase in deoxygenated blood (cyanosis)	Nail beds	Cardiopulmonary disease
		Mucous membranes	Methemoglobinemia
		Generalized	
		Generalized	
Blue	Bleeding from vessels into tissue: Petechiae (1-3 mm) Ecchymosis (>3 mm)	Localized	Thrombocytopenia
		Localized	Increased blood vessel fragility
		Generalized	Polycythemia vera
		Distal extremities, nose	Inadequate tissue perfusion
Reddish blue	Increased overall amount of hemoglobin Decreased peripheral circulation	Generalized	Chronic inflammation
		Distal extremities, nose	Exposure to sunlight
		Localized (to area of involvement)	Addison's disease
		Pressure points, areolae, palmar creases, and genitalia	
Brown	Increased melanin production	Face, areolae, vulva, linea nigra	Pregnancy; oral contraceptives (melasma)
		Localized	Nonpathogenic
		Generalized	Possible neurofibromatosis
		Distal lower extremities	Chronic venous stasis
Brown	Café au lait spots (tan-brown patches) <6 spots >6 spots Melanin and hemosiderin deposits (bronze or grayish tan color)	Exposed areas or generalized	Hemochromatosis

production. The wide variation in natural skin tones may require different techniques for patients who have darker skin. (See [Cultural Awareness](#), p. 465, for suggestions for assessing patients with darker skin.)

Describe changes in skin color by their appearance ([Table 26-2](#)). Document changes in color, and describe whether the changes are general or confined to one body region. Color changes can be seen most easily in the areas of least pigmentation, such as the oral mucosa, sclera, nail beds, and palms and soles. Inspect these areas to help confirm more subtle color changes of general body areas.

Lesions in skin disease are clinically described in terms of primary and secondary lesions ([Fig. 26-13](#)). **Primary lesions** are an initial reaction to a problem that alters one of the structural components of the skin. **Secondary lesions** are changes in the appearance of the primary lesion. These changes occur with progression of an underlying disease or in response to a topical or systemic therapeutic intervention. For example, acute dermatitis often occurs as primary

vesicles with associated **pruritus** (itching). Secondary lesions in the form of crusts occur as the patient scratches, the vesicles are opened, and the exudate dries. With chronic dermatitis, the skin often becomes **lichenified** (thickened) because of the patient's continual rubbing of the area to relieve itching.

Describe lesions by color, size, location, and shape. Note whether they occur as isolated changes or are grouped and form a distinct pattern. [Table 26-3](#) defines terms used to describe lesions.

Assess each lesion for the following ABCDE features that are associated with skin cancer (The [Skin Cancer Foundation](#), 2010; McEnroe-Petite, 2011):

- **A**symmetry of shape
- **B**order irregularity
- **C**olor variation within one lesion
- **D**iameter greater than 6 mm
- **E**volving or changing in any feature (shape, size, color, elevation, itching, bleeding, or crusting)

PRIMARY LESIONS

Macules (such as freckles, flat moles, or rubella) are flat lesions of less than 1 cm in diameter. Their color is different from that of the surrounding skin—most often white, red, or brown.

Nodules (such as lipomas) are elevated, marble-like lesions more than 1 cm wide and deep.

Patches (such as vitiligo or café au lait spots) are macules that are larger than 1 cm in diameter. They may or may not have some surface changes—either slight scale or fine wrinkles.

Cysts (such as sebaceous cysts) are nodules filled with either liquid or semisolid material that can be expressed.

Papules (such as warts or elevated moles) are small, firm, elevated lesions less than 1 cm in diameter.

Vesicles (such as in acute dermatitis) and **bullae** (such as second-degree burns) are blisters filled with clear fluid. Vesicles are less than 1 cm in diameter, and bullae are more than 1 cm in diameter.

Plaques (such as in psoriasis or seborrheic keratosis) are elevated, plateau-like patches more than 1 cm in diameter that do not extend into the lower skin layers.

Pustules (such as in acne and acute impetigo) are vesicles filled with cloudy or purulent fluid.

FIG. 26-13 Classification of skin lesions.

PRIMARY
LESIONS—cont'd

Wheals (such as *urticaria* and *insect bites*) are elevated, irregularly shaped, transient areas of dermal edema.

Erosions (such as in *varicella*) are wider than fissures but involve only the epidermis. They are often associated with vesicles, bullae, or pustules.

SECONDARY
LESIONS

Scales (such as in *exfoliative dermatitis* and *psoriasis*) are visibly thickened stratum corneum. They appear dry and are usually whitish. They are seen most often with papules and plaques.

Ulcers (such as *stage 3 pressure sores*) are deep erosions that extend beneath the epidermis and involve the dermis and sometimes the subcutaneous fat.

Crusts and oozing (such as in *eczema* and *late-stage impetigo*) are composed of dried serum or pus on the surface of the skin, beneath which liquid debris may accumulate. Crusts frequently result from broken vesicles, bullae, or pustules.

Lichenifications (such as in *chronic dermatitis*) are palpably thickened areas of epidermis with accentuated skin markings. They are caused by chronic rubbing and scratching.

Fissures (such as in *athlete's foot*) are linear cracks in the epidermis, which often extend into the dermis.

Atrophy (such as *striae* [stretch marks] and *aged skin*) is characterized by thinning of the skin surface with loss of skin markings. The skin is translucent and paper-like. Atrophy involving the dermal layer results in skin depression.

FIG. 26-13, cont'd Classification of skin lesions.

TABLE 26-3 TERMS COMMONLY USED TO DESCRIBE SKIN LESION CONFIGURATIONS

annular	Ringlike with raised borders around flat, clear centers of normal skin
circinate	Circular
circumscribed	Well-defined with sharp borders
clustered	Several lesions grouped together
coalesced	Lesions that merge with one another and appear confluent
diffuse	Widespread, involving most of the body with intervening areas of normal skin; generalized
linear	Occurring in a straight line
serpiginous	With wavy borders, resembling a snake
universal	All areas of the body involved, with no areas of normal-appearing skin

A patient who has a lesion with one or more of the ABCDE features should be evaluated by a dermatologist or surgeon. Teach patients these signs, and encourage them to perform total skin self-examination (TSSE) on a monthly basis (American Cancer Society, 2011).

In describing the location of lesions, determine whether they are generalized or localized. If the lesions are localized, identify the specific body areas involved. This information is important because some diseases have a specific pattern of skin lesions. Involvement of only the sun-exposed areas of the body is important information when considering possible causes. Rashes limited to the skinfold areas (e.g., on the axillae, beneath the breasts, in the groin) may reflect problems related to friction, heat, and excessive moisture.

Edema causes the skin to appear shiny, **taut** (tightly stretched), and paler than uninvolved skin. During skin inspection, document the location, distribution, and color of areas of edema.

Skin elasticity is also affected by edema. Using moderate pressure, place the tip of the index finger against edematous tissue to determine the degree of indentation, or pitting (see Chapter 13).

Moisture content is assessed by noting the thickness and consistency of secretions. Normally, increased moisture in the form of sweat occurs with increased activity or elevated environmental temperatures. Dampness of skinfold areas occurs as a result of decreased air circulation where the skin surfaces touch. Excess moisture can cause skin breakdown in bedridden and debilitated patients.

Overly dry skin can be caused by factors such as a dry environment, poor skin lubrication, inadequate fluid intake, and the normal processes of aging. Dry skin usually has scaling of the outer surface. Dry skin may be especially marked in areas of limited circulation, such as the feet and lower legs. It is a problem for most adults during the winter months when the air contains less moisture, living in geographic areas with little humidity, and in the hospital environment where humidity is often low.

Vascular changes or markings are classified as normal or abnormal, depending on the cause. Normal vascular markings include birthmarks, cherry angiomas (see Fig. 26-11), spider angiomas, and venous stars. Bleeding into the tissue is abnormal and results in **purpuric lesions** (bleeding under the skin that may progress from red to purple to brownish yellow), petechiae, and ecchymosis.

FIG. 26-14 Petechiae.

Petechiae are small, reddish purple lesions (<0.5 mm in diameter) that do not fade or blanch when pressure is applied (Fig. 26-14). They often indicate increased capillary fragility. Petechiae of the lower extremities often occur with stasis dermatitis, a condition usually seen in patients who have chronic venous insufficiency.

Ecchymoses (bruises) are larger areas of hemorrhage that range in size from several millimeters to many centimeters. In older adults, bruising is common after minor trauma to the skin, especially on sun-exposed areas of the body. Certain drugs (e.g., aspirin, warfarin, corticosteroids) and low platelet counts lead to easy or excessive bruising. Anticoagulants and decreased numbers of platelets disrupt clotting action, resulting in ecchymosis.

Integrity of the skin is assessed by first examining areas with actual breaks or open areas. For example, skin tears are a common finding in older people as a result of a flattening of the dermal-epidermal junction with aging (LeBlanc & Christensen, 2011). The thin, fragile skin is easily damaged by friction or shearing forces, especially if bruising is already present. Look for skin tears in these areas:

- Where constricting clothing rubs against the skin
- On the upper extremities, where the skin is grasped when assisting a patient to ambulate or change position
- Where adhesive tapes or dressings have been applied and removed

Check for the presence of multiple abrasions or early pressure-related skin changes. These findings may indicate previously unrecognized problems in mobility or sensory perception.

Describe breaks in skin integrity by their location, size, color, and distribution, as well as by the presence of drainage or any signs of infection. The evaluation of partial-thickness and full-thickness wounds, including objective criteria that describe progress toward healing, is discussed in Chapter 27.

Cleanliness of the skin is evaluated to gain information about self-care needs. Inspect the hair, nails, and skin closely for excessive soiling and offensive odor. Depending on a patient's degree of self-care deficit, hard-to-reach areas (e.g., perirectal and inguinal skinfolds, axillae, feet) may be less clean than other skin surface areas. Skin can be clean but

stained as a result of exposure to chemicals during work or leisure activities.

Patients who have cognitive problems may not pay attention to hygiene measures. Assess the cognition of any patient whose hygiene of the skin, hair, or nails appears inadequate.

Tattoos and piercings can cause or mask skin problems and should be carefully examined. Bruises and rashes can occur in tattooed areas but may be difficult to see. Examine newly pierced areas for signs of inflammation or infection. Scars may be present in old tattoos or pierced areas and should be documented. Closely examine any areas where tattoos have been removed. Skin cancer is more likely to occur in these areas.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

During skin inspection the nurse observes three lesions on the client's right knee. The lesions are round, have a raised border, and are grouped in a "smiley face" pattern. Which descriptors does the nurse use to document these observations?

- A. Annular, circinate, clustered
- B. Linear, confluent, vesicular
- C. Circumscribed, universal, pustular
- D. Serpiginous, coalesced, wheal-like

Palpation

Skin inspection alone can be misleading, especially in areas of color changes, tattoos, and piercings. Use palpation to gather additional information about skin lesions, moisture, temperature, texture, and turgor (Table 26-4). Wash hands thoroughly before and after palpating a patient's skin. Use gloves to examine nonintact skin, and use Standard Precautions when skin areas are draining.

Palpation confirms the size of the lesions and determines whether they are flat or slightly raised. The consistency of larger lesions can vary from soft and pliable to firm and solid. Subtle changes, such as the difference between a fine **macular** (flat) rash and a **papular** (raised) rash, may best be determined by palpating with your eyes closed. Ask the patient whether he or she has pain or tenderness during palpation of the skin.

In areas of excess dryness, rub your finger against the skin surface to determine the degree of flaking or scaling. Both generalized and localized changes in skin temperature can be detected by placing the back of a hand on the skin surface. Before assessing for changes in skin temperature, make certain to have warm hands. Cold hands interfere with accurate assessment and are uncomfortable for the patient.

Palpate skin surfaces to assess texture, which differs according to body region and exposure to environmental irritants. For example, areas of long-term sun exposure have a rougher texture than that of protected skin surfaces. The patient whose occupation requires repeated exposure to harsh soaps or chemicals may show skin changes related to this exposure. Increased skin thickness from scarring, lichenification, or edema usually decreases elasticity.

Turgor indicates the amount of skin elasticity. Skin turgor can be altered by a number of factors, including water content and aging. Gently pinch the patient's skin between your thumb and forefinger, and then release. If skin turgor is normal, the skin immediately returns to its original state

when released. Poor skin turgor is evidenced by "tenting" of the skin, with a gradual return to the original state (see Chapter 13). Normal loss of elasticity with aging makes the assessment of skin turgor difficult in an older patient.

NURSING SAFETY PRIORITY

Action Alert

To avoid mistaking dehydration for dry skin in an older adult, always assess skin turgor on the forehead or chest, and also assess for other indicators of dehydration.

Hair Assessment

During the skin assessment, inspect and palpate the hair for general appearance, cleanliness, distribution, quantity, and quality. Hair is normally found in an even distribution over most of the body surfaces, with the hair on the scalp, in the pubic region, and in the axillary folds thicker and coarser than hair on the trunk, arms, and legs. Although color and growth patterns vary, sudden or marked changes in hair characteristics may reflect an underlying disease process. As with skin changes, check any abnormal findings by obtaining a detailed history of the circumstances surrounding any change.

How well the hair is groomed, including the cleanliness of areas of thicker hair growth, can confirm information already gathered about a patient's social history and health care needs. If the patient has intense itching or scratches continually, examine the scalp and pubis for lice and **nits** (lice eggs). Inspect the scalp for scaling, redness, open areas, crusting, and tenderness.

Dandruff, a collection of patchy or diffuse white or gray scales on the surface of the scalp, is common. The flaking that occurs with dandruff causes many people to mistakenly think the scalp is too dry; however, it is a problem of excessive oil production. Dandruff is mainly a cosmetic problem, but a very oily scalp can induce inflammatory changes with redness and itching. Severe inflammatory dandruff can extend to the eyebrows and the skin of the face and neck. *If severe dandruff is not treated, hair loss can occur.* Teach the patient that dandruff is not caused by dryness and should be treated to prevent hair loss.

Although gradual hair loss occurs with aging, sudden asymmetric or patchy hair loss at any age is of concern. Assess the scalp for distribution and thickness of the hair, and document variations. Body hair loss, especially on the feet or lower legs, may occur as a result of circulatory problems and decreased blood flow to the area.

Hirsutism is excessive growth of body hair or hair growth in abnormal body areas. Increased hair growth across the face and chest in women is a sign of hirsutism. It may occur on the face of a woman as part of aging, is one manifestation of hormonal imbalance, and can also occur as a side effect of drug therapy. If hirsutism is present, look for changes in fat distribution and capillary fragility, which can occur in Cushing's disease, and for clitoral enlargement and deepening of the voice, which may indicate ovarian dysfunction.

Nail Assessment

Dystrophic (abnormal-appearing) nails may occur with a serious systemic illness or local skin disease involving the epidermal keratinocytes. Assess the fingernails and toenails for color, shape, thickness, texture, and the presence of lesions.

TABLE 26-4 COMMON CLINICAL FINDINGS IN SKIN PALPATION

CLINICAL FINDINGS	CAUSE	LOCATION	EXAMPLES OF PREDISPOSING CONDITIONS
Edema			
Localized	Inflammatory response	Area of injury or involvement	Trauma
Dependent or pitting	Fluid and electrolyte imbalance Venous and cardiac insufficiency	Ambulatory: dorsum of foot and medial ankle Bedridden: buttocks, sacrum, and lower back	Congestive heart failure Kidney disease Liver cirrhosis Venous thrombosis or stasis
Nonpitting	Endocrine imbalance	Generalized, but more easily seen over the tibia	Hypothyroidism (myxedema)
Moisture			
Increased	Autonomic nervous system stimulation	Face, axillae, skinfolds, palms, and soles	Fever, anxiety, activity Hyperthyroidism
Decreased	Dehydration Endocrine imbalance	Buccal mucous membranes with progressive involvement of other skin surfaces	Fluid loss Postmenopausal status Hypothyroidism Normal aging
Temperature			
Increased	Increased blood flow to the skin	Generalized Localized	Fever, hypermetabolic states Neurotrauma Inflammation
Decreased	Decreased blood flow to the skin	Generalized Localized	Impending shock, sepsis, anxiety Hypothyroidism Interference with vascular flow
Turgor			
Decreased	Decreased elasticity of the dermis (tenting when pinched)	Abdomen, forehead, or radial aspect of the wrist	Severe dehydration Sudden, severe weight loss Normal aging
Texture			
Roughness or thickness	Irritation, friction Sun damage Excessive collagen production	Pressure points (e.g., soles, palms, elbows) Localized areas of pruritus Areas of sun exposure Localized or generalized	Calluses Chronic eczema Atopic skin diseases Normal aging Scleroderma Scars and keloids
Softness or smoothness	Endocrine disturbances	Generalized	Hyperthyroidism

Many variations in color, texture, and grooming of the nails are influenced by factors unrelated to disease, such as occupation. When assessing the older adult, observe for minor variations associated with the aging process (see Fig. 26-12), such as a gradual thickening of the nail plate, the presence of longitudinal ridges, or a yellowish gray discoloration.

Color of the nail plate depends on nail thickness and transparency, amount of red blood cells, arterial blood flow, and pigment deposits (Table 26-5). Fig. 26-15 shows normal variations in nail color. Changes in color can be caused by chemical damage that occurs with some occupations and with the long-term use of nail polish. Regardless of skin color, the healthy nail blanches (lightens) with pressure.

During examination, the patient's fingers and toes should be free of any surface pressure that interferes with local blood flow or alters the appearance of the digits. To differentiate between color changes from the underlying vascular supply and those resulting from pigment deposition, blanch the nail bed to see whether the color changes with pressure. Do this by gently squeezing the end of the finger or toe, exerting

downward pressure on the nail bed, and then releasing the pressure. Color caused by vascular alterations changes as pressure is applied and returns to the original state when pressure is released. Color caused by pigment deposition remains unchanged.

Nail shape changes may be related to systemic disease. For example, fingernail clubbing occurs with impaired gas exchange. (See Fig. 32-12 in Chapter 32.)

Assess nail shape by examining the curve of the nail plate and surrounding soft tissue from all angles. Palpate the fingertips to define areas of sponginess, tenderness, or edema. Table 26-6 describes common variations in nail shape.

Thickness of the nail plate can vary with age, trauma, chronic dermatologic disease, or decreased arterial blood flow. In older patients, look for a "heaped-up" appearance of the toenails, which may occur with fungal infection (*onychomycosis*).

Consistency of the nail is described as hard, soft, or brittle. Nail plates may become hard, with increased thickening. A warm-water soak or lubrication with petroleum jelly is required to soften the nail plates before they can be trimmed.

FIG. 26-15 A, Diffuse nail pigmentation. B, Linear nail pigmentation.

Soft nail plates, which are thin and bend easily with pressure, are associated with malnutrition, chronic arthritis, myxedema, and peripheral neuritis.

Brittle nails can split, as in the patient with onychomycosis or advanced psoriasis of the fingers or toes. Splitting of the nail plate is also caused by repeated exposure to water and detergents, which damage the plate over time.

Lesions can occur around, on, within, or under the nail. Separation of the nail plate from the nail bed (*onycholysis*) creates an air pocket beneath the nail plate. The pocket first appears as a grayish white opacity. The color may change as dirt and keratin collect in the pocket, and the area begins to have a bad odor. This problem is common with fungal infections and after trauma. Separation of the nail plate may also occur with psoriasis or with prolonged chemical contact.

Inspect the soft-tissue folds around the nail plate for redness, heat, swelling, and tenderness. **Acute paronychia** (inflammation of the skin around the nail) often occurs with a torn cuticle or an ingrown toenail. If it occurs in an immunosuppressed patient, a staphylococcal infection is probable.

Chronic paronychia is more common and is an inflammation that persists for months. People at risk for chronic paronychia are men and women with frequent exposure to water, such as homemakers, bartenders, laundry workers, and nurses.

CULTURAL AWARENESS

Pallor, erythema, cyanosis, and other color changes reflective of the physical state are less visible in patients with naturally dark skin tones. Although physiologic processes are the same for both light-skinned and dark-skinned patients, the amount of skin pigmentation greatly alters how the skin appears in response to physiologic alterations. Consequently, assessment skills to detect the more subtle color changes are needed. Become familiar with the normal appearance of a dark-skinned patient's mucous membranes, nail beds, and skin tone so that variations from baseline can be identified. [Chart 26-3](#) lists specific assessment techniques for skin manifestations of health problems in people with dark skin (Gaskin, 1986).

Skin Assessment Techniques for Patients with Darker Skin

Pallor can be detected in people with dark skin by first inspecting the mucous membranes for an ash-gray color. If the lips and the nail beds are not heavily pigmented, they

TABLE 26-5 COMMON ALTERATIONS IN NAIL COLOR

ALTERATION	CLINICAL FINDINGS	SIGNIFICANCE
White	Horizontal white banding or areas of opacity Generalized pallor of nail beds	Chronic liver or kidney disease (hypoalbuminemia) Shock Anemia Early arteriosclerotic changes (toenails) Myocardial infarction
Yellow-brown	Diffuse yellow to brown discoloration Vertical brown banding extending from the proximal nail fold distally	Jaundice Peripheral lymphedema Bacterial or fungal infections of the nail Psoriasis Diabetes Cardiac failure Staining from tobacco, nail polish, or dyes Long-term tetracycline therapy Normal aging (yellow-gray color) Normal finding in dark-skinned patients Nevus or melanoma of nail matrix in light-skinned patients
Red	Thin, dark red vertical lines 1-3 mm long (splinter hemorrhages) Red discoloration of the lunula Dark red nail beds	Bacterial endocarditis Trichinosis Trauma to the nail bed Normal finding in some patients Cardiac insufficiency Polycythemia vera
Blue	Diffuse blue discoloration that blanches with pressure	Respiratory failure Methemoglobinuria Venous stasis disease (toenails)

TABLE 26-6 COMMON VARIATIONS IN NAIL SHAPE

NAIL SHAPE	CLINICAL FINDINGS		SIGNIFICANCE
Normal	Angle of 160 degrees between the nail plate and the proximal nail fold Nail surface slightly convex Nail base firm when palpated		Normal finding
Clubbing			
Early clubbing	Straightening of angle between the nail plate and the proximal nail fold to 180 degrees Nail base spongy when palpated		Hypoxia Lung cancer
Late clubbing	Angle between the nail plate and the proximal nail fold exceeds 180 degrees Nail base visibly edematous and spongy when palpated Enlargement of the soft tissue of the fingertips gives a "drumstick" appearance when viewed from above		Prolonged hypoxia Emphysema Chronic obstructive pulmonary disease Advanced lung cancer Cystic fibrosis Chronic heart disease
Spoon nails (koilonychia)			
Early koilonychia	Flattening of the nail plate with an increased smoothness of the nail surface		Iron deficiency (with or without anemia) Poorly controlled diabetes >15 yr in duration Local injury
Late koilonychia	Concave curvature of the nail plate		Psoriasis Chemical irritants Developmental abnormality
Beau's grooves	1-mm wide horizontal depressions in the nail plates caused by growth arrest (involves all nails)		Acute, severe illness Prolonged febrile state Isolated periods of severe malnutrition
Pitting	Small, multiple pits in the nail plate May be associated with plate thickening and onycholysis Most often involves the fingernails (several or all)		Psoriasis Alopecia areata

appear paler than normal for that patient. Use good lighting to assess for the absence of the underlying red tones that normally give heavily pigmented skin a healthy glow. With generalized decreased blood flow to the skin, brown skin appears yellow-brown and very dark brown skin is ash gray.

Cyanosis can be present when gas exchange is impaired. Examine the lips, tongue, nail beds, conjunctivae, and palms and soles for subtle color changes. In a patient with cyanosis, the lips and tongue are gray and the palms, soles, conjunctivae, and nail beds have a bluish tinge. To support these findings, assess for other indicators of hypoxia, including tachycardia, hypotension, changes in respiratory rate, decreased breath sounds, and changes in cognition.

Inflammation in dark-skinned patients appears as excessive warmth and changes in skin consistency or texture. Use the back of your hand to palpate areas of suspected inflammation for the increased warmth that occurs when blood flow to the skin increases. With the fingertips, palpate for hardened areas deep in the tissue, which may give the skin a "woody" feeling. Inflamed skin is tender and edematous. If edema is extensive, the skin is taut and shiny.

Skin areas where inflammation has recently resolved appear darker than the normal skin tone. This change is due

to stimulation of the melanocytes during the inflammatory process and to the increased pigment production that continues after inflammation subsides. More extensive injury to the skin with destruction of melanocytes (e.g., deep ulcer, full-thickness burn) may heal with color changes that are lighter than the normal skin tone. Unlike acute changes, chronic inflammatory changes are not tender. If scar tissue is present, the skin may feel less supple, especially over the joints. If chronic inflammatory changes are suspected, ask the patient about a history of skin problems in that area of the body.

Jaundice in a patient with dark skin is best assessed by inspecting the oral mucosa, especially the hard palate, for yellow discoloration. Inspection of the conjunctivae and adjacent sclera may be misleading because normal deposits of fat produce a yellowish hue that is visible in contrast to the dark skin around the eyes. Examine the sclera closest to the cornea for a more accurate determination of jaundice. The palms and soles of dark-skinned patients may appear yellow if they are calloused; a callus should not be mistaken for jaundice.

Skin bleeding with purpuric lesions may not be visible in areas of deep pigmentation. Areas of ecchymoses appear

CHART 26-3 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Assessing Changes in Dark Skin

Cyanosis

- Examine lips and tongue for gray color.
- Examine nail beds, palms, and soles for blue tinge.
- Examine conjunctiva for pallor.

Inflammation

- Compare affected area with nonaffected area for increased warmth.
- Examine the skin of the affected area to determine whether it is shiny or taut or pits with pressure.
- Compare the skin color of affected area with the same area on the opposite side of the body.
- Palpate the affected area and compare it with unaffected area to determine whether texture is different (affected area may feel hard or “woody”).

Jaundice

- Check for yellow tinge to oral mucous membranes, especially the hard palate.
- Examine the sclera nearest to the iris rather than the corners of the eye.

Bleeding

- Compare the affected area with the same area on the unaffected body side for swelling or skin darkening.
- If the patient has thrombocytopenia, petechiae may be present on the oral mucosa or conjunctiva.

darker than normal skin; they may be tender and easily palpable, depending on whether hematoma is present. In most cases, the patient relates a history of trauma to the area that confirms the assessment. Petechiae are rarely visible in dark skin and may be seen only in the oral mucosa and conjunctiva.

Psychosocial Assessment

Skin changes, especially when the face, hair, and hands are involved, often affect a person's body image. Encourage the patient to express his or her feelings about a change in body image or appearance. Assess his or her body language for clues indicating a disturbance in self-concept. For example, the avoidance of eye contact or the use of garments to cover the affected areas communicates concern about physical appearance. Patients with chronic skin diseases often relate a history of social isolation related to a fear of rejection by others or a belief that the skin problem is contagious.

Skin changes linked to poor hygiene are common in uneducated patients, among homeless people, and among those who have reduced cognitive functioning or mental illness. Assess the patient's overall appearance for excessive soiling, matted hair, body odor, or other self-care deficits. Confirm unsanitary living conditions by obtaining a social history. Patients may relate similar skin problems among family members, friends, and sexual contacts.

If skin problems related to poor hygiene are identified in older patients, also evaluate any physical limitations that might contribute to poor health maintenance. For example, visual or mobility problems can make it difficult for them to see or reach skin surfaces to clean them.

DECISION-MAKING CHALLENGE

Patient-Centered Care

The patient is a 43-year-old Middle-Eastern woman who is being seen because of a rough, raised area on the skin of her forehead. The area is a darker brown than her skin and has an irregular shape. She tells you this has been on her face for about 18 months and she wants it removed. In addition, you observe a very dark, 2 by 4 centimeter, slightly raised, irregularly shaped lesion near her upper lip to the right of her nose. When you look at it more closely, you can see that one edge of it spreads as a flat color change into the surrounding skin. When you ask her how long this area has been present, she tells you that she was born with this beauty mark and it is not what she wants evaluated or removed.

1. Does the forehead lesion have any concerning features? If so, which ones?
2. Does the lip lesion have any concerning features? If so, which ones?
3. What other assessment data regarding either lesion should you obtain?
4. Because the patient has dismissed issues about the lip lesion, should you pursue further evaluation of it? Provide a rationale for your response.

Diagnostic Assessment

Laboratory Assessment

When a fungal, bacterial, or viral pathogen is suspected as the cause of certain skin changes, confirmation by microscopic examination is necessary. *Always wear gloves (use Standard Precautions) when examining skin that is not intact.*

Cultures for fungal infection are obtained when superficial fungal infections are suspected. Using a tongue blade, gently scrape scales from skin lesions into a clean container and send it to the laboratory. Collect fingernail clippings and hair in a similar manner. Waiting for culture results can delay treatment of a superficial fungal infection. For this reason, the specimen is also treated with a potassium hydroxide (KOH) preparation and examined microscopically. Fungal infections show branched hyphae when viewed under a microscope after treatment with KOH. A positive KOH test often eliminates the need for a culture.

For deeper fungal infections, a piece of tissue is obtained for culture. The physician obtains the specimen by punch biopsy (see p. 468 in the *Skin Biopsy* section). When a specimen is needed for cell analysis and special fungal stains, either two specimens are obtained or one specimen is divided before being sent to the laboratory.

Cultures for bacterial infection are obtained from intact primary lesions (bullae, vesicles, or pustules), if possible. Express material from the lesion, collect it with a cotton-tipped applicator, and place the material in a bacterial culture medium specified by the laboratory. For intact lesions, **unroofing** (lifting or puncturing of the outer surface) may be needed using a sterile small-gauge needle before the material can be easily expressed. If crusts are present, remove the crusts with normal saline and swab the underlying exudate.

A biopsy of deep bacterial infections may be required to obtain a specimen for culture. If bacterial cellulitis is suspected, the physician or advanced practice nurse can inject nonbacteriostatic saline deep into the tissue and then aspirate it back; the aspirant is sent for culture.

Cultures for viral infection are indicated if a herpes virus infection is suspected. A cotton-tipped applicator is used to

obtain vesicle fluid from intact lesions. Unlike bacterial and fungal specimens, which can remain at room temperature until being transported to the laboratory, viral culture tubes are placed on ice immediately after specimens are obtained and are transported to the laboratory as soon as possible.

Other Diagnostic Assessment

Other tests for diagnosis of skin problems include biopsy, special noninvasive examination techniques, and skin testing for allergy (discussed in Chapter 22).

Skin Biopsy. A small piece of skin tissue may be obtained for diagnosis or to assess the effectiveness of an intervention. Check with the physician to determine the number, location, and type of skin biopsies to be performed. Depending on the size, depth, and location of the skin changes, the physician may perform a punch biopsy, shave biopsy, or scalpel excision (excisional biopsy).

Punch biopsy is the most common technique. A small circular cutting instrument, or “punch,” ranging in diameter from 2 to 6 mm, is used. After the site is injected with a local anesthetic, a small plug of tissue is cut and removed. The site may be closed with one or two sutures if it is on the face or leg. Some physicians allow the biopsy site to heal without suturing.

Shave biopsies remove only the portion of the skin elevated above the surrounding tissue when injected with a local anesthetic. A scalpel or razor blade is moved parallel to the skin surface to remove the tissue specimen. Shave biopsies are usually indicated for superficial or raised lesions. Suturing is not needed.

Excisional biopsy is rarely used for skin problems. When needed, larger or deeper specimens are obtained by excision with a scalpel. Deep incisions are made and then sutured after the specimen is removed. Unlike punch and shave biopsies, excisional biopsies involve more discomfort for the patient while the site is healing.

Patient Preparation. Explain to the patient what to expect. Emphasize that a biopsy is a minor procedure with few, if any, complications. If a punch or shave biopsy is planned, reassure him or her that scarring is minimal because of the small size of the tissue removed. If an excisional biopsy is planned, tell the patient that a scar similar to that of a healed surgical incision will result.

Procedure. Establish a sterile field, and assemble all needed supplies and instruments. Local anesthesia is provided by local infiltration using a small-gauge (25-gauge) needle to reduce discomfort during injection. Although preparation of the biopsy site differs according to the physician’s preference, the skin is simply wiped with alcohol in most cases.

The most uncomfortable time for the patient is during the injection of a local anesthetic agent, which produces a burning

or stinging sensation. Reassure him or her that the discomfort will subside as the anesthetic takes effect. Talking the patient through the procedure with a quiet voice, in combination with a gentle touch, may have a calming effect.

After removal, tissue specimens for pathologic study are placed in 10% formalin for fixation. Specimens for culture are placed in sterile saline solution. Bleeding of the biopsy site may be controlled by applying localized pressure or a topical hemostatic agent. If topical treatment does not stop the bleeding, suturing may be used.

Follow-up Care. After bleeding is under control and any sutures have been placed, the site is covered with an adhesive bandage or a dry gauze dressing. Instruct the patient to keep the dressing dry and in place for at least 8 hours. Teach him or her to clean the site daily after the dressing is removed. Tap water or saline can be used to remove any dried blood or crusts. An antibiotic ointment may be prescribed to reduce the risk for infection. The biopsy site may be left open unless a covering is preferred for cosmetic reasons or because the site is an area often soiled. Instruct the patient to report any redness or excessive drainage. Sutures are usually removed 7 to 10 days after biopsy.

Wood’s Light Examination. A handheld, long-wavelength ultraviolet (black) light or Wood’s light is sometimes used during physical examination. Exposure of some skin infections with this light produces a specific color, such as blue-green or red, that can be used to identify the infection. Hypopigmented skin is more prominent when it is viewed under black light, which makes evaluation of pigment changes in light-skinned patients easier. This examination is always carried out in a darkened room and does not cause discomfort.

Diascopy. Diascopy is a painless technique that eliminates erythema caused by increased blood flow to the skin, thereby easing the inspection of skin lesions. A glass slide or lens is pressed down over the area to be examined, blanching the skin and revealing the shape of the lesions.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

Which technique for obtaining a specimen for bacterial culture is most correct for the nurse to use with a client who has crusted skin lesions on the upper back?

- A. Remove several crusts, and swab the underlying exudate.
- B. Dampen the culture swab with sterile water, and then roll the swab over the central crusts.
- C. Apply a gauze bandage to the area, remove it after 1 hour, and send the entire gauze to the laboratory.
- D. Clean the area with an antibacterial solution, remove a crust from the center of the cluster of lesions, and send it to the laboratory.

NURSING CONCEPT REVIEW

What should you expect to notice in a patient with adequate body protection related to skin function?

Vital signs

- Body temperature within normal range

Physical assessment

- Skin intact (no rashes, abnormal lesions, open areas, or drainage)
- Skin color normal (no cyanosis, pallor, jaundice, inflammation, or areas of uneven pigmentation)

NURSING CONCEPT REVIEW—cont'd

- Skin texture and turgor normal (no edema, tenting, flaking, scaling, excessive oiliness, or excessive thickening)
- Oral mucous membranes moist and pink
- Nail beds pink with good capillary refill
- Fingertips and nails normal-shaped (no clubbing, nail splitting, nail separation, or increased nail thickness)
- Body hair distributed evenly over the body, no patchy areas of hair loss
- Scalp free from dandruff, no itching

Psychological assessment

- Patient's eye contact good
- No unusual "hiding" of body areas normally visible in public
- Skin, hair, and nails clean and free of odor

GET READY FOR THE NCLEX® EXAMINATION!**KEY POINTS**

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Assist all patients with limited mobility to change positions at least every 2 hours.
- Wash your hands before and after touching any skin lesions.
- Use Standard Precautions when providing care to a patient who has areas of nonintact skin or skin with an abnormal appearance.
- Use lift sheets when moving patients with fragile skin.

Health Promotion and Maintenance

- Encourage all patients to reduce sun exposure and exposure to ultraviolet (UV) light.
- Teach patients to examine all skin areas on a monthly basis for new lesions and changes to existing lesions.
- Encourage all patients to bathe, shampoo the hair, and keep fingernails clean and trimmed.

- Teach all patients the ABCDE method of evaluating a lesion for melanoma.

Psychosocial Integrity

- Allow the patient the opportunity to express concerns about a change in body image that results from changes in the skin, hair, or nails.
- Explain all procedures, restrictions, drugs, and follow-up care to the patient and family.
- Check the cognitive function of any patient whose hygiene of the skin, hair, and nails appears inadequate.

Physiological Integrity

- Document any known specific allergies that have skin manifestations.
- Keep patients' skinfold areas clean and dry.
- Position patients who are confined to bed in a way that promotes air circulation to skinfold areas.
- Ask any patient who has started taking a newly prescribed or over-the-counter drug whether he or she has noticed any skin changes that occurred since starting the drug.

Concept Map: Pressure Ulcer
Key Points
Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Use principles of infection control to prevent transmission when caring for a patient with a skin infection.
2. Supervise skin care delegated to licensed practical nurses/licensed vocational nurses (LPNs/LVNs) or unlicensed assistive personnel (UAP).
3. Teach the patient with mobility problems and his or her caregivers how to reduce and relieve skin pressure in the home environment.
4. Ensure that the skin of incontinent patients is kept clean and dry.

Health Promotion and Maintenance

5. Use appropriate risk assessment tools to perform a focused skin assessment and re-assessment to determine risk for pressure ulcer development and adequacy of the skin's protective functions.
6. Teach all people how to perform thorough skin self-examination (TSSE) to monitor for skin cancer.
7. Teach all people ways to reduce risk for skin cancer.
8. Instruct the patient with a skin infection and his or her caregivers how to avoid spreading the infection.
9. Assess the ability of the patient with a skin problem to see and reach the affected area and care for the problem.

Psychosocial Integrity

10. Assess the patient's and family's feelings about a chronic skin condition or visible scar.
11. Support the patient and family in coping with changes in skin integrity and in body image.
12. Encourage the patient with a visible wound or other skin problem to participate in the care of the wound.

Physiological Integrity

13. Compare wound healing by first, second, and third intention.
14. Evaluate wounds for size, depth, presence of infection, and indications of healing.
15. Differentiate the manifestations for these pressure ulcer categories: stage 1 through stage 4, unstageable ulcers, and suspected deep tissue injury.
16. Coordinate with the health care team to plan an individualized strategy for pressure ulcer prevention for a specific patient at increased risk.
17. Identify the key features of psoriasis.
18. Coordinate nursing interventions for care of the patient with psoriasis in the community.
19. Identify key features of melanoma and other skin cancers.

As discussed in Chapter 26, the skin plays an important role in *protection*. Like the wall surrounding a castle, it provides a strong barrier, in this case to invasion by harmful microorganisms.

Skin problems are common, especially among older adults. Changes in structural integrity reduce the skin's protective function to some degree, and the cause of the problem is often difficult to determine. In addition to its primary functions, the skin also reflects underlying medical conditions. Thus problems may truly arise in the skin, or they may be a symptom of a systemic disease or injury.

Drugs and other interventions for any health problem can trigger a skin response or reaction. Skin problems can interfere with the medical or surgical treatment of other conditions. Age-related changes and problems caused by immobility, chronic disease, debility, and change in immune function increase the older patient's risk for skin damage.

MINOR SKIN IRRITATIONS

DRYNESS

Pathophysiology

Dry skin (**xerosis**) is a common problem, especially in older patients. It is seen as a fine flaking of the stratum corneum (outermost skin layer). The problem is usually worse on the lower legs where blood flow is poorer. Generalized pruritus (itching) often occurs with dry skin. In patients with chronic skin conditions, unrelieved itching causes the patient to scratch and rub the skin in an attempt to relieve the intense itching. These actions may result in secondary skin lesions, excoriations, **lichenification** (thickening), and infection.

Xerosis is worse in areas with dry climates and higher altitudes, such as in the southwestern part of the United States. Central heating and air-conditioning reduce the humidity in the air and increase skin dryness. Wind, cold, and sunlight also worsen the problem. Frequent bathing with harsh soap and hot water further dries the skin, especially if moisturizers are not applied immediately after bathing when skin is damp.

PATIENT-CENTERED COLLABORATIVE CARE

Nursing interventions focus on teaching the patient and family how to maintain healthy skin, rehydrate the outer skin layers, and relieve itching. Chart 27-1 lists practical ways to avoid overdrying the skin. Remind the patient that bathing with moisturizing soaps, oils, and lotions may reduce dryness. Some soaps and body washes, especially those described as "antimicrobial" and those with perfumes and other scents, may make dry skin worse. Limiting the use of soap to soiled or skinfold areas can also reduce dryness. A 20-minute soak in a warm bath, followed by application of an emollient cream or lotion, will help rehydrate the skin and reduce itching. If the patient cannot take a tub bath, teach him or her to wrap the trunk and extremities in warm, moist towels covered by plastic sheeting or a clean garbage bag for 15 to 20 minutes before applying moisturizers. Skin creams or lotions are more effective when applied to slightly damp skin within 2 to 3 minutes after bathing.

CHART 27-1 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Prevention of Dry Skin

- Use a room humidifier during the winter months or whenever the furnace is in use.
- Take a complete bath or shower only every other day (wash face, axillae, perineum, and any soiled areas with soap daily).
- Use tepid water.
- Use a superfatted, nonalkaline soap instead of deodorant soap.
- Rinse the soap thoroughly from your skin.
- If you like bath oil, add the oil to the water at the end of the bath.
- Take care to avoid falls; oil makes the tub slippery.
- Pat rather than rub skin surfaces dry.
- Avoid clothing that continuously rubs the skin, such as tight belts, nylon stockings, or pantyhose.
- Maintain a daily fluid intake of 3000 mL unless contraindicated for another medical condition.
- Do not apply rubbing alcohol, astringents, or other drying agents to the skin.
- Avoid caffeine and alcohol ingestion.

Inform patients that, contrary to popular belief, the cream or lotion is *not* what makes the skin soft and supple. Water is the agent that softens the outer skin layers. Lubricating creams and lotions seal in the moisture provided by water, promoting suppleness and preventing flaking. Some skin lotions are **hydrophilic** (water seeking) and actually draw moisture from the skin, making the dryness worse if they are not applied directly to damp skin.

PRURITUS

Pathophysiology

Pruritus (itching) is a distressing symptom that may or may not occur with skin disease. It is caused by stimulation of itch-specific nerve fibers at the dermal-epidermal junction. Physical or chemical agents either act directly on these nerve fibers or activate chemical mediators, such as histamine, which then act on the itch receptors.

Itching is a subjective symptom similar to pain. Thus the sensation varies among patients in location and severity. Regardless of the underlying cause, patients usually report that itching is worse at night when there are fewer distractions. Other conditions that make itching worse include poor skin hydration, increased skin temperature, perspiration, and emotional stress.

PATIENT-CENTERED COLLABORATIVE CARE

The priority nursing interventions focus on increasing patient comfort and preventing skin injury. Patients usually try to relieve itching by scratching or rubbing the skin, a response that further stimulates the itch receptors and causes a pattern referred to as the "**itch-scratch-itch**" cycle. When itching occurs as a symptom of skin lesions, relief can usually be obtained by treatment of the underlying skin disorder with topical or systemic drugs. Systemic diseases, such as liver and venous disorders, can also cause itching without skin lesions. Liver disease often increases the buildup of bilirubin in the

skin, which stimulates itch receptors. Pruritus can also be associated with too little or too much blood flow to an area (especially the feet and legs).

Plan care to promote comfort and prevent disruption of skin integrity that can result from vigorous scratching. Because dry skin worsens itching, emphasize proper bathing and skin moisturizing techniques (see [Chart 27-1](#)). Encourage patients to keep the fingernails trimmed short, with rough edges filed to reduce skin damage from scratching and to prevent secondary infection. Tell patients that wearing mittens or splints at night can help prevent inadvertent scratching during sleep. If the patient cannot perform self-care, teach the family (for home care) and unlicensed assistive personnel (UAP) to trim the patient's fingernails and apply mittens or gloves. As always, be sure to stress the importance of not breaking the skin or digging into nail corners when trimming the nails of patients with diabetes.

A cool sleeping environment along with comfort measures such as a cool shower and application of moisturizers may help promote sleep. Additional measures such as using sleep-promoting herbal teas or sedating antihistamines at bedtime (when the side effect of drowsiness is welcome) may provide an uninterrupted night's sleep. Therapeutic baths with colloidal oatmeal preparations or tar extracts may also provide temporary relief.

If antihistamines are prescribed, closely monitor the patient's response to therapy so that the dosage can be adjusted as needed. The anti-inflammatory properties of topical steroid preparations and other topical agents are increased if the drug is applied to slightly damp skin.

Using topical drugs under an occlusive dressing increases the dose of anti-inflammatory being delivered. Avoid occluding treated areas unless specifically ordered by the health care provider.

SUNBURN

Sunburn is a first-degree or superficial burn and a very common skin injury. Excessive exposure to ultraviolet (UV) light injures the dermis, stimulating an inflammatory response that dilates the capillaries, leading to redness, tenderness, edema, and occasional blister formation. When large areas of the body are sunburned, systemic inflammatory symptoms, such as headache, nausea, and fever, may be produced.

Erythema (redness) and pain begin within a few hours after sunburn has occurred and increase in intensity for 1 to 2 days before subsiding. Management is directed toward promoting comfort and includes cool baths and soothing lotions, such as bland lubricants or refrigerated moisturizing lotions. Antibiotic ointments are used only if blistering of the skin causes infection. If pain is severe, topical corticosteroids and NSAIDs may reduce the inflammation temporarily.

URTICARIA

Urticaria (hives) is white or red edematous papules or plaques of various sizes. This problem is usually caused by exposure to allergens (different triggers for different people), which releases histamine in the dermal tissue. Blood vessel dilation and leakage of plasma proteins lead to formation of lesions or wheals. The exact cause is rarely identified although drugs, foods, infections, autoimmune diseases, cancer, and physical stimuli often trigger urticaria.

Management focuses on removal of the triggering substance and relief of symptoms. Because the skin reaction is caused by histamine release, antihistamines such as diphenhydramine (Benadryl) are helpful. Teach the patient to avoid overexertion, alcohol consumption, and warm environments (e.g., warm or hot showers), which contribute to blood vessel dilation and make the symptoms worse. In addition, alcohol may increase any sedating effect of antihistamines, increasing the risk for falls and other accidents.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

A female business professional has extremely dry skin on her legs. In addition to using lotions after bathing, she asks the nurse about other measures to help reduce the dryness. What is the nurse's best response?

- A. "Wear long-legged pajamas to sleep in rather than nightgowns."
- B. "Avoid wearing pantyhose or nylon stockings for more than 2 hours at a time."
- C. "Leave the fat-containing soap on your skin when bathing rather than rinsing it off."
- D. "Bathe in water that is as warm as you can stand to stimulate the release of body oils from your sebaceous glands."

TRAUMA

Pathophysiology

Skin trauma can vary from an aseptic surgical incision to a grossly infected, draining pressure ulcer with deep tissue destruction. Injury to the skin starts a series of actions to repair the skin and re-establish this protective barrier.

Phases of Wound Healing

Wound healing occurs in three phases: the inflammatory (lag) phase, the proliferative (connective tissue repair) phase, and the maturation (remodeling) phase. [Table 27-1](#) lists the key events of normal wound healing. The length of each phase depends on the type of injury, the patient's overall health status, and whether the wound is healing by first, second, or third intention ([Fig. 27-1](#)).

A wound without tissue loss, such as a clean laceration or a surgical incision, can be closed with sutures or staples. The wound edges are brought together with the skin layers lined up in correct anatomic position (**approximated**) and held in place until healing is complete. This type of wound heals by **first intention** because closing the wound eliminates dead space, thereby shortening the three phases of tissue repair. Inflammation resolves quickly, and connective tissue repair is minimal, resulting in less remodeling and a thin scar.

Deeper tissue injuries or wounds with tissue loss, such as a chronic pressure ulcer or venous stasis ulcer, result in a cavity-like defect that requires gradual filling in of the dead space with connective tissue. This healing occurs by **second intention** and prolongs the repair process.

Wounds at high risk for infection, such as surgical incisions that enter a nonsterile body cavity or traumatic wounds that occur under unclean conditions, may be intentionally left open for several days. After **debris** (dead cells and tissues) and exudate have been removed (**debrided**) and inflammation has subsided, the wound is closed by first intention. This type of healing involves delayed primary closure (**third intention**) and results in a scar similar to that found in wounds

TABLE 27-1 NORMAL WOUND HEALING

Inflammatory Phase

- Begins at the time of injury or cell death and lasts 3 to 5 days.
- Immediate responses are vasoconstriction and clot formation.
- After 10 minutes, vasodilation with increased capillary permeability and leakage of plasma (and plasma proteins) into the surrounding tissue.
- Migration of white blood cells (especially macrophages) into the wound.
- Clinical manifestations of local edema, pain, erythema, and warmth.

Proliferative Phase

- Begins about the fourth day after injury and lasts 2 to 4 weeks.
- Fibrin strands form a scaffold or framework.
- Mitotic fibroblast cells migrate into the wound, attach to the framework, divide, and stimulate the secretion of collagen.
- Collagen, together with ground substance, builds tough and inflexible scar tissue.
- Capillaries in areas surrounding the wound form “buds” that grow into new blood vessels.
- Capillary buds and collagen deposits form the “granulation” tissue in the wound, and the wound contracts.
- Epithelial cells grow over the granulation tissue bed.

Maturation Phase

- Begins as early as 3 weeks after injury and may continue for a year.
- Collagen is reorganized to provide greater tensile strength.
- Scar tissue gradually becomes thinner and paler in color.
- The mature scar is firm and inelastic when palpated.

that heal by first intention. Healing can be impaired by many factors (Table 27-2).

Mechanisms of Wound Healing

When injury occurs, the body restores skin integrity through three processes: re-epithelialization, granulation, and wound contraction. The depth of injury and extent of tissue loss determine how and to what degree each of these processes contributes to wound healing.

Partial-Thickness Wounds. Partial-thickness wounds are more superficial, involving damage to the epidermis and upper layers of the dermis. These wounds heal by **re-epithelialization**, the production of new skin cells by undamaged epidermal cells in the basal layer of the dermis, which also lines the hair follicles and sweat glands (Fig. 27-2). Skin injury is followed immediately by local inflammation. The inflammatory response causes the formation of a fibrin clot and the release of growth factors that stimulate epidermal cell division (mitosis). New skin cells move into open spaces on the wound surface, where the fibrin clot acts as a frame or scaffold to guide cell movement. Regrowth across the open area (**resurfacing**) is only one cell layer thick at first. As healing continues, the cell layer thickens and stratifies (forms layers) to resemble normal skin. A healed wound re-establishes the protective barrier properties of the skin with keratin production.

In a healthy patient, healing of a partial-thickness wound by re-epithelialization takes about 5 to 7 days. This process occurs more rapidly in tissue that is hydrated, oxygenated, and has few microorganisms present.

Full-Thickness Wounds. In deep partial-thickness wounds and full-thickness wounds, damage extends into the

lower layers of the dermis and underlying subcutaneous tissue. As a result, most of the epithelial cells at the base of the wound have been destroyed. Thus re-epithelialization is not the major healing process for this type of wound. Removal of the damaged tissue results in a defect that must be filled with scar tissue (**granulation**) for healing to occur. During the proliferative phase of healing, new blood vessels form at the base of the wound and fibroblastic cells begin moving into the wound space. Fibroblasts deposit new collagen to replace the damaged tissue.

Some of these fibroblasts act like smooth muscle cells and begin to pull the wound edges inward along the path of least resistance (**contraction**) (see Fig. 27-1). This causes the wound to decrease in size at a uniform rate of about 0.6 to 0.75 mm/day. Complete closure of a wound by contraction depends on the mobility of the surrounding skin as tension is applied to it. If tension in the surrounding skin exceeds the counterforce of wound contraction, healing will be delayed until undamaged epidermal cells at the wound edges can bridge the defect. Unlike re-epithelialization in partial-thickness wounds, which results in the return of a near-normal epithelial barrier, the bridging of epithelial cells across a large area of granulation tissue results in an unstable barrier. A venous leg ulcer is one example of a skin defect that heals poorly by contraction. Re-epithelialization of these chronic wounds often results in a thin epidermal barrier that is easily re-injured.

Re-epithelialization, granulation, and contraction do not continue indefinitely. Natural healing processes can slow down and even stop in the presence of infection, unrelieved pressure, or mechanical obstacles. For example, dead tissue not only supports the overgrowth of organisms but also obstructs collagen deposition and wound contraction. Therefore thorough wound débridement is necessary for healing to occur. In the case of chronic wounds, healing may cease spontaneously and without an obvious cause. In addition, infection in chronic wounds may not show the expected manifestations. Often the only manifestation is an increase in wound size or failure of the wound to decrease in size (Broderick, 2009).

CONSIDERATIONS FOR OLDER ADULTS

As skin ages, the process of wound healing becomes less efficient. Both re-epithelialization and wound contraction slow, and replacement of connective tissue is reduced. Thus the strength of a healed wound in an older adult is reduced and the area is at greater risk for re-injury. When aging skin is further hindered from healing by inadequate nutrition, incontinence, or immobility, any wound in an older adult has a high risk for becoming a chronic wound. Although prevention strategies provide the best outcome, aggressive treatment of any degree of loss of skin integrity, no matter how small, should be started as soon as it is discovered in an older adult (Bianchi & Cameron, 2008; Touhy & Jett, 2010).

PATIENT-CENTERED COLLABORATIVE CARE

Management of skin trauma varies with the depth and type of injury. The collaborative management for any type of skin trauma focuses on enhancing wound healing, preventing infection, and restoring function to the area. Effective management of pressure ulcers or of burns includes interventions that support a healing environment (see Chapter 28).

The process of wound healing

► Healing by first intention

Clean incision

Early suture

"Hairline" scar

An aseptically made wound with minimal tissue destruction and minimal tissue reaction begins to heal as the edges are approximated by close sutures or staples. No open areas or dead spaces are left to serve as potential sites of infection.

► Healing by second intention (granulation) and contraction

Gaping, irregular wound

Granulation and contraction

Growth of epithelium over scar

An infected or chronic wound or one with tissue damage so extensive that the edges cannot be smoothly approximated is usually left open and allowed to heal from the inside out. The nurse periodically cleans and assesses the wound for healthy tissue production. Scar tissue is extensive, and healing is prolonged.

► Healing by third intention (delayed closure)

Infected wound

Granulation

Closure with wide scar

A potentially infected surgical wound may be left open for several days. If no clinical signs of infection occur, the wound is then closed surgically.

FIG. 27-1 The process of wound healing.

PRESSURE ULCERS

Pathophysiology

A **pressure ulcer** is tissue damage caused when the skin and underlying soft tissue are compressed between a bony

prominence and an external surface for an extended period. Although they commonly occur over the sacrum, hips, and ankles, *pressure ulcers can occur on any body surface*. For example, nasal cannula tubing that is too tight can cause pressure ulcers behind the ears or in the nares.

TABLE 27-2 CAUSES OF IMPAIRED WOUND HEALING

CAUSE	MECHANISM
Altered Inflammatory Response	
Local	
Arteriosclerosis	Reduced local tissue circulation, resulting in ischemia, impaired leukocytic response to wounding, and increased probability of wound infection
Diabetes	
Vasculitis	
Thrombosis	
Venous insufficiency	
Lymphedema	
Pharmacologic vasoconstriction	
Irradiated tissue	
Crush injuries	
Primary closure under tension	
Systemic	
Leukemia	Systemic inhibition of leukocytic response, resulting in impaired host resistance to infection
Prolonged administration of high-dose anti-inflammatory drugs:	
• Corticosteroids	
• Aspirin	
Impaired Cellular Proliferation	
Local	
Wound infection	Prolonged inflammatory response, which can result in low tissue oxygen tension and further tissue destruction
Foreign body	
Necrotic tissue	
Repeated injury or irritation	
Movement of wound (e.g., across a joint)	
Wound desiccation or maceration	
Systemic	
Aging	Impaired cellular proliferation and collagen synthesis
Chronic stress	
Nutritional deficiencies:	Decreased wound contraction
• Calories	
• Protein	
• Vitamins	
• Minerals	
• Water	
Impaired oxygenation:	
• Pulmonary insufficiency	
• Heart failure	
• Hypovolemia	
Cirrhosis	
Uremia	
Prolonged hypothermia	
Coagulation disorders	
Cytotoxic drugs	

Tissue compression from pressure restricts blood flow to the skin, resulting in reduced tissue perfusion and oxygenation and, eventually, leading to cell death. Ulcers occur most often in people with limited mobility because they cannot change their position to relieve pressure. Sensory impairment is also a contributing factor. Patients who cannot feel or communicate the pain that occurs with unrelieved pressure are more likely to develop pressure ulcers. Once formed, these chronic wounds are slow to heal, resulting in increased morbidity and health care costs. Complications associated with chronic pressure ulcers include sepsis, kidney failure, infectious arthritis, and osteomyelitis.

Other factors increase the risk for pressure ulcer formation. Friction and shear are mechanical forces that impair skin integrity and set the stage for skin breakdown. Excessive

**FIG. 27-2** Re-epithelialization.

skin moisture, such as urinary or fecal incontinence, increases the risk for skin damage when external mechanical forces are applied. Nutritional status is also an important concern. Protein malnutrition not only makes normal tissue more prone to breakdown but also delays healing (Slachta, 2008).

Mechanical Forces

Pressure occurs as a result of gravity. Dependent tissues in contact with a fixed surface experience varying degrees of pressure. Pressure is determined by the amount of weight exerted at the point of contact, the distribution of weight at the point of contact, and the density of the contacting surface. Excessive or prolonged pressure can compress blood vessels at the point of contact, such as over bony prominences. Unrelieved pressure leads to ischemia, inflammation, and tissue necrosis. Pressure occurs when the patient is positioned on a hard surface that does not diffuse his or her weight or when he or she remains in the same position too long.

Friction occurs when surfaces rub the skin and irritate or directly pull off epithelial tissue. Such forces are generated when the patient is dragged or pulled across bed linen.

Shear or shearing forces are generated when the skin itself is stationary and the tissues below the skin (e.g., fat, muscle) shift or move (Fig. 27-3). The movement of the deeper tissue layers reduces the blood supply to the skin, leading to skin hypoxia, anoxia, ischemia, inflammation, and necrosis.

Gravity plays a role in the development of shearing forces. A shear injury usually occurs when a patient is in bed in a semi-sitting position and gradually slides downward. Often the skin over the sacrum does not slide down at the same pace as the deeper tissues; thus the skin is mechanically “sheared,” causing blood vessels to stretch and break. Shearing leads to

FIG. 27-3 Shearing forces pulling skin layers away from deeper tissue. The skin is “bunched up” against the back of the mattress while the rest of the bone and muscle in the area presses downward on the lower part of the mattress. Blood vessels become kinked, obstructing circulation and leading to tissue death.

soft-tissue ischemia and deep tissue injury, even though no external break in skin integrity is observed.

CONSIDERATIONS FOR OLDER ADULTS

Older adults are at particular risk for skin tears and pressure ulcers because of the presence of age-related skin changes. Progressive flattening of cells at the dermal-epidermal junction predisposes older people to skin tears from mechanical shearing forces, such as the removal of tape and friction from tightly applied restraints. In addition, skin moisture and irritation from incontinence combined with friction over bony prominences can lead to partial-thickness skin destruction and pressure ulcer formation. Patients with cognitive impairments may not readily report discomfort from inadequate pressure relief. **If pressure is unrelieved, tissue destruction progresses to full-thickness injury.**

Incidence/Prevalence

Pressure ulcer development is a problem found among patients in the acute care setting, long-term care facility, and home care setting. Although patient care has improved in many ways and new products are available for prevention and treatment, 3% to 14% of hospitalized patients still experience pressure ulcer formation (Dunleavy, 2008).

Health Promotion and Maintenance

Pressure ulcers can be prevented if the risk is recognized and intervention begins early (Chart 27-2) (Ackerman, 2011). Key health care team members for pressure ulcer prevention and management are the certified wound care specialist and the dietitian.

A pressure ulcer prevention program consists of two steps: (1) early identification of high-risk patients, and (2) implementation of aggressive intervention for prevention with the use of pressure-relief or pressure-reduction devices. Pressure mapping is a method for identifying specific anatomic areas at risk for breakdown and planning interventions for patients who are bedridden or wheelchair bound. The process of pressure mapping involves the use of a computerized tool that measures pressure distribution for

CHART 27-2 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Preventing Pressure Ulcers

Positioning

- Pad contact surfaces with foam, silicon gel, air pads, or other pressure-relieving pads.
- Do not keep the head of the bed elevated above 30 degrees to prevent shearing.
- Use a lift sheet to move a patient in the bed. Avoid dragging or sliding him or her.
- When positioning a patient on his or her side, do not position directly on the trochanter.
- Reposition an immobile patient at least every 2 hours while in bed and at least every 1 hour while sitting in a chair.
- Do not place a rubber ring or donut under the patient's sacral area.
- When moving an immobile patient from a bed to another surface, use a designated slide board well lubricated with talc or use a mechanical lift.
- Place pillows or foam wedges between two bony surfaces.
- Keep the patient's skin directly off plastic surfaces.
- Keep the patient's heels off the bed surface using bed pillow under ankles.

Nutrition

- Ensure a fluid intake between 2000 and 3000 mL/day.
- Help the patient maintain an adequate intake of protein and calories.

Skin Care

- Perform a daily inspection of the patient's entire skin.
- Document and report any manifestations of skin infection.
- Use moisturizers daily on dry skin, and apply when skin is damp.
- Keep moisture from prolonged contact with skin:
 - Dry areas where two skin surfaces touch, such as the axillae and under the breasts.
 - Place absorbent pads under areas where perspiration collects.
 - Use moisture barriers on skin areas where wound drainage or incontinence occurs.
- **Do not massage bony prominences.**
- Humidify the room.

Skin Cleaning

- Clean the skin as soon as possible after soiling occurs and at routine intervals.
- Use a mild, heavily fatted soap or gentle commercial cleanser for incontinence.
- Use tepid rather than hot water.
- In the perineal area, use a disposable cleaning cloth that contains a skin barrier agent.
- While cleaning, use the minimum scrubbing force necessary to remove soil.
- Gently pat rather than rub the skin dry.
- Do not use powders or talcs directly on the perineum.
- After cleansing, apply a commercial skin barrier to those areas in frequent contact with urine or feces.

a person sitting in a chair or lying on a mattress (Hanson et al., 2007). The map is displayed as colored areas on the computer screen based on temperature differences. Shades of red indicate areas of greater heat production and are associated with increased pressure loads. Shades of blue indicate cooler areas under lower pressure. When used in combination with more traditional risk assessment tools, pressure mapping appears to help identify problem areas before visual changes occur and allows for more targeted prevention strategies.

Effective risk identification and prevention measures include education of the patient and the caregiver. Documentation of risk assessment, implementation of prevention measures, and education of all people involved in the care of the patient at risk for pressure ulcer formation are key to the plan's success (Dunleavy, 2008). Periodic re-assessment of risk and continuing evaluation are critical, especially when the patient's condition changes.

Identification of High-Risk Patients

As suggested by The Joint Commission's National Patient Safety Goals (NPSGs), all patients admitted to a health care facility or home care agency should be assessed for pressure ulcer risk. The use of a risk assessment tool increases the chances of identifying those patients at greater risk for skin breakdown. The Braden Scale (Fig. 27-4) is the most commonly used skin risk assessment tool. This validated tool helps the nurse assess and document the various risk categories for pressure ulcer formation including mental status, activity and mobility, nutritional status, and incontinence.

Mental status changes and decreased sensory perception determine whether the patient is a partner in the prevention of pressure ulcers. When the patient understands that turning and shifting of weight prevent tissue damage, the risk for pressure ulcers decreases. Stroke, head injury, organic brain disease, Alzheimer's disease, or other problems with cognition increase the risk for pressure ulcer formation.

Independent mobility is a direct factor in the risk for pressure ulcer formation. Patients who have unimpaired mobility and can respond to pain are at low risk for pressure ulcer formation. *Regardless of age, any patient who requires assistance with turning and positioning or who is unable to verbalize discomfort is at higher risk for pressure ulcer formation.* Anyone who is confined to bed or a chair also is at higher risk than a patient who requires assistance only with ambulation.

Nutritional status is a critical risk factor for pressure ulcer development and for successful healing (Slachta, 2008). Intact skin and wound healing depend on a positive nitrogen balance and adequate serum protein levels. The patient in negative nitrogen balance not only heals more slowly but also is at greater risk for accelerated tissue destruction. Draining wounds contribute to protein loss and require more aggressive intervention.

Nutritional status assessment includes laboratory studies; evaluation of weight and recent weight change; ability of the patient to consume an adequate diet; and the need for vitamin, mineral, or protein supplementation. Serum albumin and prealbumin levels are often used to monitor nutritional status. Prealbumin is a more sensitive marker because it has a shorter half-life. *Nutrition is considered inadequate when the serum albumin level is less than 3.5 g/dL, the prealbumin level is less than 19.5 mg/dL, or the lymphocyte count is less than 1800/mm³.* However, serum protein levels are affected by a number of other factors including level of hydration, metabolic stress, and infection. Therefore laboratory values are valuable only when supported by additional assessment information. Other indicators of inadequate nutrition include poor daily intake of food and fluids with a weight loss greater than 5% change in 30 days or greater than 10% change in 180 days (Dorner et al., 2009).

A positive nitrogen balance requires an intake of 30 to 35 calories per kilogram of body weight daily with a protein

intake of 1.25 to 1.5 g/kg/day. Up to 2 g/kg/day of protein may be needed when nutritional deficits are severe or protein loss is ongoing. Vitamin and mineral supplementations are based on the patient's nutritional status.

Incontinence results in prolonged contact of the skin with such substances as urea, bacteria, yeast, and enzymes carried in urine and feces. These substances are irritants that destroy the integrity of the skin's barrier, predisposing that patient to skin breakdown. Excessive moisture macerates intact skin, further increasing the risk for breakdown. Daily inspection of the skin for any areas of redness, maceration, or skin breakdown is a major part of pressure ulcer prevention. Maintenance of clean, dry, intact skin also assists in the prevention process. The skin should be washed with a pH-balanced soap to maintain the normal acid level. Creams or lotions are used to lubricate and moisturize the skin. Barrier ointments protect intact skin from urine and feces when incontinence is present. Absorbent pads or garments must be changed immediately with each incontinence episode to avoid prolonged skin contact with urine or feces.

NURSING SAFETY PRIORITY

Action Alert

Teach all nursing care personnel and family members not to massage reddened areas directly because this action can damage capillary beds and increase tissue necrosis.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

The newly admitted client has all of the following laboratory test values. Which value suggests to the nurse that the client may be at an increased risk for pressure ulcer formation?

- A. International normalized ratio (INR) of 1.5
- B. White blood cell (WBC) count of 5200/mm³
- C. Serum sodium concentration of 134 mEq/L
- D. Serum prealbumin concentration of 15.2 mg/dL

Pressure-Relieving and Pressure-Reducing Techniques

The cornerstone in the prevention (and treatment) of pressure ulcers is adequate pressure relief. A factor in pressure relief is the **capillary closing pressure**, which is the amount of pressure needed to occlude skin capillary blood flow, in the area at risk. The normal capillary closing pressure ranges from 12 to 32 mm Hg. An effective pressure-relieving device is one that keeps tissue pressure *below* the capillary closing pressure to ensure adequate tissue perfusion and oxygenation. *Most devices have a standardized guaranteed pressure-relief reading; however, these readings do not ensure that capillary blood flow for any given patient is adequate. Observe skin color, integrity, and temperature directly to determine capillary flow adequacy.*

Devices are classified according to whether they relieve pressure or merely reduce pressure. In addition, devices are further classified as dynamic or static. Dynamic systems alternate inflation and deflation of the device through the use of electricity. Static devices made of gel, water, foam, or air are in a constant state of inflation that distributes the patient pressure load over a larger area and reduces the pressure experienced by any particular area.

Patient's name	Evaluator's name		Date of assessment
Sensory perception Ability to respond meaningfully to pressure-related discomfort	1. Completely limited Unresponsive to painful stimuli (does not moan, flinch, or grasp) because of diminished level of consciousness or sedation OR limited ability to feel pain over most of body surface	2. Very limited Responds only to painful stimuli; cannot communicate discomfort except by moaning or restlessness OR has a sensory impairment that limits the ability to feel pain or discomfort over half of the body	3. Slightly limited Responds to verbal commands but cannot always communicate discomfort or need to be turned OR has some sensory impairment that limits ability to feel pain or discomfort in one or two extremities 4. No impairment Responds to verbal commands; has no sensory deficit that would limit ability to feel or voice pain or discomfort
Moisture Degree to which skin is exposed to moisture	1. Constantly moist Skin is kept moist almost constantly by perspiration, urine; dampness is detected every time the client is moved or turned	2. Very Moist Skin is often but not always moist; linen must be changed at least once a shift	3. Occasionally moist Skin is occasionally moist, requiring an extra linen change approximately once a day 4. Rarely moist Skin is usually dry; linen requires changing only at routine intervals
Activity Degree of physical activity	1. Bedfast Confined to bed	2. Chairfast Ability to walk severely limited or nonexistent; cannot bear own weight and must be assisted into chair or wheelchair	3. Walks occasionally Walks occasionally during the day but for very short distances, with or without assistance; spends the majority of each shift in bed or chair 4. Walks frequently Walks outside the room at least twice a day and inside the room at least once every 2 hours during waking hours
Mobility Ability to change or control body position	1. Completely immobile Does not make even slight changes in body or extremity position without assistance	2. Very limited Makes occasional slight changes in body or extremity position but unable to make frequent or significant changes independently	3. Slightly limited Makes frequent though slight changes in body or extremity position independently 4. No limitations Makes major and frequent changes in position without assistance
Nutrition Usual food intake pattern	1. Very poor Never eats a complete meal; rarely eats more than a third of any food offered; eats two servings or less of protein (meat or dairy products) per day; takes fluids poorly; does not take a liquid dietary supplement OR is NPO or maintained on clear liquids or IV for more than 5 days	2. Probably inadequate Rarely eats a complete meal and generally eats only about half of any food offered; protein intake includes only three servings of meat or dairy products per day; occasionally will take a dietary supplement OR receives less than optimal amount of liquid diet or tube feeding	3. Adequate Eats over half of most meals; eats a total of four servings of protein (meat, dairy products) each day; occasionally will refuse a meal, but will usually take a supplement if offered OR is receiving tube feeding or total parenteral nutrition, which probably meets most nutritional needs 4. Excellent Eats most of every meal; never refuses a meal; usually eats a total of four or more servings of meat and dairy products; occasionally eats between meals; does not require supplementation
Friction and shear	1. Problem Requires moderate to maximum assistance in moving; complete lifting without sliding against sheets is impossible; frequently slides down in bed or chair, requiring frequent repositioning with maximum assistance; spasticity, contractures, or agitation leads to almost constant friction	2. Potential problem Moves feebly or requires minimum assistance during a move; skin probably slides to some extent against sheets, chair, restraints, or other devices; maintains relatively good position in chair or bed most of the time but occasionally slides down	3. No apparent problem Moves in bed and in chair independently and has sufficient muscle strength to lift up completely during move; maintains good position in bed or chair at all times
Scoring system: 15-16 = mild risk, 12-14 = moderate risk, <11 = severe risk			Total score

FIG. 27-4 The Braden Scale for predicting pressure ulcer risk. IV, Intravenous; NPO, nothing by mouth.

Pressure-relief/pressure-reduction products come in many forms, such as specialty beds, mattress replacements, overlays, and assistive devices. Choosing the correct product is important in the success of the prevention plan. Re-evaluate the selected product in use daily for effectiveness in reducing pressure, providing comfort, and eliminating “bottoming out.” Bottoming out occurs when the selected product is not providing adequate pressure relief and the patient’s bony prominences sink into the mattress or cushion.

Pressure-relief devices consistently reduce skin pressure below capillary closing pressure. These devices are recommended for patients who need:

- Prevention of skin breakdown because they cannot turn (e.g., immobility, loss of sensation)
- Prevention of extension of skin breakdown that has already occurred
- Promotion of healing for breakdown present on several turning surfaces

Pressure-reduction devices lower pressure below that of a standard hospital mattress or chair surface but do not reduce pressure consistently below the capillary closing pressure. These devices are effective for preventing pressure ulcers only when used together with a turning schedule and other skin care measures.

Frequent repositioning of bedbound patients, as described in [Chart 27-2](#), is critical in reducing pressure over bony prominences. A good plan for positioning is the 30-degree rule. This plan ensures that the patient is positioned and propped so that whatever part of the body is elevated is tilted back at least a 30-degree angle to the mattress rather than resting directly on a dependent bony prominence. This rule applies to side-lying as well as head-of-bed elevation positions. The patient who requires greater head elevation because of respiratory difficulties should be tilted forward more than 30 degrees with pillows behind the back to keep pressure off of the sacral/coccyx area. Often positioning is delegated to UAP. Teach UAP the importance of proper positioning, and demonstrate how to perform it. Also teach family members to use these techniques in the home.

The patient at risk for pressure ulcers in bed is also at risk while sitting. Carefully assess for proper wheelchair or regular chair cushioning. Collaborate with physical therapists and rehabilitation specialists for selection of these products. High-risk patients who are chair bound should also be periodically assisted to a standing position to promote tissue perfusion and prevent breakdown over the sacral area.

Even with an appropriate mattress or cushion, the patient needs to change or be helped to change positions periodically. Many facilities require turning and positioning every 2 hours. *However, pressure can occur in less time, and the actual turning or repositioning schedule for each patient must be individualized.* When this action is delegated to UAP, teach them the importance of maintaining a repositioning schedule.

Use pillows and other positioning or padding devices to keep heels pressure-free at all times for high-risk patients. Assess heel positioning every 4 hours to ensure that pressure is not redistributed to another high-risk area, such as the ankles or sides of the feet. Check heels even more frequently when devices that hide the feet (e.g., boots, heel protectors) are used, especially if the patient has a peripheral vascular problem. In addition to the heels, check knees and elbows at

regular intervals, especially when the patient is in a side-lying position.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

When taking a history from the patient with a pressure ulcer, identify the cause of skin loss, as well as factors that may impair healing. Ask about the specific circumstances of the skin loss. Often patients with chronic pressure ulcerations have a history of delayed healing or recurrence of the ulcer after healing has occurred. Because pressure-related skin loss is common among severely debilitated patients, determine whether a patient has any of these contributing factors:

- Prolonged bedrest
- Immobility
- Incontinence
- Diabetes mellitus
- Inadequate nutrition or hydration
- Altered mental status (decreased sensory perception, cognitive problems)
- Peripheral vascular disease

Physical Assessment/Clinical Manifestations

Inspect the entire body, including the back of the head, for areas of skin injury or pressure. Give special attention to bony prominences (e.g., the heels, sacrum, elbows, knees, trochanters, posterior and anterior iliac spines) and areas that are vulnerable to excessive moisture. In addition, assess the patient’s general appearance for issues related to skin health, such as body weight and the proportion of weight to height. Obese patients, as well as thin patients, are at increased risk for malnutrition and pressure ulcer formation. Check overall cleanliness of the skin, hair, and nails. Determine whether any loss of mobility or range of joint motion has occurred. *This assessment should not be delegated to UAP.*

Wound Assessment

The appearance of pressure ulcers changes with the depth of the injury. [Chart 27-3](#) lists the features of the six categories or stages of pressure ulceration, and [Fig. 27-5](#) shows examples.

Assess wounds for location, size, color, extent of tissue involvement, cell types in the wound base and margins, exudate, condition of surrounding tissue, and presence of foreign bodies. Document this initial assessment to serve as a starting point for determining the intervention plan and its effectiveness. How often a wound is assessed is determined by the written policies and procedures at the facility or agency. Weekly documented assessment is the standard in many long-term care facilities; however, daily assessment is needed when the patient is in an acute care setting. *Also assess the wound at each dressing change, comparing the existing wound features with those documented previously to determine the current state of healing or deterioration.*

For intact areas that are red (in lighter-skinned patients), press firmly with fingers at the center of the area and assess whether the area **blanches** (lightens) with pressure. An area that blanches with pressure and then returns to normal when

CHART 27-3 KEY FEATURES

Pressure Ulcers**Suspected Deep Tissue Injury**

- The intact skin area appears purple or maroon.
- Blood-filled blisters may be present.
- Before the above-listed changes appeared, the tissue in this area may first have been painful.
- Other changes that may have preceded the discoloration include that the area may have felt more firm, boggy, mushy, warmer, or cooler than the surrounding tissue.

Stage 1

- Skin is intact.
- Area, usually over a bony prominence, is red and does not blanch with external pressure.
- For patients with darker skin that does not blanch:
 - Observable pressure-related alteration of intact skin; changes are compared with an adjacent or opposite area and include one or more of these:
 - Skin color (darker or lighted than the comparison area)
 - Skin temperature (warmth or coolness)
 - Tissue consistency (firm or boggy)
 - Sensation (pain, itching)
- The ulcer appears as a defined area of persistent redness in lightly pigmented skin, whereas in darker skin tones, the ulcer may appear with persistent red, blue, or purple hues.

Stage 2

- Skin is not intact.
- There is partial-thickness skin loss of the epidermis or dermis.
- Ulcer is superficial and may be characterized as an abrasion, a blister (open or fluid-filled), or a shallow crater.
- Bruising is *not* present.

Stage 3

- Skin loss is full thickness.
- Subcutaneous tissues may be damaged or necrotic.
- Damage extends down to but not through the underlying fascia; bone, tendon, and muscle are *not* exposed.
- The depth can vary with anatomic location; areas of thin skin (e.g., the bridge of the nose) may show only a shallow crater, whereas thicker tissue areas with larger amounts of subcutaneous fat may show a deep, crater-like appearance.
- Undermining and tunneling may or may not be present.

Stage 4

- Skin loss is full thickness with exposed or palpable muscle, tendon, or bone.
- Often includes undermining and tunneling.
- Sinus tracts may develop.
- Slough and eschar are often present on at least part of the wound.

Unstageable

- Skin loss is full thickness, and the base is completely covered with slough or eschar, obscuring the true depth of the wound.

Data from National Pressure Ulcer Advisory Panel (NPUAP). (2010, January). Updated staging system. Retrieved October 2010, from www.npuap.org.

pressure is removed indicates color changes related to blood vessel dilation rather than tissue damage or inflammation. When blanching does not occur with pressure, the redness is more likely to be a manifestation of skin injury. Document whether the reddened area blanches with pressure.

Record the location and size of the wound first. Wounds are sized by length, width, and depth using millimeters or centimeters. In standardizing wound size for documentation and communication purposes, assess the wound as a clock

face with the 12 o'clock position in the direction of the patient's head and the 6 o'clock position in the direction of the patient's feet. Always measure the length from the 12 o'clock position to the 6 o'clock position and the width between the 9 o'clock position and the 3 o'clock position. Measure depth as the distance from the deepest portion of the wound base to the skin level. Use disposable paper tape measures to obtain the length and width of a wound. Touch the bottom of the wound with a cotton-tipped applicator or swab and mark the place on the swab that is level with the skin surface to obtain wound depth. Then measure the area of the swab between the tip and the mark. When all caregivers use this format, measurement is accurate and wound progress can be determined (Hanson et al., 2007).

Inspect the wound margins for **cellulitis** (inflammation of the skin cells) extending beyond the area of injury. Progressive tissue destruction, seen as an increase in the size or depth of the ulcer and increased wound drainage, usually indicates impairment in the patient's ability to resist infection if proper measures have been taken to relieve pressure.

Inspect the wound for the presence or absence of necrotic tissue. Because of the depth of tissue destruction, a full-thickness pressure ulcer is often covered by a layer of black, gray, or brown nonviable, denatured collagen called wound **eschar**.

In the early stages of wound healing, the eschar is dry, leathery, and firmly attached to the wound surface. As the inflammatory phase of wound healing begins and removal of wound debris progresses, the eschar starts to lift and separate from the tissue beneath. This nonliving eschar is a good breeding ground for bacteria normally found on the skin surface, as well as those introduced by incontinence or other means. As bacteria increase, they release enzymes that soften necrotic tissue. This tissue becomes softer and more yellow. In the presence of bacterial colonization, wound exudate increases substantially; the color and odor of wound exudate indicate the major organism present. The features of wound exudate are listed in [Table 27-3](#).

Beneath the separating dead tissue, granulation tissue appears. Early granulation is pale pink, progressing to a beefy red color as it grows and fills the wound. Palpate the wound to determine the texture of the granulations. Healthy granulation tissue is moist and has a slightly spongy texture. Wounds with poor local arterial blood supply or that have stopped healing appear dry with granulation tissue that is hard (fibrotic) when palpated. Venous obstruction causes an excessively moist ulcer surface with a deep reddish purple color (reflective of the deoxygenated blood beneath the ulcer surface).

Pressure ulcers may involve more extensive tissue destruction than is first seen on inspection. Separation of the skin layers at the wound margins from the underlying granulation tissue is known as **undermining**. Inspect undermined areas for gradual filling with healthy granulations and for wound-healing progress. Palpate the bony prominences for deep hardening of the surrounding soft tissue, which often occurs with deep tissue ischemia.

After ischemia has occurred, continued pressure over the area increases tissue destruction from the deep tissue layers toward the surface, resulting in the formation of tunnels. This "hidden" wound may first have a small opening in the skin with purulent drainage. If such an opening is observed, use a

FIG. 27-5 Various stages of pressure ulcers. **A**, Stage 1 pressure ulcer. **B**, Stage 2 pressure ulcer. **C**, Stage 3 pressure ulcer. **D**, Stage 4 pressure ulcer. **E**, Unstageable ulcer. **F**, Suspected deep tissue injury.

cotton-tipped applicator to probe gently for a much larger tunnel or pocket of necrotic tissue beneath the opening. Additional tunnels may also occur along the main wound. Check all wounds for tunneling and, if present, document the location and length of each tunnel.

Psychosocial Assessment

The patient with pressure ulcers may have an altered body image. Ineffective coping patterns emerge as the patient and family strive to adhere to changes in lifestyle that are needed for healing. In addition, chronic ulcers are often painful and costly to treat.

Assess the patient's and family's knowledge of the treatment goals at each stage of the healing process, as well as adherence to the prescribed treatment regimen. Also assess the patient's skills in cleaning the wound and applying a dressing. Poor adherence to pressure ulcer care procedures may reflect an inability to accept the diagnosis or to cope with the pain, cost, or potential scarring associated with prolonged healing. Depending on the patient's activity level and the location of the ulcer, assistance of a family member or home care nurse may be needed to provide initial care of the pressure ulcer at home.

Explore with the patient specific changes in ADLs that are needed to relieve pressure and promote healing. Promote increased activity whenever possible to enhance circulation to the affected tissue. Leg position changes may be needed for chronic leg ulcers, depending on whether or not peripheral vascular problems contribute to their formation. For patients who have arterial insufficiency, having the legs and feet in a dependent position works with gravity to help ensure adequate blood flow to the lower legs. When arterial blood flow is adequate but venous return is impaired, elevation of the legs may be needed for healing. When the patient is bedridden, frequent repositioning to relieve pressure (every 2 hours in bed, every 1 hour in a chair) can be labor intensive. In the home, repositioning, incontinence management, and dressing changes are often needed around the clock, disrupting family routines and contributing to stress.

Laboratory Assessment

A wound that is exposed is always *contaminated* but is not always *infected*. *Contamination* is the presence of organisms without any manifestation of infection. The normal immune defenses of the body keep the number of bacteria to a minimum and prevent infection. *Wound infection* is contamination with pathogenic organisms to the degree that growth and spread cannot be controlled by the body's immune defenses. Wounds that are red and indurated with moderate to heavy exudate and an odor should be cultured to identify the causative organism and determine sensitivity to antibiotics. *The presence of purulent exudate alone does not indicate a local or systemic infection because pus formation occurs when necrotic tissue liquefies and separates.*

If wounds are extensive, if the patient is severely immunocompromised, or if local blood supply to the wound is impaired, bacterial growth may exceed the body's ability to defend against invasion into deeper tissue layers. The result is deep wound infection and eventually bacteremia and sepsis (systemic infection).

Swab cultures are helpful only in identifying the types of bacteria present on the ulcer surface and may be misleading when trying to identify or quantify bacteria in deeper tissues. Wound biopsies allow the numbers of bacteria to be analyzed, but these tests are time consuming, costly, and unavailable in many laboratories. Therefore clinical indicators of infection (cellulitis, progressive increase in ulcer size or depth, changes in the quantity and quality of exudate) and systemic signs of bacteremia (e.g., fever, elevated white blood cell [WBC] count) are used to diagnose an infection.

Other Diagnostic Assessment

Additional laboratory studies are performed on the basis of the suspected cause of the wound. For pressure ulcers to show progress toward healing, the factors contributing to delayed healing must be diagnosed and treated. For example, noninvasive and invasive arterial blood flow studies are indicated if arterial occlusion is suspected in delayed healing of a pressure ulcer on the heel or ankle. Blood tests to establish specific nutritional deficiencies (e.g., prealbumin, albumin, total protein) are helpful in treating the debilitated, malnourished patient with a pressure ulcer.

TABLE 27-3 TYPES OF WOUND EXUDATE

CHARACTERISTICS	SIGNIFICANCE
Serosanguineous Exudate	
Blood-tinged amber fluid consisting of serum and red blood cells	Normal for first 48 hr after injury Sudden increase in amount precedes wound dehiscence in wounds closed by first intention
Purulent Exudate	
Creamy yellow pus	Colonization with <i>Staphylococcus</i>
Greenish blue pus causing staining of dressings and accompanied by a "fruity" odor	Colonization with <i>Pseudomonas</i>
Beige pus with a "fishy" odor	Colonization with <i>Proteus</i>
Brownish pus with a "fecal" odor	Colonization with aerobic coliform and <i>Bacteroides</i> (usually occurs after intestinal surgery)

DECISION-MAKING CHALLENGE

Patient-Centered Care; Evidence-Based Practice; Safety

The patient is a 77-year-old man who has had chronic obstructive pulmonary disease (COPD) for 20 years. He lives with his divorced daughter and three grandchildren. During the day he is alone while the daughter and grandchildren are at work and school. He is being admitted for exacerbation of the COPD. He continues to smoke two packs of cigarettes daily and uses oxygen by nasal cannula whenever he is not smoking. He weighs 220 lbs and is 5 feet 6 inches tall.

1. What risk factors does this patient have for pressure ulcer development? Explain how the identified factors increase his risk.
2. What additional assessment data should you obtain?
3. Given his diagnosis, in what position do you expect to place him? Does this position increase or decrease his risk for pressure ulcer formation? If so, where is/are the ulcer(s) likely to develop?
4. At 220 pounds, is he likely to have adequate nutrition? Why or why not?

ANALYSIS

Priority problems for patients with pressure ulcers are:

1. Open wounds related to vascular insufficiency and trauma
2. Potential for infection and wound deterioration related to insufficient wound management

PLANNING AND IMPLEMENTATION

The Concept Map on p. 484 addresses care issues related to patients who have or are at risk for pressure ulcers.

Managing Wounds

Planning: Expected Outcomes. The patient with a pressure ulcer is expected to demonstrate progress to complete wound healing and not develop new pressure ulcers. Indicators include:

- Presence of granulation, re-epithelialization, and scar tissue formation
- Decreased wound size
- Absence of new pressure ulcers

Interventions. Wound care techniques for pressure ulcers vary according to each patient's needs and the health care provider's preferences. Surgery with aggressive removal of necrotic tissue may be indicated for some patients, whereas a nonsurgical approach to ulcer débridement is preferred for an older patient who has adequate defenses but is too ill or debilitated for surgery.

Nonsurgical Management. General interventions for pressure ulcer care are listed in [Chart 27-4](#). Nonsurgical intervention of pressure ulcers is often left to the discretion of the nurse, who coordinates with the health care provider and

certified wound care specialist (if available) to select a method of wound dressing on the basis of the identified goal of wound management. Many agencies have guidelines or protocols for wound dressings based, for example, on wound size and depth and presence of drainage.

Dressings. A properly designed dressing can speed healing by removing unwanted debris from the ulcer surface, protecting exposed healthy tissues, and creating a barrier between the body and the environment until the ulcer is closed. *For a patient with a draining, necrotic ulcer, the dressing must also remove excessive exudate and loose debris without damaging epithelial cells or newly formed granulation tissue. If necrosis is extensive and the eschar is thick, dead tissue must be surgically or chemically removed before further débridement with dressings can be effective.* Depending on the dressing material used, dressings help remove debris either through **mechanical débridement** (mechanical entrapment and detachment of dead tissue), **topical chemical débridement** (enzyme preparations applied topically to loosen necrotic tissue), or by **natural chemical débridement** (creating an environment that promotes self-digestion of dead tissues by naturally-occurring bacterial enzymes [*autolysis*]) ([Table 27-4](#)).

After all the dead tissue has been removed, protection of any exposed tendons, bone, and newly formed collagen is critical to pressure ulcer care. The ideal environment for healing is a clean, *slightly* moist ulcer surface with minimal bacterial colonization. Heavy moisture from an excessively draining ulcer or a dressing that is too wet interferes with healing by promoting the growth of organisms and causing maceration (mushiness) of healthy tissue. Likewise, if a clean ulcer surface is exposed to air or if highly absorbent dressing materials are used for prolonged periods, the drying effect can dehydrate surface cells, form scabs, and convert the wound to a deeper injury.

Assess the ulcer for necrotic tissue and the quantity of exudate. Coordinate with a wound care specialist to select a dressing material with properties that promote an optimal environment for healing. For example, a material that does not stick to the wound surface and does not remove fragile epithelial cells when it is changed is the dressing of choice for protecting new tissue. Depending on the amount of drainage, select either a hydrophobic or a hydrophilic material:

- A **hydrophobic** (nonabsorbent, waterproof) material is useful when the wound is relatively free of drainage and

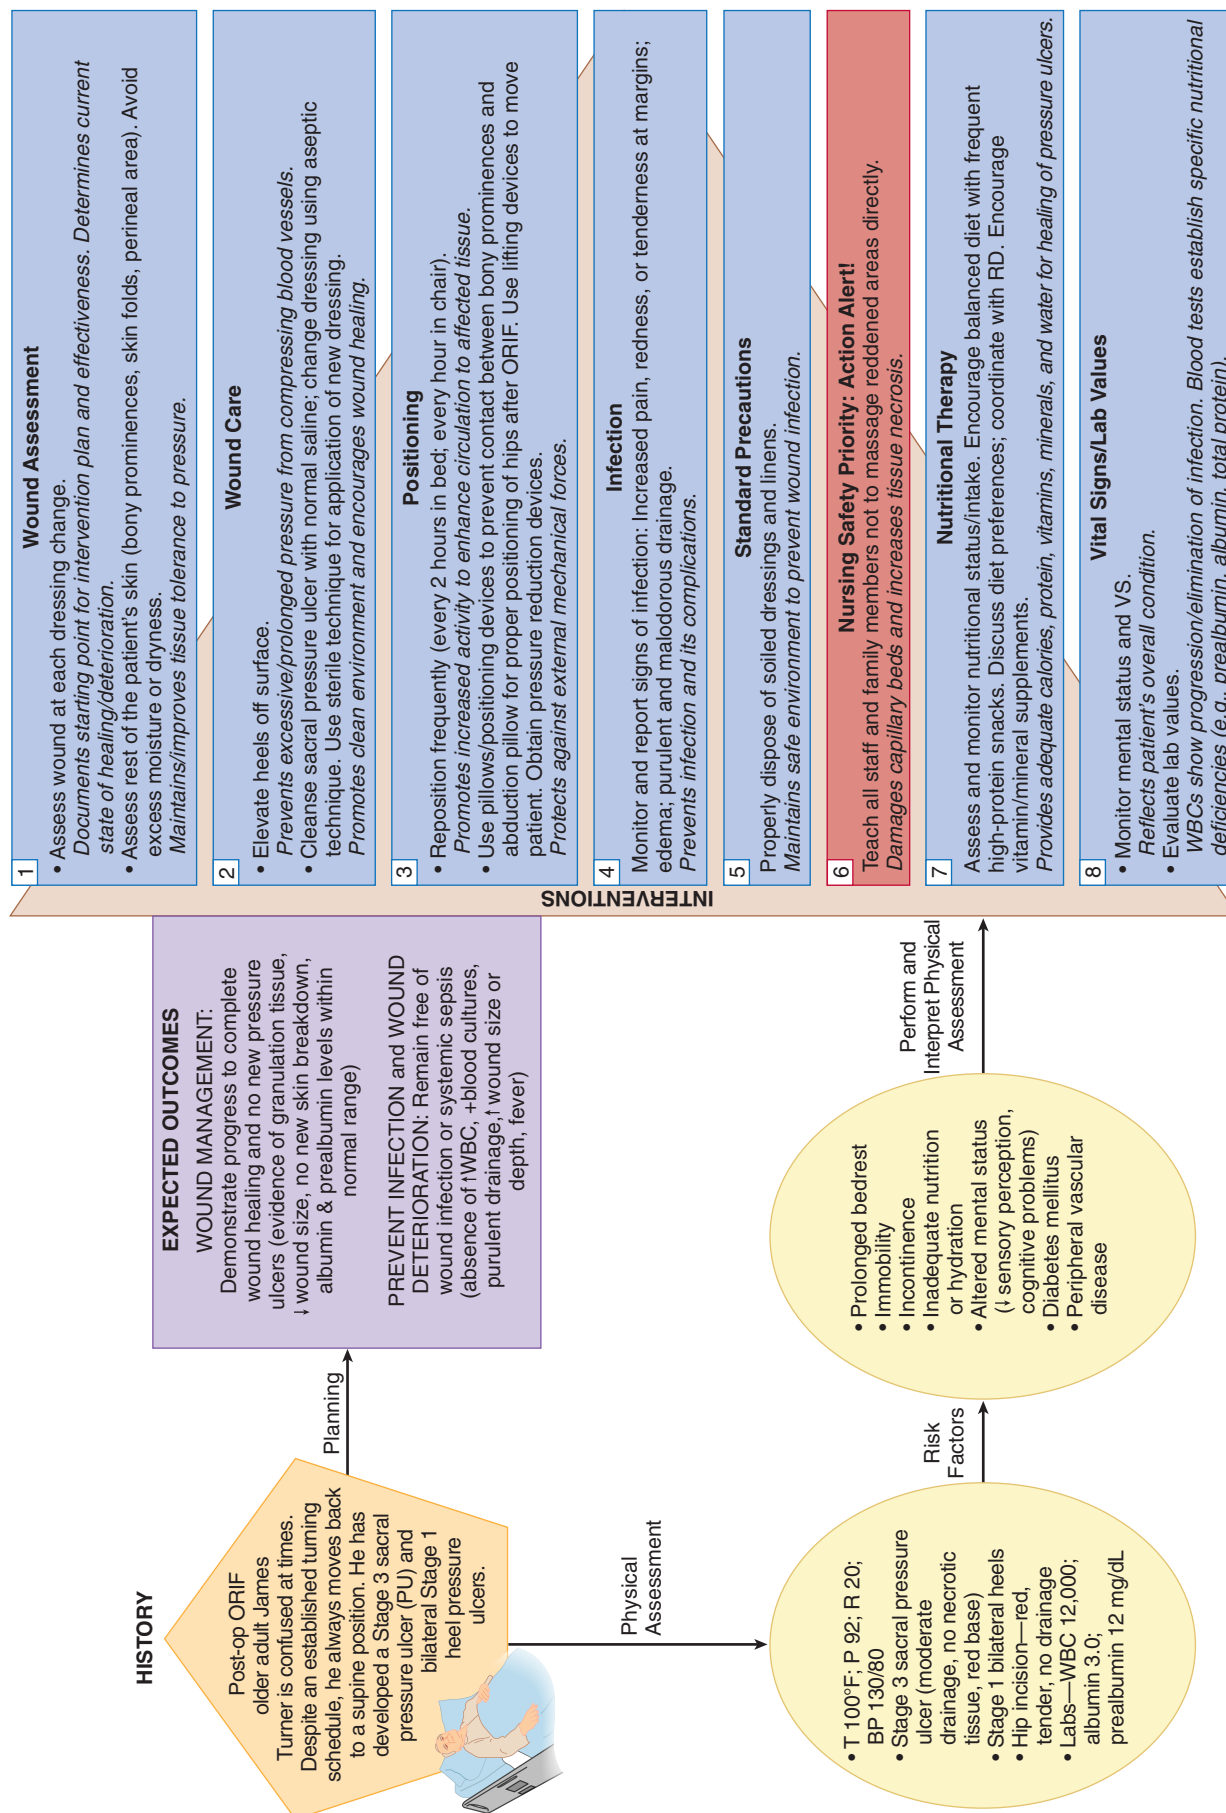

CHART 27-4 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE**Wound Management of Pressure Ulcers**

- If ulcer is covered, remove old dressings/coverings daily (unless the dressing type is to remain in place until it loosens naturally).
- Measure wound size at greatest length and width using a disposable paper tape measure or, for asymmetric ulcers, by tracing the wound onto a piece of plastic film or sheeting (plastic template) at least daily.
- Compare all subsequent measurements against the initial measurement.
- Assess the ulcer for presence of necrotic tissue and amount of exudates.
- Assess and document the condition of the skin surrounding the pressure ulcer in terms of color, temperature, texture, moisture, and appearance.
- Remove or trim loose bits of tissue (may be done by a certified wound care specialist, physical therapist, advanced practice nurse, or other as specified by the agency and the state's nurse practice act).
- Cleanse the ulcer with saline or a prescribed solution (after diluting it as per manufacturer's directions or prescriber's instructions).
- Rinse and dry the ulcer surface.
- In collaboration with the certified wound care specialist, select and apply the dressing materials most appropriate for the volume of wound drainage.
- If possible, avoid positioning the patient on the pressure ulcer.
- Re-position at least every 1 to 2 hours to prevent ulcer extension or generation of additional pressure ulcers.
- Use prescribed pressure-relieving and pressure-reducing devices and techniques as described in [Chart 27-2](#).

TABLE 27-4 COMMON DRESSING TECHNIQUES FOR WOUND DÉBRIDEMENT

TECHNIQUE	MECHANISM OF ACTION
Wet-to-damp saline-moistened gauze	As with the wet-to-dry technique, necrotic debris is mechanically removed but with less trauma to healing tissue.
Continuous wet gauze	The wound surface is continually bathed with a wetting agent of choice, promoting dilution of viscous exudate and softening of dry eschar.
Topical enzyme preparations	Proteolytic action on thick, adherent eschar causes breakdown of denatured protein and more rapid separation of necrotic tissue.
Moisture-retentive dressing	Spontaneous separation of necrotic tissue is promoted by autolysis.

Concept Map: Pressure Ulcer

the purpose is to protect the ulcer from external contamination.

- A **hydrophilic** (absorbent) material draws excessive drainage away from the ulcer surface, preventing maceration.

A variety of synthetic materials with different absorbent properties are available (Table 27-5). Unlike cotton gauze dressings, these may be left intact for extended periods. Biologic and synthetic skin substitutes are available that can also prevent tissue dehydration and promote healing (see Chapter 28). However, the use of these products for chronic wounds is often cost prohibitive.

The frequency of dressing changes depends on the amount of necrotic material or exudate. Dry gauze dressings are changed when “strike through” occurs or when the outer layer of the dressing first becomes saturated with exudate. Gauze dressings used for débridement, such as those placed on a wound wet, allowed to become damp, and then removed, are changed often enough to take off any loose debris or exudate, usually every 4 to 6 hours.

! NURSING SAFETY PRIORITY

Action Alert

Change synthetic dressings when exudate causes the adhesive seal to break and leakage to occur.

Before reapplying any dressing, gently clean the ulcer surface with saline or a nontoxic wound cleanser as prescribed. If an antibacterial cleanser is prescribed, dilute the agent to reduce tissue toxicity and then rinse and dry the surface thoroughly before applying the dressing.

Physical Therapy. The use of daily whirlpool treatments along with dressing changes for débridement can help remove dead tissue. The ulcerated area is immersed in or saturated with warm tap water that contains an antibacterial cleansing agent. Continuous agitation of the water loosens the debris and washes away exudate and particles. During treatment, the ulcer surface is cleansed with a gauze pad. After treatment, the therapist or wound specialist often uses instruments to trim away any obvious bits of dead tissue that are still loosely attached to the ulcer surface.

Drug Therapy. Clean, healthy granulation tissue has a blood supply and is capable of providing white blood cells and antibodies to the ulcer surface to combat infection. If extensive necrosis is present or if local tissue defenses are impaired, topical antibacterial agents are often needed to control bacterial growth. (Chapter 28 details the advantages and uses of topical antimicrobial agents.) In the absence of infection, antibiotics are avoided because of the danger of the development of resistant strains of bacteria.

Nutrition Therapy. Successful healing of pressure ulcers depends on adequate nutritional stores of calories, protein, vitamins, minerals, and water. Nutritional deficiencies are common among older adults and chronically ill patients. These deficiencies increase the risk for skin breakdown and delayed healing of wounds that are already present. Severe protein deficiency inhibits all stages of the healing process and impairs host defenses against bacterial invasion.

Coordinate with the dietitian to encourage the patient to eat a well-balanced diet, emphasizing protein, vegetables, fruit, whole grain breads and cereals, and vitamins. Fats are needed in the diet also to ensure formation of cell

membranes. (See Chapter 63 for a complete discussion of nursing actions to ensure adequate nutrition.) If the patient cannot eat sufficient amounts of food, other types of feedings may be needed to increase protein and caloric intake (see Chapter 63). Vitamin and mineral supplements are also indicated.

New Technologies. For chronic ulcers that remain open for months, new technologies have had some success. These include electrical stimulation, vacuum-assisted wound closure, hyperbaric oxygen therapy, topical growth factors, and skin substitutes.

Electrical stimulation is the application of a low-voltage current to a wound area to increase blood vessel growth and promote granulation. This treatment is usually performed by a certified wound care specialist. A single electrode can be applied directly to a wound through a sterile dressing, or multiple electrodes can be applied around a wound. The voltage is delivered in “pulses” that may cause the patient to feel a “tingling” sensation. Usually electrical stimulation is performed for 1 hour a day, five to seven days a week. This form of treatment is not used with patients who have a pacemaker or who have a wound over the heart.

Vacuum-assisted wound closure (VAC), also known as *negative pressure wound therapy (NPWT)*, has been used successfully to reduce or even close chronic ulcers by removing fluids or infectious materials from the wound and enhancing the formation of granulation tissue. This technique requires that a suction tube be covered by a special sponge and sealed in place. Per manufacturer’s instructions, the foam dressing is changed every 48 to 72 hours and not less than three times weekly. During that time, continuous low-level negative pressure is applied through the suction tube. Duration of the treatment is determined by the wound’s response. It should not be used in areas where skin cancer is located. Failure of VAC therapy is often due to the inability to maintain an adequate and consistent dressing seal (Rock, 2011).

Bleeding complications from this procedure have resulted in a closer look at its effectiveness and dangers (Wallis, 2010). Newer devices often use continuous pressure and higher pressures. Current evidence does not support greater effectiveness in closing chronic wounds than more traditional methods. Serious bleeding and even deaths have occurred with VAC, and now these devices received a preliminary warning from the Food and Drug Administration (FDA) to exclude high-risk patients from its use. Any patient who is receiving this therapy must be monitored at least every 2 hours for manifestations of bleeding at or near the wound site while the device is in use.

! NURSING SAFETY PRIORITY

Critical Rescue

Do not use a continuous vacuum-assisted closure device with any patient who is on anticoagulant therapy; has some degree of reduced tissue health near the wound (e.g., with radiation therapy or poor nutrition); or has any exposed blood vessels, nerves, or organs in the wound area.

Hyperbaric oxygen (HBO) therapy is the administration of oxygen under high pressure, raising the tissue oxygen concentration. This type of therapy is costly and usually reserved for life- or limb-threatening wounds such as burns, necrotizing soft-tissue infections, brown recluse spider bites,

TABLE 27-5 COMMONLY USED DRESSING MATERIALS

	ALGINATE	BIOLOGIC DRESSING	COTTON GAUZE DRESSING	FOAM	HYDROCOLLOIDAL	HYDROGEL DRESSING	ADHESIVE TRANSPARENT FILM*
Indications	Hemostasis Débridement Absorption Protection	Débridement after eschar removal Protection Test before skin grafts (pigskin and cadaver skin) Burns Dormant, nonhealing wounds that do not respond to other topical therapies	Continuous Dry Absorption Protection (nonadherent contact layer) Continuous Wet Delivery of topical agent Débridement (autolysis) Protection Wet to Damp Atraumatic mechanical débridement	Insulation Débridement Absorption Protection	Débridement Absorption Protection	Débridement Absorption Protection	Débridement† Protection (partial-thickness lesions) Secondary (cover) dressing
Advantages	Highly absorbent Biodegradable Easy application Nonadhesive Can be used as packing for deep wounds Can be used for infected wounds	Most “natural” wound covering Reduces pain Conforms to uneven wound surfaces Acts as a catalyst for healing Alternative to autograft	Readily available Good mechanical débridement <i>if used properly</i> Effective delivery of topical agents	Absorbent Insulates wound Easy application Nonadhesive (most products) Conforms to uneven wound surfaces	Absorbent Excludes bacteria Waterproof Reduces pain Easy application Easy to store Painless removal	Absorbent Nonadhesive Reduces pain Conducive to use with topical agents Conforms to uneven wound surfaces Amorphous form can be used as a filler Easy to store	Wound visualization Good adhesion Waterproof Reduces pain Cost-effective Easy to store
Disadvantages	Requires secondary dressing to secure Can cause desiccation of tissue if drainage is minimal Foul odor and gelling may be confused with infection	Requires secondary dressing to secure Very expensive Skin substitutes require skill to apply	Delayed healing if used improperly Pain on removal Requires frequent dressing changes	Poor barrier function Requires secondary dressing to secure	Nontransparent Softening and loss of shape with pressure, heat, and friction Odor with dressing removal Expensive Requires use of “fillers” for deep, draining lesions	Poor barrier function Only partial wound visualization Requires secondary dressing to secure Can promote growth of <i>Pseudomonas</i> and other microorganisms	Difficult to apply properly Nonabsorbent Adhesive to normal and healing tissue Limited to superficial lesions
Dressing changes	When dressing is saturated (every 3-5 days) or more frequently	Topical growth factors: daily Skin substitutes: varies (similar to grafts)	Necrotic base: every 4-6 hr Clean base: every 12-24 hr	When dressing is saturated or more frequently	Necrotic base: every 24 hr Clean base: on leakage of exudates	Necrotic base: every 6-8 hr Clean base: every 24 hr	Necrotic base: every 24 hr Clean base: on leakage of exudates

*Also available in nonadhesive forms.

†Use with caution in patients with leukopenia or vascular disease.

osteomyelitis, and diabetic ulcers. The patient is enclosed in a large chamber and exposed to 100% oxygen at pressures greater than normal atmospheric (sea level) pressure. Systemic oxygen enhances the ability of white blood cells to kill bacteria and reduce swelling. Treatment usually lasts from 60 to 90 minutes. Smaller topical oxygen delivery devices are also available. These devices are applied directly over an open wound to promote local tissue oxygenation (Thackman et al., 2008).

Topical growth factors are biologically active substances that stimulate cell movement and growth. These factors are deficient in chronic wounds, and topical application is currently being studied as a way to stimulate wound healing. For example, platelet-derived growth factor (PDGF) stimulates the movement of fibroblasts into the wound space. Use of this and other growth factors has been found to be more successful in clean, surgically débrided chronic wounds (Woo et al., 2007).

Skin substitutes are engineered products that aid in the temporary or permanent closure of different types of wounds. These products vary widely in design and application and are used mainly for surgically débrided wounds, such as a full-thickness pressure ulcer before reconstruction with skin grafts or muscle flaps (van der Veen et al., 2010).

Surgical Management. Surgical management of a pressure ulcer includes removal of necrotic tissue and skin grafting or use of muscle flaps to close wounds that cannot heal by re-epithelialization and contraction. Not all wounds are candidates for grafting. Those with poor blood flow are unlikely to have successful graft take and heal.

Preoperative Care. Before surgery, care is focused on preparing the ulcer to accept a skin graft or muscle flap. Monitor potential donor sites, taking care to maintain the integrity of the donor skin and to avoid minor injuries that may result in infection and graft loss.

Operative Procedure. The operative procedures used for surgical management of pressure ulcers include débridement and grafting. One or both of these procedures may be done.

Surgical débridement is the removal of thick, adherent wound crust (eschar) using a scalpel or scissors. It may be performed to hasten the removal of the dead tissue, a potential source of infection. *The longer open wounds exist, the greater the risk for sepsis or prolonged hospitalization.* Depending on the size and depth of the ulcer and the projected blood loss, débridement can be performed at the bedside or in the treatment room by a wound care specialist or advanced practice nurse. When the wound is large or has a risk for excessive bleeding, débridement is performed in an operating room. In any case, the patient should receive sedation or a local anesthetic before the procedure. Although necrotic tissue does not have sensation, the healthy tissue at the point of attachment may have sensation.

Grafting is used for wound closure when full-thickness ulcers cannot close and when natural healing would result in loss of joint function, an unacceptable cosmetic appearance, or a high potential for wound recurrence. Successful skin grafting requires a clean and granulating or freshly excised ulcer bed. Partial-thickness (split-thickness) or full-thickness strips of skin are removed from the donor area, transferred to the ulcer, and sutured or stapled in place. Full-thickness free grafts and myocutaneous flaps are used to cover deep,

FIG. 27-6 A full-thickness pedicle flap of skin is separated and rotated to cover the wound. Blood vessels are left intact. The resultant defect is either primarily closed or covered with skin grafts. The flap is held in place with staples or sutures.

massive ulcers or ulcers in which vital structures, such as bone or tendon, are exposed.

Unlike free grafts, a pedicle flap is a full-thickness flap of skin that is raised and rotated to cover the defect, with one edge of the flap still attached to the site of origin to provide a blood supply (Fig. 27-6). Because all skin layers are removed, full-thickness donor sites are closed surgically or covered with additional split-thickness skin grafts. Partial-thickness donor sites heal spontaneously if infection is avoided.

When extensive surgical débridement has been performed on a large wound that does not have an adequate blood supply for grafting, other closure methods may be needed. If there is sufficient healthy skin around the débrided wound, the edges may be pulled together and surgically closed. Otherwise, the wound is managed with dressings until it closes by contraction and scar formation.

Postoperative Care. After surgery, graft sites are immobilized with bulky cotton pressure dressings for 3 to 5 days to allow vascularization, or “take,” of the newly grafted skin. Do not disturb the dressing, and encourage elevation and complete rest of the grafted area to allow blood vessels to connect the graft with the wound bed. Any activity that might cause movement of the dressing against the body and separation of the graft from the wound is prohibited.

After dressings are removed, monitor the graft for indications of failure to vascularize, nonadherence to the wound, or graft necrosis. If a pedicle flap has been used to cover the wound, inspect the edges of the flap at least every 4 hours for changes in color. *A pale flap with delayed capillary filling when blanched may have inadequate arterial perfusion.* A dusky color or sharp line of color change suggests inadequate venous or lymphatic drainage. Other techniques to monitor trends of blood flow in the graft, depending on the graft's location, include pulse oximetry, Doppler ultrasonography, and transcutaneous oxygen determination.

Nursing care of partial-thickness donor sites aims to protect the area from injury and infection until re-epithelialization can occur and to promote comfort. A pressure dressing is usually placed over the donor area to promote hemostasis. After 24 to 48 hours, this outer dressing is removed, revealing a single wound contact layer of fine-mesh gauze or synthetic mesh material.

Today most donor sites are dressed with moisture-retentive dressings, such as synthetic transparent films. However, if the

donor site is treated with dry exposure, promote air circulation to the wound by positioning the patient to avoid pressure on the site and using an overbed cradle to tent the sheets. After the dressing has dried and formed a “scab,” keep the wound dry and undisturbed until healing is evident (at 10 to 14 days). As the donor site heals, the gauze and dried blood lift away from the new epithelium beneath. Trimming the separating gauze close to the skin surface reduces the chance of the patient catching the loose end of the dressing on an object and removing the still-adherent gauze before healing is complete.

The donor sites initially may be more painful than graft sites. Administer analgesics as prescribed, and provide other comfort measures as needed. Reposition the patient during the immediate period after surgery to promote comfort only if movement of the graft site can be avoided. Offer or delegate the intervention of back rubs to help relieve muscle spasms that occur with reduced mobility. Pay attention to relieving pressure over unaffected bony prominences that may lead to additional ulcers.

Graft and donor sites on posterior body surfaces present a particular problem. For the graft or flap to become fully vascularized or for the donor sites to dry, the patient must be immobilized in a side-lying or prone position for 7 to 10 days.

An alternative to this positioning is the use of special low-pressure or air-fluidized beds, such as the Clinitron bed, KinAir bed, or FluidAir bed, which not only reduce ischemia of the graft or flap while the patient is supine but also help prevent breakdown of intact skin. A major limitation to the use of these beds is cost, which is usually outweighed by the potential for decreased morbidity and length of hospital or long-term care stay.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

Which intervention does the nurse use to promote “take” of a graft placed on the client’s right heel?

- A. Elevate the client’s right foot by placing pillows under the leg from the knee to the ankles.
- B. Position the client on the abdomen with the right foot hyperextended for at least 4 hours daily.
- C. Ensure that the grafted area is pressed tightly to the bed to promote adherence to the wound bed.
- D. Assess the circulation distal to the graft every hour and compare the findings with those from the left foot.

Preventing Infection and Wound Deterioration

Planning: Expected Outcomes. The patient with a pressure ulcer is expected to remain free of wound infection or systemic sepsis. Indicators include that the patient will have mild or no:

- White blood cell elevation
- Positive blood culture
- Purulent drainage
- Increase in wound size or depth
- Fever

Interventions. Priority nursing interventions focus on preventing wound infections and identifying wound infections early to prevent complications.

Monitoring the ulcer’s appearance using objective criteria allows evaluation of the response to treatment and early

recognition of infection. If an ulcer shows no progress toward healing within 7 to 10 days or worsens, the treatment plan should be re-evaluated. [Chart 27-5](#) outlines objectives of monitoring wounds with and without tissue loss. Patients who are at highest risk for infection are those who are older, have white blood cell (WBC) disorders, are receiving steroid therapy, or have wounds with a compromised blood supply.

Preventing infection and its complications starts with monitoring the ulcer’s progress. Routinely check for manifestations of wound infection: increased pain, tenderness, and redness at the wound margins; edema; and purulent and malodorous drainage. Report these signs to the health care provider:

- Sudden deterioration of the ulcer as evidenced by an increase in the size or depth of the lesion
- Changes in the color or texture of the granulation tissue
- Changes in the quantity, color, or odor of exudate

These changes may occur with or without clinical signs of bacteremia, such as fever, an elevated WBC count, and positive blood cultures. Use the previously described interventions to prevent the formation of new pressure ulcers and to prevent early-stage ulcers from progressing to deeper wounds (see [Chart 27-2](#)).

Maintaining a safe environment can help prevent wound infection. Because of the variety of organisms in the hospital environment, keeping an ulcer totally free of bacteria is impossible. Optimal ulcer management is based on maintaining acceptably low levels of organisms through meticulous wound care and reducing contamination with pathogenic organisms that could lead to sepsis and possible death, especially in older adults. *Teach all personnel to use Standard Precautions and to properly dispose of soiled dressings and linens.*

Community-Based Care

Patients with pressure ulcers may be in acute care, subacute care, long-term care, or home care settings. If pressure ulcer therapy requires hospitalization, most patients with pressure ulcers are discharged before complete wound closure is achieved. Discharge may be to the home setting or to a long-term care facility, depending on the degree of debilitation and other patient factors.

Home Care Management

Care of the ulcer in the patient’s home is similar to care in the hospital. Most dressing supplies and pressure-relief devices can be easily obtained at the local pharmacy or medical supply store. If débridement of the ulcer is still needed, a handheld shower device or forceful irrigation of the wound with a 35-mL syringe and 19-gauge angiocatheter can be substituted for whirlpool therapy.

Many patients cannot change their own dressings because of distress over an altered body image or the pain of dressing removal. Others depend on family members or support personnel because of limited physical mobility or inability to reach the wound.

For some patients, drastic changes in daily activities are needed to promote healing. Patients with pressure ulcers on the legs may need frequent rest periods with leg elevation to avoid or reduce edema. Immobile patients with pressure ulcers require around-the-clock repositioning as

CHART 27-5 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Monitoring the Wound

VARIABLE	FREQUENCY OF ASSESSMENT	RATIONALE
Wounds Without Tissue Loss		
Examples Surgical incisions and clean lacerations closed primarily by sutures or staples		
Observations (using first postoperative dressing change as baseline)		
Check for the presence or absence of increased:	At least every 24 hr until sutures or staples are removed	To detect cellulitis (bacterial infections)*
Localized tenderness		
Swelling of the incision line		
Erythema of the incision line >1 cm on each side of wound		
Localized heat		
Check for the presence or absence of:	At least every 24 hr until sutures or staples are removed	To detect abscess formation related to presence of foreign body (suture material) or deeper wound infection*
Purulent drainage from any portion of the incision site		
Localized fluctuance (from fluid accumulation) and tenderness beneath a portion of the wound when palpated		
Check for the presence or absence of approximation (sealing) of wound edges with or without serosanguineous drainage	At least every 24 hr until sutures or staples are removed	To detect potential for wound dehiscence
Wounds with Tissue Loss		
Examples Partial- or full-thickness skin loss caused by pressure necrosis, vascular disease, trauma, etc., and allowed to heal by secondary intention		
Observations		
Wound Size		
Measure wound size at greatest length and width using a disposable paper tape measure or, for asymmetric ulcers, by tracing the wound onto a piece of plastic film or sheeting (plastic template)	At least every week, usually every 48-72 hr	To detect increase in wound size and depth secondary to infectious process
Compare all subsequent measurements against the initial measurement		
Ulcer Base		
Check for the presence or absence of:	At least every 24 hr	To detect the need for débridement or the response to treatment (necrotic tissue) and to detect local wound infection (frequent dressing changes and foul odor)
Necrotic tissue (loose or adherent)		
Foul odor from wound when dressing is changed		
Note the frequency of dressing changes or dressing reinforcements owing to drainage		
Wound Margins		
Check for the presence or absence of:	At least every 24 hr or at each dressing change	To detect wound infection*
Erythema and swelling extending outward >1 cm from wound margins		
Increased tenderness at wound margins		
Systemic Response		
Check for the presence or absence of elevated body temperature or WBCs or positive blood culture	Check temperature daily; if elevated, check WBCs and blood culture	To detect bacteremia

WBCs, White blood cells.

*The wounds of patients who are severely immunosuppressed or those wounds with compromised blood supply may not exhibit a typical inflammatory response to local wound infection.

often as every 2 to 4 hours to prevent further breakdown, which takes its toll on family members or other caregivers. Explain the rationale for activity changes to the patient and family, and explore alternative ways of coping with these changes.

Some patients may need to continue the use of special beds or mattress overlays at home. Although these items can be expensive, their use at home can keep the patient out of other, more-costly health care settings. Coordinate with the case manager to work with the insurance company in providing these important aids for quality patient care.

Teaching for Self-Management

Before the patient is discharged, the patient or caregiver who will be performing the wound care should demonstrate facility in removing the dressing, cleaning the wound, and applying the dressing. When choosing a dressing to be used at home, consider the patient's or caregiver's ability to apply the dressing properly. If the patient's finances are limited, also address the cost of the dressing material. Some dressings may be easier to apply and less expensive than other materials. At times, the more expensive dressing materials that require less frequent changing may be preferred. Explain the

manifestations of wound infection, and remind the patient and family to report their presence to the health care provider or wound care clinic.

Encourage the patient to eat a balanced diet with frequent high-protein snacks. Discuss diet preferences with the patient, and coordinate with the dietitian in suggesting foods that promote wound healing. Vitamin and mineral supplements may be prescribed to prevent or treat dietary deficiencies.

If the patient is incontinent, emphasize the need to keep the skin clean and dry. If bowel and bladder training are not possible, discuss the use of absorbent underpads, briefs, and topical moisture barrier creams and ointments as a method to reduce skin exposure to urine and feces.

Health Care Resources

A home care nurse may be needed for a few visits to follow wound progress after the patient is discharged. As indicated by The Joint Commission's NPSGs, the hospital nurse provides details of ulcer size and appearance and any special wound care needs in a hand-off report to the nurse in the home, who can then accurately judge changes in ulcer appearance. **Chart 27-6** is a guideline for a focused assessment of the patient with pressure ulcers.

To reduce waste and to help decrease the overall cost of treatment, emphasize proper use of dressing materials. Clean tap water and nonsterile supplies are acceptable for treatment of chronic wounds in the home and are less costly than sterile products. Nonsterile dressing materials can often be purchased in bulk from a local medical supply store at reduced cost. Stress the importance of properly cleaning reused items and of handwashing before touching any supplies.

The patient with activity restrictions may need daily assistance from a home care aide. Collaborate with a physical therapist or occupational therapist to help the patient and family continue rehabilitation efforts in the home.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Evidence-Based Practice; Safety

The patient described on p. 482 has developed a stage 2 pressure ulcer on his coccyx and has been discharged to home. His daughter is concerned about caring for this wound and wonders if he should stay at the hospital until the wound has completely healed.

1. What will you tell the daughter about extending the hospital stay?
2. How will you address the daughter's concerns about caring for the wound?
3. What adjustments at home may be needed to help this wound heal?
4. What resources can you suggest?

EVALUATION: OUTCOMES

Evaluate the care of the patient with a pressure ulcer on the basis of the identified priority patient problems. The expected outcomes include that the patient will:

- Experience progress toward wound closure healing by secondary intention as evidenced by granulation, epithelialization, and reduction or resolution of wound size
- Re-establish skin integrity and restore skin barrier function
- Remain infection free

CHART 27-6 HOME CARE ASSESSMENT

The Patient at Risk for Pressure Ulcers

Assess cardiovascular status:

- Presence or absence of peripheral edema
- Hand-vein filling in the dependent position
- Neck-vein filling in the recumbent and sitting positions
- Weight gain or loss

Assess cognition and mental status:

- Level of consciousness
- Orientation to time, place, and person
- Can the patient accurately read a seven-word sentence containing no words more than three syllables?

Assess condition of skin:

- Assess general skin cleanliness
- Observe all skin areas, paying particular attention to bony prominences and those areas in greatest contact with the bed and other firm surfaces
- Measure and record any areas of redness or loss of integrity
- If possible, photograph areas of concern
- Note the presence or absence of skin tenting over the sternum or the forehead
- Note the moistness of skin and mucous membranes
- If wounds are present, remove dressings (noting condition of dressings), cleanse the wound, and compare with previous notations of wound condition:

Presence, amount, and nature of exudate

Use a disposable paper tape measure to measure wound diameter and depth

Amount (%) and type of necrotic tissue

Presence of granulation/epithelium

Presence or absence of cellulitis

Presence or absence of odor

Take the patient's temperature.

Assess the patient's understanding of illness and compliance with treatment:

- Manifestations to report to health care provider
- Drug therapy plan (correct timing and dose)
- Ambulation or positioning schedule
- Dressing changes/skin care
- Nutrition modifications (24-hour diet recall)

Assess the patient's nutritional status:

- Change in muscle mass
- Lackluster nails, sparse hair
- Recent weight loss of more than 10% of usual weight
- Impaired oral intake
- Difficulty swallowing
- Generalized edema

Specific indicators for these outcomes are listed for each priority patient problem under the Planning and Implementation section (see earlier).

COMMON INFECTIONS

Pathophysiology

Skin infections can be bacterial, viral, or fungal. **Chart 27-7** lists key features and common locations of each type.

Bacterial Infections

Bacterial skin lesions usually start at the hair follicle, where bacteria easily collect and grow in the warm, moist environment. **Folliculitis** is a superficial infection involving only the upper portion of the follicle and is usually caused by *Staphylococcus*. The rash is raised and red and usually shows small pustules. **Furuncles** (boils) are also caused by *Staphylococcus*,

CHART 27-7 KEY FEATURES

Common Skin Infections

CLINICAL MANIFESTATIONS	DISTRIBUTION
Bacterial Infections Folliculitis Isolated erythematous pustules occur singly or in groups; hairs grow from centers of many of the lesions. Occasional papules are present. There is little or no associated discomfort. There is no residual scarring.	Areas of hair-bearing skin, especially buttocks, thighs, beard area, and scalp
Furuncle Small, tender, erythematous nodules become pus filled and more tender over time. Lesions may be single or multiple and also recurrent. Regional lymphadenopathy is sometimes present; fever is rare. Occasional scarring results.	Areas of hair-bearing skin, especially buttocks, thighs, abdomen, posterior neck regions, and axillae
Cellulitis Localized area of inflammation may enlarge rapidly if not treated. Redness, warmth, edema, tenderness, and pain are present. On rare occasions, blisters are present. Cellulitis is often accompanied by lymphadenopathy and fever.	Lower legs, areas of persistent lymphedema, and areas of skin trauma (e.g., leg ulcer, puncture wound)
Viral Infections Herpes Simplex Grouped vesicles are present on an erythematous base. Vesicles evolve to pustules, which rupture, weep, and crust. Older lesions may appear as punched-out, shallow erosions with well-defined borders. Lesions are associated with itching, stinging, or pain. Secondary bacterial infection with necrosis is possible in immunocompromised patients.	Type 1 classically on the face and type 2 on the genitalia, but either may develop in any area where inoculation has occurred; recurrent infections occur repeatedly in the same skin area
Herpes Zoster (Varicella Zoster) Lesions are similar in appearance to herpes simplex and also progress with weeping and crusting. Grouped lesions present unilaterally along a segment of skin following the pathway of a spinal or cranial nerve (dermatomal distribution). Eruption is preceded by deep pain and itching. Postherpetic neuralgia is common in older adults. Secondary infection with necrosis is possible in immunocompromised patients.	Anterior or posterior trunk following involved dermatome; face, sometimes involving trigeminal nerve and eye
Fungal Infections Dermatophytosis Annular or serpiginous patches are present with elevated borders, scaling, and central clearing. Itching is common. Lesions may be single or multiple.	Anywhere on the body
Candidiasis Erythematous macular eruption occurs with isolated pustules or papules at the border (satellite lesions). Candidiasis is associated with burning and itching. Oral lesions (thrush) appear as creamy white plaques on an inflamed mucous membrane. Cracks or fissures at the corners of the mouth may be present.	Skinfold areas: perineal and perianal region, axillae, beneath breasts, and between the fingers; under wet or occlusive dressings Lesions possibly present on the oral or vaginal mucous membranes

but the infection is much deeper in the follicle (Fig. 27-7). This larger, sore-looking, raised bump may or may not have a pustular “head” at its point. **Cellulitis** is a generalized infection with either *Staphylococcus* or *Streptococcus* and involves the deeper connective tissue.

Minor skin trauma usually occurs before the appearance of folliculitis and furuncles and may or may not contribute to the development of cellulitis. Patients may spread the infection to other parts of their bodies by scratching or rubbing the skin with fingernails that have organisms under them. Furuncles are more likely to occur in areas of heat and moisture, such as in the hair-bearing skinfold areas. Cellulitis can occur as a result of secondary bacterial infection of an open wound, or it may be unrelated to skin trauma.

An increasingly common skin problem is infection with methicillin-resistant *Staphylococcus aureus* (MRSA) (Leung-Chen, 2008). This infection can range from mild folliculitis to extensive furuncles. It is easily spread to other body areas and to other people by direct contact with infected skin and by contact with articles of clothing, bed linens, athletic equipment, towels, and other objects used by a person with MRSA. The infection does not respond to cleansing with antibacterial soaps or most types of topical and many oral antibiotic therapies (Mendyk, 2008). If MRSA infects a wound or gains access into the blood, deep wound infection, sepsis, organ damage, and death can occur (Holcomb, 2008). The incidence of the problem is highest among adults living in communal environments, such as dormitories or prisons, and

FIG. 27-7 A furuncle.

among patients in hospitals or other health care residential settings. (See Chapter 25 for more detailed MRSA discussion.)

Viral Infections

Herpes simplex virus (HSV) infection is the most common viral infection of adult skin. HSV infections are of two types. Type 1 (HSV-1) infections cause the classic recurring cold sore. The severity of the disease increases with age and is worse when the patient is immunosuppressed. Genital herpes, caused by type 2 infection (HSV-2), is also recurrent (see Chapter 76).

After the first infection, the virus remains in the body in a dormant state in the nerve ganglia and the patient has no symptoms. Reactivation stimulates the virus to travel the pathway of sensory nerves to the skin, where lesions reappear. In healthy people, recurrence of HSV infection is triggered by physical or psychological stressors, such as dry lips, sunburn, trauma, fever, menses, and fatigue. The virus can also be spread by direct contact between an actively infected person and a susceptible host. *Autoinoculation*, or transfer of either viral type from one part of the body to another, is also possible.

The time span between episodes and the severity of each attack vary. Outbreaks of oral herpes simplex usually last 3 to 10 days. The patient sheds virus and is contagious for the first 3 to 5 days. The patient may have tingling or burning of the lip before any lesion is evident.

The most common clinical picture of HSV-1 infection is isolated or grouped vesicles on a red base. The infection can occur anywhere on the skin and may be spread by respiratory droplets or by direct contact with an active lesion or virus-containing fluid (e.g., saliva). The lesions are painful and unsightly.

Herpetic whitlow is a form of herpes simplex infection occurring on the fingertips of medical personnel who have come in contact with viral secretions. This form of herpes can easily be spread to patients. Immunosuppressed patients are at increased risk for severe and persistent eruptions that can lead to life-threatening complications.

Herpes zoster (shingles), also known as varicella zoster, is caused by reactivation of the dormant varicella-zoster virus (VZV) in patients who have previously had chickenpox. The dormant virus resides in the dorsal root ganglia of the sensory

FIG. 27-8 Herpes zoster (shingles).

nerves. The lesions of herpes zoster infections are similar to those of herpes simplex, but they have a different distribution pattern (Fig. 27-8). Multiple lesions occur in a segmental distribution on the skin area innervated by the infected nerve. Herpes zoster eruptions usually occur after several days of discomfort, which may vary from minor irritation and itching to severe, deep pain. The eruption usually lasts several weeks. **Postherpetic neuralgia**, severe pain persisting after the lesions have resolved, is a common complication in older patients. Early diagnosis of herpes zoster and prompt treatment with anti-viral drugs help decrease the duration and severity of postherpetic neuralgia.

Herpes zoster is a disease of immunosuppression, occurring most often and with greater severity in older people or in anyone who is immunosuppressed for any reason. The disorder can be accompanied by fever and malaise, often progressing to visceral involvement. *It is contagious to people who have not previously had chickenpox and have not been vaccinated against the disease.* Contagion is most likely when the lesions are present as fluid-filled blisters. Keeping patients with these lesions separated from other patients in the environment until the lesions have crusted reduces the risk for transmitting the virus to others. Complications include full-thickness skin necrosis, Bell's palsy, or eye infection, and scarring if the virus is introduced into the eye.

The vaccine *Zostavax* is available to prevent VZV reactivation and shingles. The Centers for Disease Control and Prevention (CDC) recommends the vaccine for anyone older than 60 years who has a healthy immune system. In 2011 the FDA approved this drug for use starting at age 50 years (FDA, 2011). This one-time subcutaneous injection is reported to reduce the incidence of shingles by as much as 64% (Wielowski, 2009). Cost remains a factor in widespread adoption (about \$100 per dose), and few insurance carriers currently include this coverage.

Fungal Infections

Dermatophyte infections, especially superficial infections, can differ in lesion appearance, body location, and species of the infecting organism. The term *tinea* is used to

describe dermatophytoses; this term is then followed by the location description. For example *tinea pedis* involves the foot (athlete's foot), *tinea manus* involves the hands, *tinea cruris* involves the groin (jock itch), *tinea capitis* involves the head, and *tinea corporis* involves the rest of the body (ringworm).

Depending on the species, dermatophytes live mainly in the soil, on animals, and on humans. Superficial infection can start only if conditions are right for inoculation and maintenance of the organism in the outer layers of the skin.

Dermatophyte infections occur when the infecting organism comes in contact with impaired skin in a susceptible host. Most infections are spread by direct contact with infected humans or animals. Certain types of infections, such as *tinea capitis* and *tinea corporis*, can be transmitted by means of inanimate objects. For example, *tinea capitis* can be spread by sharing contaminated combs, brushes, hats, pillowcases, and similar objects with people who have poor personal hygiene.

Candida albicans, also known as *yeast infection*, is another common superficial fungal infection of skin and mucous membranes. The organism is present almost everywhere and easily grows in a warm, moist environment. Risk factors for this infection include immunosuppression, long-term antibiotic therapy, diabetes mellitus, and obesity. The incidence is higher in hot, humid climates.

Infected skin has a moist, red, irritated appearance and usually causes itching and burning. Common areas for infection include the perineum, vagina, axillae, under the breasts, and in the mouth (where it is known as *thrush*).

Prevention is aimed at keeping skinfold areas clean and dry. Turning patients and positioning to enhance airflow also aid in prevention. When the infection is present, meticulous cleanliness and the use of topical antifungal agents are needed. Inspect skinfold areas as part of the daily skin assessment on any patient with mobility problems. Teach UAP how to position patients for best exposure of infection-prone areas to the air. Stress the importance of changing bed linens and patient gowns whenever they are damp. Report the presence of infection manifestations to the health care provider.

Health Promotion and Maintenance

Prevention of skin infections, especially bacterial and fungal infections, involves avoiding the offending organism and practicing good personal hygiene to remove the organism before infection can occur. *Handwashing and not sharing personal items with others are the best ways to avoid contact with some of the most easily transmitted organisms, including MRSA.* Chart 27-8 highlights strategies to teach patients and family members to prevent spread of the infection to other body areas and to other people (Mendyk, 2008).

For older adults who have had chickenpox and are, therefore, at risk for shingles (herpes zoster), a new vaccine has been approved, Zostavax. Its use is recommended for any adult older than 50 years who does not currently have shingles (FDA, 2011). It is given as a one-time subcutaneous injection. The drug should not be given as an IM or IV injection and should not be given to anyone who is immunosuppressed. The most common side effect is an injection site reaction of erythema, pain, tenderness, swelling, warmth, or pruritus.

CHART 27-8 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Preventing the Spread of MRSA

- Avoid close contact with others, including participation in contact sports, until the infection has cleared.
- Take all prescribed antibiotics exactly as prescribed for the entire time prescribed.
- Keep the infected skin area covered with clean, dry bandages.
- Change the bandage whenever drainage seeps through it.
- Place soiled bandages in a plastic bag, and seal it closed before placing it in the regular trash.
- Wash your hands with soap and warm water before and after touching the infected area or handling the bandages.
- Shower (rather than bathe) daily, using an antibacterial soap.
- Wash all uninfected skin areas before washing the infected area, or use a fresh washcloth to wash the uninfected areas.
- Use each washcloth only once before laundering, and avoid using bath sponges or puffs.
- Sleep in a separate bed from others until the infection is cleared.
- Avoid sitting on or using upholstered furniture.
- Do not share clothing, washcloths, towels, athletic equipment, shavers or razors, or any other personal items.
- Clean surfaces that may have come into contact with your infected skin, drainage, or used bandages (e.g., bathroom counters, shower/bath stalls, toilet seats) with household disinfectant or bleach water mixed daily (1 tablespoon of liquid bleach to 1 quart of water).
- Wash all soiled clothing and linens with hot water and laundry detergent. Dry clothing either in a hot dryer or outside on a clothesline in the sun.
- Urge family members and close friends to shower daily with an antibacterial soap.
- If another person assists you in changing the bandages, make certain he or she uses disposable gloves, pulls them off inside out when finished, places them with the soiled bandages in a sealed bag, and washes his or her hands thoroughly.

MRSA, Methicillin-resistant *Staphylococcus aureus*.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

To differentiate among the possible causes of the lesions, concentrate on risk factors for each type of infection. If the location and appearance of lesions suggest a bacterial infection, explore any recent history of skin trauma as well as past or current staphylococcal or streptococcal infections. Determine living conditions, home sanitation, personal hygiene habits, and leisure or sport activities. Ask whether fever and malaise are also present.

Lesions appearing on the lips, in the mouth, or in the genital region are more likely to be a possible viral infection. Ask about:

- A history of similar lesions in the same location
- Presence of burning, tingling, or pain
- Recent stress factors that preceded the outbreak
- Recent contact with an infected person

Information that the same type of lesions has occurred before is important in helping differentiate viral from bacterial lesions. If herpes zoster is suspected, ask whether the patient has had chickenpox in the past and about a history of

shingles. Also determine whether the patient has received the shingles prevention vaccination *Zostavax*.

The type of information you should ask a patient with probable dermatophyte infection depends on the location of the lesions. If tinea corporis or tinea capitis is present, assess the social and environmental factors that may have contributed to infection, such as direct contact with an infected person, poor personal hygiene practices, or frequent contact with animals. If tinea cruris and tinea pedis are suspected, ask about the type and frequency of athletic activities.

Physical Assessment/Clinical Manifestations

Because most skin infections are contagious, take precautions to prevent the spread of infection when performing a physical assessment. Chart 27-7 lists the manifestations of common skin infections.

Laboratory Assessment

When pustules are present in bacterial infections, the infecting organism is confirmed by swab culture of the purulent material. Blood cultures may be helpful, especially if the patient also has a fever and malaise.

Viral infections are confirmed by *Tzanck smear* and viral culture. Tzanck smear is a cytologic examination in which cells from the base of a lesion are examined under a microscope. The presence of multinucleated giant cells confirms a viral infection, although the exact virus is not identified.

For suspected fungal infections, scales from the lesions are scraped, prepared with potassium hydroxide (KOH), and examined under a microscope. The presence of fungal hyphae confirms the diagnosis. In addition to a KOH test, a fungal culture may be needed. Occasionally a skin biopsy is performed to obtain organisms for identification.

INTERVENTIONS

Most skin infections heal well with nonsurgical management. Surgery may be required when an infectious agent is present in deep tissue layers. *Priority nursing interventions focus on patient and family education to prevent infection spread to other body areas or to other people (see Chart 27-8).* Meticulous skin care is needed for prevention of infection spread. In some instances, drug therapy is needed.

Skin care with proper cleansing is the most effective intervention. Teach patients with bacterial infections to bathe daily with an antibacterial soap. Instruct them to not squeeze any pustules or crusts but to remove them gently so that topical drugs can be more easily absorbed. Teach the patient to apply warm compresses twice a day to furuncles or areas of cellulitis to increase comfort.

Applying astringent compresses, such as Burow's solution, to viral lesions for 20 minutes three times a day promotes crust formation and healing. Compresses also relieve the irritation and pain associated with herpetic infection. Teach the patient to avoid constricting garments that rub lesions and increase irritation.

Most superficial skin infections resolve more quickly if the involved skin is allowed to dry between treatments. Excessive moisture, especially if occluded by dressings, clothing, or bedding, promotes growth of organisms. If the patient is bedridden, position him or her for optimal air circulation to the area and avoid occlusive dressings or garments.

Transmission-Based Precautions may be needed to reduce the spread of organisms to other people. For most superficial bacterial infections, proper handwashing prevents cross-contamination. However, when hospitalized patients are colonized with *Staphylococcus* that is resistant to antibiotic therapy, strict adherence to isolation procedures is necessary.

Of the dermatophyte infections, tinea capitis, tinea corporis, and tinea pedis are most easily transmitted to others. Teach patients to avoid sharing personal items, such as hairbrushes, articles of clothing, or footwear. Repeated infections transmitted by dogs or cats may mean that patients have to get rid of a family pet to control infections.

Drug therapy for superficial infections involves topical agents. Mild bacterial infections of the skin usually resolve with topical antibacterial treatment. Patients with extensive infections, especially if fever or lymphadenopathy is present, require systemic antibiotic therapy. The most common systemic drugs used for bacterial skin infections are penicillins and cephalosporins. For those who are allergic to drugs from these classes, tetracyclines, macrolides, or aminoglycoside antibiotics may be used. For patients infected with MRSA or other drug-resistant organisms, drug therapy may involve IV vancomycin or oral linezolid or clindamycin. Nursing implications related to therapy with these drugs are presented in Chart 27-9.

Acyclovir (Zovirax), valacyclovir (Valtrex), or famciclovir (Famvir) is used for the treatment of viral infections. Topical treatment decreases the numbers of active viruses on the skin surface and reduces pain in herpetic infections and localized lesions in immunocompromised patients. Topical treatment is of little benefit in recurrent infection. IV administration is limited to severe primary infections and immunosuppressed patients with symptoms of systemic infection.

Topical antifungal agents are used for patients with dermatophyte and yeast infections. An imidazole cream is applied to the infected skin at least twice a day until the lesions have cleared. To prevent recurrence, therapy is usually continued for 1 to 2 weeks after clearing. In some instances, antifungal powders may also help suppress fungal growth. For widespread or resistant fungal infections, systemic antifungal agents, such as ketoconazole (Nizoral), are given.

CUTANEOUS ANTHRAX

Cutaneous anthrax is an infection caused by the spores of the bacterium *Bacillus anthracis*. In the United States, the most common risk factor is contact with an infected animal. Those most at risk for cutaneous anthrax include farm workers, veterinarians, and tannery and wool workers. This organism has now become a tool for terrorism.

! NURSING SAFETY PRIORITY

Action Alert

Consider the possibility of bioterrorism whenever lesions consistent with cutaneous anthrax appear in patients who do not have a history of exposure to infected animals.

The infection can be confined to the skin, or it may be systemic. At first a raised vesicle appears on an exposed body area such as the head or arms (Fig. 27-9). The lesion may itch

CHART 27-9 COMMON EXAMPLES OF DRUG THERAPY

Methicillin-Resistant Staphylococcus aureus (MRSA)

DRUG AND DOSAGE	NURSING IMPLICATIONS	RATIONALE
Vancomycin (Lyphocin, Vancocin) 500 mg IV every 6 hr	Ensure that IV access is patent. Administer drug over at least 60 min and never as a bolus or by IV push. Observe patient for widespread flushing. Check IV site at least every 2 hr for a change in blood return, redness or pain, or the feeling of hard or "cordlike" veins above the site. Ask the patient about any diarrhea or presence of watery stools.	If extravasated, drug is highly tissue damaging. When given more rapidly, drug causes hypotension, dysrhythmias, and histamine release. Drug triggers a histamine release causing "red man syndrome." Drug is irritating to veins and can trigger thrombophlebitis.
Clindamycin (Cleocin) 150-300 mg orally every 6 hr or 300-600 mg IM or IV 2-4 times daily	When given IV, administer slowly (over 30-60 min). Check liver function tests. Ask the patient about any diarrhea or presence of watery stools	Rapid administration can induce shock and cardiac arrest. Drug can induce liver damage. Drug changes the intestinal flora and can lead to pseudomembranous colitis.
Linezolid (Zyvox) 400-600 mg orally or IV every 8-12 hr	Take blood pressure at least every 4 hr, especially for anyone who has hypertension. Check IV site at least every 2 hr for a change in blood return, redness or pain, or the feeling of hard or "cordlike" veins above the site. Ask the patient about any diarrhea or presence of watery stools. Observe for increased bruising or oozing of blood from gums or at injection sites.	Drug constricts blood vessels and may trigger hypertensive crisis. Drug is irritating to veins and can trigger thrombophlebitis. Drug changes the intestinal flora and can lead to pseudomembranous colitis. Drug reduces platelet and red blood cell numbers, increasing the risk for bleeding.

FIG. 27-9 Cutaneous anthrax. Note ulcer with vesicular ring, induration, and erythema (A). As eschar forms, induration lessens, surrounding desquamation occurs, but erythema persists (B).

and often resembles an insect bite. Within a few days, the center of the vesicle becomes hemorrhagic and sinks inward. An area of necrosis and ulceration begins. Usually this process is painless. The tissue around the wound swells and can become quite edematous. With necrosis, an eschar forms (see Fig. 27-9). The two features that distinguish anthrax lesions from insect bites or other skin lesions are that it is painless and that eschar forms regardless of treatment. Patients may have only one lesion, or there may be multiple lesions, usually in the same body area.

Some patients develop glandular symptoms with cutaneous anthrax. The entire area becomes edematous and tender. Fever and chills may be present, as may enlarged lymph nodes.

Diagnosis is made based on the appearance of the lesions, a culture that is positive for the organism, or the presence of anthrax antibodies in the patient's blood. Cultures are most easily obtained in the vesicle stage. Once the eschar is formed, a biopsy may be needed for culture. Blood cultures should be obtained from patients who have a fever.

Oral antibiotics for 60 days are indicated for patients who have no edema or systemic symptoms and whose lesions are not located on the head or neck. The antibiotics of choice are ciprofloxacin (Cipro) or doxycycline (Doryx, Vibramycin). For patients who have a fever, have lesions on the head or neck, are pregnant, or have extensive edema, antibiotics are given IV and then followed by an oral course of 60 days.

PARASITIC DISORDERS

Parasitic skin disorders occur most often in patients with poor hygiene and substandard living conditions or in those who are homeless. Any patient who shows obvious signs of a self-care deficit should be examined for these contagious parasitic infections.

PEDICULOSIS

Pathophysiology

Pediculosis is an infestation by human lice: *pediculosis capitis* (head lice), *pediculosis corporis* (body lice), and *pediculosis pubis* (pubic, or crab, lice). Human lice are oval and 2 to 4 mm long. The female louse lays hundreds of eggs, called *nits*, which are deposited at the hair shaft base in hair-bearing areas.

PATIENT-CENTERED COLLABORATIVE CARE

The most common symptom of pediculosis is itching (**pruritus**). Excoriation from scratching may or may not be present. In addition to causing discomfort, these parasites can also be carriers of disease (e.g., typhus, recurrent fever).

Pediculosis capitis occurs more commonly in women than in men, especially on the sides and back of the scalp. Itching, the result of biting of the scalp by the parasites, is intense. It is most commonly transmitted by children and pets. A secondary infection may also be present from scratching.

Because the louse is difficult to see, examine the scalp for visible white flecks attached to the hair shaft near the scalp—the nits of the female louse. Matting and crusting of the scalp and a foul odor indicate a probable secondary infection.

Pediculosis corporis is caused by lice that live and lay eggs in the seams of clothing. The parasites also cause itching. The only visible sign of infestation may be excoriations on the trunk, abdomen, or extremities (Rushing, 2008).

Pediculosis pubis causes intense itching of the vulvar or perirectal region. Pubic lice, which are more compact and crablike in appearance than body lice, can be contracted from infested bed linens or during sexual intercourse with an infected person. Although these lice are usually found in the genital region, they can also infest the axillae, the eyelashes, and the chest.

The treatment of pediculosis is chemical killing of the parasites with topical sprays, creams, shampoos, such as permethrin (Elimite), lindane (Bio-Well, Kwell, Kwellada), or topical malathion (Ovide, Prioderm). Oral agents may also be used, such as ivermectin (Stromectol). In the case of pediculosis capitis, areas where the patient's head has rested (e.g., on pillows or chair backs) are also treated. Clothing and bed linens should be washed in hot water with detergent or dry-cleaned. The use of a fine-toothed comb helps remove nits from an infested scalp but alone does not cure the infection. In all cases of louse infestation, social contacts are treated when possible.

SCABIES

Scabies is a contagious skin disease caused by mite infestations. Scabies infections are transmitted by close and prolonged contact with an infested companion or infested

FIG. 27-10 Scabies. Note the lines indicating burrowing of the organism under the skin.

bedding. Infestation is common among patients with poor hygiene or crowded living conditions. The scabies mite is carried by pets and is found among schoolchildren, homeless people, and institutionalized older patients.

Scabies is manifested by curved or linear ridges in the skin (Fig. 27-10). The itching is more intense than with pediculosis, and patients often report that the itching becomes unbearable at night.

The visible white skin ridges are formed by burrowing of the mite into the outer skin layers. Closely examine the skin between the fingers and on the palms and inner aspects of the wrists, where these ridges are most common. A hypersensitivity reaction to the mite results in excoriated erythematous papules, pustules, and crusted lesions on the elbows, nipples, lower abdomen, buttocks, and thighs and in the axillary folds. Male patients can also have excoriated papules on the penis.

Infestation is confirmed by taking a scraping of a lesion and examining it under the microscope for mites and eggs. Close contacts also should be examined for possible infestation.

Treatment involves the use of scabicides, such as permethrin (Acticin), lindane (Kwell, Kildane, Scabene, Thionex), malathion (Ovide), or benzyl benzoate (Ascabiol) (Munn, 2008; Snow, 2007). Laundering clothes and personal items with hot water and detergent is sufficient to eliminate the mites.

BEDBUGS

A common emerging parasite is the bedbug, *Cimex lectularius*. Infestations are becoming increasingly common as a result of travel and resistance to pesticides (Sutton & Thomas, 2008; Willson, 2011). This pest does not live on humans; however, it feeds on human blood for its survival. Although bedbugs do not carry disease, the bite usually causes an itchy discomfort, and when a person is bitten extensively, anemia may result (Pritchard & Hwang, 2009). The most common

mode of infestation is carrying the “hitch-hiking” bug home from an infested environment such as a hotel room. This problem is not related to socioeconomic level or to a lack of cleanliness.

One myth is that the insect is so small that it cannot be seen by the human eye. The adult bedbug is the approximate size, shape, and color of an apple seed. After feeding, it may double in size and have a red or black color. The insect bites a human host, usually at night, injects saliva that contains an anticoagulant, and then sucks blood for 3 to 10 minutes. The bite area resembles a mosquito or flea bite with a raised bite mark surrounded by a wheal. The degree of itching and redness is related to how allergic the person is to the insect's saliva. There is no particular body area more susceptible to bites; however, one insect can bite multiple times, resulting in clusters of bite marks.

Management of the patient with bedbug bites is symptomatic for discomfort from itching, usually with topical antihistamines. When the discomfort is more widespread, systemic antihistamines may be used. For patients with severe allergic reactions, more extensive anti-inflammatory therapy with corticosteroids may be needed. When scratching has resulted in infection, topical antibiotic therapy may be needed. Because humans do not harbor the insect, the usual topical insecticides are not needed.

Bedbugs can live almost anywhere, hiding in cracks and crevices after feeding. They can live and lay their eggs in soft upholstery or in wooden crevices. Unlike many other parasites, after feeding they leave the host. A common telltale feature is the presence of blood spots on bed linen or clothing from feeding. Often, the bugs themselves can be found hiding under the welting around the mattress.

Eradicating the infestation and preventing re-infestations require considerable effort and can be frustrating. Profoundly infested upholstered furniture may need to be removed. New furniture and bedding should not be placed in the home until the infestation is eradicated or these items will just become new homes for bedbugs. Heat can kill the insects and their eggs. Washable clothing and linens can be cleaned by laundering them in hot water and drying them with the dryer set on high for at least 5 minutes. Items that cannot be washed in water can be bagged in dark plastic and left in hot sunshine for hours to raise the temperature high enough (above 98° F) to kill the insect. Steam cleaning of carpets and drapes can eliminate the insects hiding in these areas. However, the home environment itself usually needs the extensive eradication efforts of a licensed professional pest control company with experience in the management of bedbugs.

COMMON INFLAMMATIONS

Pathophysiology

The inflammatory skin conditions have many nonspecific manifestations, including severe itching, lesions with indistinct borders, and different distribution patterns. The cause of the eruption may or may not be identifiable. Inflammatory rashes can evolve from acute to chronic conditions.

Most inflammatory rashes are related to allergic immune responses. The responses may be triggered by external skin exposure to allergens or by exposure of the internal environment to allergens and irritants. The result is tissue destruction or skin changes induced by antibodies or cellular mediators

of the immune system. (A more detailed description of these immune mechanisms is presented in [Chapter 19](#).)

The specific cause of inflammatory rashes is not always known. When this is the case, the catch-all diagnosis of *non-specific eczematous dermatitis*, or *eczema*, is often used.

Contact dermatitis is an acute or chronic rash caused either by direct contact with an irritant substance, resulting in toxic injury to the skin, or by contact with an allergen, resulting in a cell-mediated immune reaction.

Atopic dermatitis is a chronic rash that occurs with respiratory allergies and atopic skin disease. The mechanism is unknown, but atopic dermatitis is made worse by factors that include dry or irritated skin, food allergies, chemicals, or stress. (Atopic reactions are described in [Chapter 22](#).)

PATIENT-CENTERED COLLABORATIVE CARE

Because all the inflammatory skin eruptions appear similar, data collected from the patient are needed to identify the cause. Inflammatory skin problems differ from eczematous dermatitis in the chronicity of the disease, the distribution of lesions, and associated symptoms. [Chart 27-10](#) lists the manifestations of many types of inflammatory skin conditions. Diagnosis is based on patient history and clinical data.

If the cause of the rash is identified, avoidance therapy is used to reverse the reaction and clear the rash. For example, if a new soap for handwashing causes contact dermatitis of the hands, teach patients to avoid that irritating substance. Even when the cause is unclear, certain irritants may cause the rash to worsen and increase discomfort. Additional interventions promote comfort through suppression of the inflammatory response.

Steroid therapy with topical, intralesional, or systemic steroids is prescribed to suppress inflammation. The vehicle used to deliver a topical steroid depends on the body area involved. Because a side effect of oral corticosteroids (e.g., prednisone) is adrenal suppression, patients receiving long-term therapy must taper their drug dosages rather than stop them abruptly.

Remember that corticosteroids never cure the inflammation. During active disease, these drugs reduce manifestations and relieve associated discomfort. Moisten dressings with warm tap water and place over topical steroids for short periods to increase absorption. Avoid applying topical steroids under occlusive dressings unless specifically prescribed by the health care provider.

! NURSING SAFETY PRIORITY

Drug Alert

Caution patients not to apply topical corticosteroids to potentially infected skin lesions anywhere on the body, but especially on the face. These agents suppress the local immune response and can worsen the infection. The skin on the face is thinner and absorbs topical steroids more quickly, making the patient more vulnerable to steroid side effects.

Avoid applying oil-based ointments and pastes to the sweaty skinfold areas because maceration and blocking of pores may result in folliculitis. Water-soluble creams are the better drug formulations for these areas. Lotions and gels prevent matting of the hair and are more appropriate for

CHART 27-10 KEY FEATURES

Common Inflammatory Skin Conditions**CLINICAL MANIFESTATIONS****Nonspecific Eczematous Dermatitis**

Evolution of lesions from vesicles to weeping papules and plaques.
Lichenification occurs in chronic disease.
Oozing, crusting, fissuring, excoriation, or scaling may be present.
Itching is common.

Contact Dermatitis

Localized eczematous eruption with well-defined, geometric margins that are consistent with contact by an irritant or allergen.
Usually seen in the acute form, but may become chronic if exposure is repeated.
Allergy to plants (e.g., poison ivy or oak) classically occurs as linear streaks of vesicles or papules.

Atopic Dermatitis

Hallmark in adults is lichenification with scaling and excoriation.
Extremely itchy.
Face involvement is seen as dry skin with mild to moderate erythema, perioral pallor, and skinfolds beneath the eyes (Dennie-Morgan lines).
Associated with linear markings on the palms.

Drug Eruption

Bright red erythematous macules and papules are found. Skin blisters in extreme cases.
Lesions tend to be confluent in large areas.
Moderately itchy.
Fever is rare.
Dehydration and hypothermia can occur with extensive involvement.
Condition clears only after offending drug has been discontinued.

DISTRIBUTION

Anywhere on the body; localized eczema commonly involves the hands or feet.

Cosmetic/perfume allergy: head and neck.
Hair product allergy: scalp.
Shoe/rubber allergy: dorsum of feet.
Nickel allergy: earlobes.
Mouthwash/toothpaste allergy: perioral region.
Airborne contact allergy (e.g., paint, ragweed): generalized.

Face, neck, upper chest, and antecubital and popliteal fossae.

Generalized.
Involvement begins on trunk, proceeds distally (legs are the last to be involved).

hairy areas, such as the scalp. Stiff ointments or pastes, such as thick zinc oxide pastes, are applied to localized areas because they cling to the skin where applied and resist spreading to uninvolved skin.

Antihistamines provide some relief of itching but may not keep the patient totally symptom free. The sedative effects of antihistamines are often better tolerated if the patient takes most of the daily dose near bedtime. Teach patients to avoid driving or operating heavy machinery if these drugs are taken during the day.

Comfort measures such as cool, moist compresses and lukewarm baths with bath additives have a soothing effect, decrease inflammation, and help débride crusts and scales. Colloidal oatmeal preparations, tar extracts, cornstarch, or oils are often added to baths to relieve itching.

PSORIASIS**Pathophysiology**

Psoriasis is a lifelong disorder that has exacerbations and remissions. Even though psoriasis cannot be cured, patients can usually achieve control of symptoms with proper treatment.

Psoriasis is a scaling disorder with underlying dermal inflammation. The problem is an abnormality in the growth of epidermal cells in the outer skin layers. Normally, cells at the basement membrane of the epidermis take about 28 days to reach the outermost layer where they are shed. In a person with psoriasis, the rate of cell division is speeded up so that cells are shed every 4 to 5 days.

Psoriasis appears to be an autoimmune reaction resulting from overstimulation of the immune system. Langerhans' cells in the skin respond to antigens, leading to T-lymphocyte activation. These cells target the keratinocytes, causing increased cell division and plaque formation.

GENETIC/GENOMIC CONSIDERATIONS

A strong genetic predisposition has been recognized in at least 30% of cases, and several genes appear to be involved in expression of the disease. It is likely that the disorder is multifactorial, in that a genetic predisposition exists but environmental factors influence disease occurrence, disease severity, and response to different treatments. Always ask about a family history when assessing the patient with psoriasis.

For many people with psoriasis, there is no family history of the disease. Many environmental factors lead to outbreaks and influence the severity of clinical symptoms, but these vary from person to person. Triggering factors may be local or systemic. A psoriatic lesion may appear after skin trauma (Koebner's phenomenon, in which a previously injured area is more susceptible to development of cancer or chronic skin problems) such as surgery, sunburn, or excoriation.

Patients with psoriasis often improve in warmer climates where there is more exposure to sunlight. Systemic factors that can aggravate the disease include infections (severe streptococcal throat infection, *Candida* infection, upper respiratory tract infection), hormonal changes (during puberty and menopause), stress, drugs (lithium, beta-blocking agents, indomethacin, antimalarials), obesity, and the presence of other diseases (Christopher & Meires, 2008).

FIG. 27-11 **A**, Psoriasis vulgaris in a white patient. **B**, Psoriasis vulgaris in a patient with dark skin.

Some patients with psoriasis also develop a debilitating arthritis. Psoriatic arthritis may be mild or can lead to severe joint changes similar to those seen in rheumatoid arthritis. The association of arthritis with psoriasis strongly suggests that psoriasis is really a systemic connective tissue disorder rather than a simple skin disease. See [Chapter 20](#) for more discussion of connective tissue disorders and arthritis.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

In addition to collecting routine epidemiologic data, ask the patient about any family history of psoriasis, including the age at onset, a description of the disease progression, and the pattern of recurrences. Ask the patient to describe the current flare-up of psoriasis, including whether the onset was gradual or sudden, where the lesions first appeared, whether there have been any changes in severity over time, and whether fever and itching are present. Explore possible precipitating factors, including recent skin trauma, upper respiratory tract infection, recent surgeries, menopause status, past and current use of drugs, and recent stress. Ask about previous interventions and the effectiveness of each in reducing symptoms.

Physical Assessment/Clinical Manifestations

The appearance of psoriasis and its course vary among patients. Typically during flare-ups of the disease, lesions thicken and extend to involve new areas of the body. As psoriasis responds to treatment, lesions become thinner with less scaling.

Psoriasis vulgaris is the most common type of psoriasis, with thick, reddened papules or plaques covered by silvery white scales ([Fig. 27-11](#)). Borders between the lesions and normal skin are sharply defined. Patches are less red and moister in skinfold areas because of sweat-induced maceration. Lesions are usually present in the same areas on both sides of the body (bilateral distribution). The more common sites are the scalp, elbows, trunk, knees, sacrum, and outside surfaces of the limbs. The facial skin is rarely affected. The

patient may have only a few isolated lesions, or the entire skin surface may be affected.

Exfoliative psoriasis (erythrodermic psoriasis) is an explosively eruptive and inflammatory form of the disease with generalized erythema and scaling. It does not form obvious lesions. Examine for signs of dehydration and hypothermia or hyperthermia related to this severe inflammatory reaction. The increased blood vessel dilation and blood flow to the skin can reduce fluid volume through evaporative water loss from the skin surface.

Palmoplantar pustulosis (PPP) is a form of psoriasis that causes pustules on the palms of the hands and soles of the feet. PPP has multiple pustules scattered on the fleshy surfaces of the hands and feet among reddened hyperkeratotic plaques. Pustules turn brown, peel, and eventually crust over. The course of the disease is usually cyclic, with new outbreaks of pustules occurring after older lesions have resolved. PPP is difficult to treat and is associated with social and physical disabilities that negatively impact quality of life ([Frankel & Goldenburg, 2010](#)).

INTERVENTIONS

The different approaches to therapy are based on the extent of disease, the patient's distress, the physician's preference, and the response of the psoriasis to treatment. Patients must understand that no cure for psoriasis exists yet. Therapy is aimed at reducing cell proliferation and inflammation. *Priority nursing strategies include teaching the patient about the disease and its treatment and providing emotional support for the changes in body image often experienced with psoriasis.*

Topical Therapy

The topical agents used to treat psoriasis are topical steroids, topical tar and anthralin preparations, and ultraviolet (UV) light.

Corticosteroids have anti-inflammatory actions. When applied to psoriatic lesions, corticosteroids suppress cell division. The effectiveness of a topical steroid depends on its potency and ability to be absorbed into the skin. The more potent agents are used to treat patients with psoriasis.

Teach patients to enhance the skin penetration of these drugs by applying the steroid directly to the skin and, when possible, to use warm, moist dressings and an occlusive outer

wrap of plastic (film, gloves, booties, or similar garments) if specifically prescribed.

Tar preparations applied to the skin suppress cell division and reduce inflammation. These drugs are available as solutions, ointments, lotions, gels, and shampoos. The use of coal tar ointments is usually limited to inpatient care and specialized outpatient treatment clinics because these ointments are messy, cause staining, and have an unpleasant odor.

Topical therapy with anthralin (Anthraforte , Dritho-creme, Lasan), a hydrocarbon similar in action to tar, also relieves chronic psoriasis. These drugs can be used alone or in combination with coal tar baths and UV light.

Teach the patient to apply the high-potency anthralin, suspended in a stiff paste, to each lesion for short periods (not exceeding 2 hours). The drug is a strong irritant and can cause chemical burns. Remind the patient to check for local tissue reaction and to take care to prevent this drug from coming into contact with uninvolved skin.

Other topical therapies can be effective for many patients with mild to moderate psoriasis. These drugs include calcipotriene (Dovonex), a synthetic form of vitamin D that regulates skin cell division, and tazarotene (Tazorac). Tazorac is **teratogenic** (can cause birth defects) even when used topically. Teach women of childbearing age using this drug to adhere to strict contraception measures.

Ultraviolet Light Therapy

Ultraviolet (UV) radiation is a physical agent commonly used as a topical treatment in many skin conditions, including psoriasis. Ultraviolet B (UVB) light, which produces more energy, is responsible for the obvious biologic effects of the sun, such as burning. Ultraviolet A (UVA) light emits a lower level of energy, requiring longer exposure time before cellular destruction occurs. Although the sun is an inexpensive source of UV radiation, better availability and intensity control occur with the use of artificial light sources. These sources include lamps or cabinets containing UV tubes. *The use of commercial tanning beds is not recommended for the patient with psoriasis.*

Ultraviolet therapy is limited by the potency and distance of the source from the skin, as well as the exposure time. Potency and distance remain constant, and the time of exposure is gradually increased to achieve a mild suntan effect without burning or tenderness. The patient's skin type, ranging from fair to darkly pigmented, affects his or her risk for burning and determines the exposure times. Because of the extremely high intensity of most artificial UVB light sources, treatments are measured in seconds of exposure; patients must wear eye protection during treatment.

Teach patients to inspect the skin carefully each day for signs of overexposure. If patients have tenderness on palpation and have clinical signs of severe erythema or blister formation, notify the health care provider before therapy is resumed.

Psoralen and UVA (PUVA) treatments involve the ingestion of a photosensitizing agent (psoralen) 2 hours before exposure to UVA light. Because UVA light produces less energy than UVB light, the onset of erythema and skin darkening may be delayed as long as 96 hours after exposure. Treatments are limited to two or three times a week and are not given on consecutive days. Exposure is gradually increased until tanning occurs. As with UVB exposure, dosages are

adjusted according to the erythema reaction of normal skin as well as the response of psoriatic lesions.

Teach the patient to check for redness with edema and tenderness. If these symptoms are present, treatment must be interrupted until they subside. Because of the strong photosensitizing properties of psoralen, patients must wear dark glasses during treatment and for the remainder of the day. Long-term side effects of both UVB and PUVA therapies include premature aging of the skin, actinic keratosis, and an increased risk for skin cancer.

Systemic Therapy

A better understanding of the role of the immune system in the cause of psoriasis has led to biologic therapies to manage moderate to severe plaque disease. Biologic agents alter the immune response, thus preventing overstimulation of keratinocytes. Although precautions vary with the specific mechanism of action, these drugs induce immunosuppression and patients are at an increased risk for serious infection.

NURSING SAFETY PRIORITY

Drug Alert

Instruct patients to discontinue the biologic agent and notify the health care provider immediately if manifestations of infection occur.

Biologics approved by the FDA for the treatment of moderate to severe plaque psoriasis include adalimumab (Humira), alefacept (Amevive), etanercept (Enbrel), infliximab (Remicade), and ustekinumab (Stelara). None of these drugs should be used by patients who are pregnant or breast-feeding ([Chart 27-11](#)).

Teach the patient or caregiver to administer injectable drugs. Demonstrate the proper techniques for drawing up the drug aseptically, selecting an appropriate site, and performing the actual injection. Have the patient or caregiver perform a return demonstration. Reinforce correct techniques, and help the patient or caregiver practice until he or she is proficient at the skill. Infliximab is indicated for severe, disabling psoriasis and is administered by IV infusion, usually in an outpatient infusion center or physician's office where the patient can be closely monitored during the infusion.

Other systemic treatment for the patient whose disease is resistant to topical therapy includes a cytotoxic agent, such as low-dose methotrexate (Folex, Mexate). Because of the liver-damaging side effects of methotrexate, liver studies are recommended before therapy is started and at least yearly thereafter. Small doses are usually effective in clearing the lesions. This treatment is avoided for patients who have liver damage, bone marrow suppression, or impaired kidney function. In addition, this drug is also teratogenic and should not be used during pregnancy or breast-feeding.

Additional systemic drugs that induce immunosuppression may be used when lesions do not respond to other therapies. Such agents include cyclosporine (Sandimmune) and azathioprine (Imuran). The many health risks associated with these therapies must be considered along with the potential benefits.

Emotional Support

Often patients' self-esteem suffers not only because of the presence of skin lesions but also because of the

CHART 27-11 COMMON EXAMPLES OF DRUG THERAPY

Plaque Psoriasis

AGENT	ROUTE	DOSE	FREQUENCY
adalimumab (Humira)	Subcutaneous	Loading dose: 80 mg Maintenance dose: 40 mg	Loading dose followed by maintenance dose every other week starting 1 week after the loading dose.
alefacept (Amevive)	Intramuscular	15 mg	Once a week for 12 weeks followed by a 12-week drug-free interval. Cycle may be repeated based on response.
etanercept (Enbrel)	Subcutaneous	50 mg	Twice weekly for 3 months followed by once-a-week injections.
infliximab (Remicade)	Intravenous	5 mg/kg	Infusions at 0, 2, and 6 weeks, then every 8 weeks.
ustekinumab (Stelara)	Subcutaneous	90 mg	Initial dose 90 mg; second dose 4 weeks later Maintenance injections of 90 mg subcutaneously every 12 weeks starting at week 16 after initial dose.

unpleasantness of some of the treatments. Tar not only looks dirty but also has a very unpleasant odor. Bed linens and pajamas become stained, further discouraging social interaction.

Encourage the patient and family members to express their feelings about having an incurable skin problem that can alter appearance. Urge patients to contact other people with the disorder. Group discussions with family members or significant others can increase the socialization process.

The use of touch takes on an added significance for patients with psoriasis. For example, shake the patient's hand during an introduction or place a hand on the patient's shoulder when explaining a procedure. *Do not wear gloves during these social interactions. Touch, more than any other gesture, communicates acceptance of the person and the skin problem.*

NCLEX EXAMINATION CHALLENGE**Health Promotion and Maintenance**

Which precaution is most important for the nurse to teach a client prescribed adalimumab (Humira)?

- A. Drinking a full glass of water when taking each drug dose
- B. Reducing the drug dosage when psoriasis symptoms decrease
- C. Reporting symptoms of infection to the prescriber immediately
- D. Avoiding sunlight and tanning beds for the duration of drug therapy

BENIGN TUMORS**Cysts**

Cysts are firm, flesh-colored nodules that contain liquid or semisolid material. Unlike cancerous growths, which are hard and firmly attached to underlying structures, a cyst moves and indents on palpation. Often there is a central pore through which the material can be expressed if the lesion is squeezed.

The most common cyst is an epidermal inclusion cyst. These growths are often asymptomatic and can be located anywhere, but they occur most often on the head and trunk. The most common cyst on the scalp is the sebaceous (pilar) cyst.

If the patient wants to have a cyst removed for any reason, surgical excision with primary closure is performed with a local anesthetic agent. The surgeon removes the entire cyst wall during excision to prevent recurrence.

FIG. 27-12 Seborrheic keratosis.

A **pilonidal cyst** is a lesion of the sacral area that often has a sinus track extending into deeper tissue structures. As this cyst fills or becomes infected, it can become tender. An incision and drainage can be performed, but the cyst is likely to refill. The cure for this cyst is surgical removal, and the area heals by second intention, which may take 4 to 8 weeks.

Seborrheic Keratoses

Seborrheic keratoses are a common problem of older people. These benign epidermal neoplasms are gradually acquired after middle age and are often mistaken for actinic keratoses or pigmented skin cancers. They may occur anywhere but are more commonly found on the face, neck, upper trunk, and arms.

On inspection, seborrheic keratoses appear as multiple “pasted-on” papules or plaques ranging in color from flesh tones to brown or black (Fig. 27-12). The surface of the lesion has a rough, greasy, wartlike texture on palpation.

Seborrheic keratoses are removed only for cosmetic reasons or if a lesion becomes irritated from friction. Cryosurgery or curettage is performed.

Keloids

A keloid is overgrowth of a scar with an excessive accumulation of collagen and ground substance. Keloids are more common in darker-skinned people and often arise at sites of surgical incisions, burns, and ear piercing (Fig. 27-13).

On physical examination, a keloid is an elevated, protruding lesion that extends beyond the edges of the original injury. These lesions can be cosmetically disfiguring. Treatment is

TABLE 27-6 COMMON SKIN CANCERS

CLINICAL MANIFESTATIONS	DISTRIBUTION	COURSE
Actinic Keratosis (Premalignant) Small (1-10 mm) macule or papule with dry, rough, adherent yellow or brown scale Base may be erythematous Associated with yellow, wrinkled, weather-beaten skin Thick, indurated keratoses more likely to be malignant	Cheeks, temples, forehead, ears, neck, backs of hands, and forearms	May disappear spontaneously or reappear after treatment. Slow progression to squamous cell carcinoma is possible.
Squamous Cell Carcinoma Firm, nodular lesion topped with a crust or with a central area of ulceration Indurated margins Fixation to underlying tissue with deep invasion	Sun-exposed areas, especially head, neck, and lower lip Sites of chronic irritation or injury (e.g., scars, irradiated skin, burns, leg ulcers)	Rapid invasion with metastasis via the lymphatics occurs in 10% of cases. Larger tumors are more prone to metastasis.
Basal Cell Carcinoma Pearly papule with a central crater and rolled, waxy borders Telangiectasias and pigment flecks visible on close inspection	Sun-exposed areas, especially head, neck, and central portion of face	Metastasis is rare. May cause local tissue destruction. 50% recurrence rate related to inadequate treatment.
Melanoma Irregularly shaped, pigmented papule or plaque Variegated colors, with red, white, and blue tones	Can occur anywhere on the body, especially where nevi (moles) or birthmarks are evident Commonly found on upper back and lower legs Soles of feet and palms in dark-skinned people	Horizontal growth phase followed by vertical growth phase. Rapid invasion and metastasis with high morbidity and mortality.

FIG. 27-13 A keloid.

difficult and not always successful. Small lesions may be controlled with intralesional steroid injections. Because surgical excision alone can result in an even larger scar, surgery is usually combined with another form of therapy, such as intralesional steroid injections or low-dose radiotherapy. Pressure dressings or elastic garments worn over the skin for 1 year after excision or steroid injection may also help keep the lesion flat.

Nevi

A **nevus**, or mole, is a benign growth of the pigment-forming cells. These lesions are classified according to their location within the layers of the skin.

Normal nevi have regular, well-defined borders and are uniform in color, ranging from light colors to dark brown. The lesion's surface may be rough or smooth. Because about 50% of malignant melanomas arise from moles, nevi with irregular or spreading borders and those with multiple colors should be considered highly suspicious. Other abnormal findings include sudden changes in the size of the lesion and reports of itching or bleeding.

Unsightly nevi or those subject to repeated irritation or trauma can be removed. Biopsy of any suspicious lesions is performed to rule out malignancy.

SKIN CANCER

Pathophysiology

Overexposure to sunlight is the major cause of skin cancer, although other factors are associated. Because sun damage is an age-related skin finding, screening for suspicious lesions is an important part of physical assessment of the older adult. The most common skin cancers are actinic or solar keratosis, squamous cell carcinoma, basal cell carcinoma, and melanoma. Table 27-6 describes common skin cancers.

Etiology and Genetic Risk

Actinic keratoses are premalignant lesions of the cells of the epidermis. These lesions are common in people with chronically sun-damaged skin. Progression to squamous cell carcinoma may occur if lesions are untreated.

Squamous cell carcinomas are cancers of the epidermis. They can invade locally and are potentially metastatic. Lesions on the ear, lip, and external genitalia are more likely to invade and spread than those found elsewhere on the body.

FIG. 27-14 Squamous cell carcinoma.

FIG. 27-15 Basal cell carcinoma.

FIG. 27-16 Melanoma.

(Fig. 27-14). Chronic skin damage from repeated injury or irritation also predisposes to this malignancy.

Basal cell carcinomas arise from the basal cell layer of the epidermis (Fig. 27-15). Early malignant lesions often go unnoticed, and although metastasis is rare, underlying tissue destruction can progress to include vital structures. Genetic predisposition and chronic irritation are risk factors; however, UV exposure is the most common cause.

Melanomas are pigmented cancers arising in the melanin-producing epidermal cells (Fig. 27-16). Risk factors include genetic predisposition, excessive exposure to UV light, and the presence of one or more precursor lesions that resemble

CHART 27-12 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Prevention of Skin Cancer

- Avoid sun exposure between 11 AM and 3 PM.
- Use sunscreens with the appropriate skin protection factor for your skin type.
- Wear a hat, opaque clothing, and sunglasses when you are out in the sun.
- Keep a “body map” of your skin spots, scars, and lesions to detect when changes have occurred.
- Examine your body monthly for possibly cancerous or precancerous lesions.
- Seek medical advice if you note any of these:
 - A change in the color of a lesion, especially if it darkens or shows evidence of spreading
 - A change in the size of a lesion, especially rapid growth
 - A change in the shape of a lesion, such as a sharp border becoming irregular or a flat lesion becoming raised
 - Redness or swelling of the skin around a lesion
 - A change in sensation, especially itching or increased tenderness of a lesion
 - A change in the character of a lesion, such as oozing, crusting, bleeding, or scaling

unusual moles. *This skin cancer is highly metastatic, and a person's survival depends on early diagnosis and treatment.*

Lighter skin and less pigmentation are genetically inherited traits. Also, a genetic mutation that is inherited in an autosomal-dominant pattern has been found for some cases of familial melanoma. The mutation occurs in a suppressor gene resulting in loss of control of cell growth. Two such mutated genes are *CDKN2A*, *CDK4*, and *BRAF*.

Incidence/Prevalence

The incidence of skin cancer is highest among light-skinned races and people older than 60 years (American Cancer Society, 2011). The incidence is higher among those who work outdoors, live at higher altitudes or lower latitudes, or spend significant amount of time sunbathing. Occupational exposure to arsenic or other chemical carcinogens also increases risk. The incidence of melanoma has increased during the past 30 years, accounting for 2% of all cancers and 1% of all cancer deaths (American Cancer Society, 2011).

Health Promotion and Maintenance

The single most effective prevention strategy for skin cancer is avoiding or reducing skin exposure to sunlight. However, even when people understand the cause of skin cancer and the seriousness of the disease, preventive behaviors are not always practiced. Common prevention practices include avoiding direct sunlight, using sunscreen, and wearing protective clothing (including hats) whenever a person is in the sun to prevent severe sunburn. *Teach all people to avoid tanning beds and salons.* Chart 27-12 lists methods of prevention to reduce the risk for skin cancer (McEnroe-Petitte, 2011).

Secondary prevention, early detection, is critical to survival with melanoma. Teach all people to be aware of their skin markings. Keeping a total body spot and lesion map can provide baseline information about suspicious lesions and help identify changes in a lesion or lesions earlier. Once a

map is made, the person should systematically inspect his or her body monthly for new lesions and for changes in any existing lesions by performing *thorough skin self-examination (TSSE)*. Often a partner is needed to help evaluate skin spots or lesions on the back. Some people find taking pictures of their skin on a regular basis makes identifying changes easier. Teach everyone to evaluate all skin lesions using the ABCDE guide for melanoma (see [Chapter 26](#)) and to consult his or her health care provider to examine any lesion having unusual characteristics. When lesions, such as moles, are present, they should be monitored yearly by a dermatologist or other health care professional.

Monthly TSSE is critically important for patients who have already had a melanoma lesion. A major positive influence for TSSE practice is working with a partner in this examination.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

In addition to age and race, ask the patient about any family history of skin cancer and any past surgery for removal of skin growths. Recent changes in the size, color, or sensation of any mole, birthmark, wart, or scar are also significant. Ask about which geographic regions he or she has lived in and where he or she currently resides. Obtain information about occupational and recreational activities in relation to sun exposure, as well as any occupational history of exposure to chemical carcinogens (e.g., arsenic, coal tar, pitch, radioactive waste, radium). Ask whether any skin lesions are repeatedly irritated by the rubbing of clothing.

Skin that has been injured previously is at greater risk for cancer development, an effect known as *Koebner's phenomenon*. Ask the patient if he or she has ever experienced a severe skin injury that resulted in a scar. Examine all scarred skin areas for the presence of potentially cancerous lesions.

Skin cancers vary in their appearance and distribution. Although most skin cancers appear in sun-exposed areas of the body, inspect the entire skin surface. Systematically examine the skin for any unusual lesions, particularly moles, warts, birthmarks, and scars. Also examine hair-bearing areas of the body, such as the scalp and genitalia. Palpate lesions to determine surface texture. Document the location, size, color, and surface features of all lesions and any subjective reports of tenderness or itching. Use the ABCDE method of evaluating all lesions for possible melanoma (see [Chapter 26](#)).

[Table 27-6](#) lists facts about common skin cancers. Punch, shave, or excisional biopsy of suspicious lesions is necessary to determine whether a skin lesion is benign or malignant.

INTERVENTIONS

Surgical and nonsurgical interventions are combined for the effective management of skin cancer. Treatment is determined by the size and severity of the malignancy, the location of the lesion, and the age and general health of the patient.

Surgical Management

Surgical intervention is the most common means of managing any type of skin cancer. It can range from local removal

of small lesions, with minimal discomfort and positive cosmetic results, to massive excision of large areas of the skin and underlying tissue for treatment of melanoma.

Cryosurgery involves the local application of liquid nitrogen (-200°C) to isolated lesions, causing cell death and tissue destruction. Local anesthesia is seldom needed because most patients have only minor discomfort during the procedure. Prepare patients for swelling and increased tenderness of the treated area when the skin thaws. Tissue freezing is followed in 1 to 2 days by hemorrhagic blister formation. Instruct patients to clean the sites with hydrogen peroxide to prevent infection. A topical antibiotic may also be prescribed.

Curettage and electrodesiccation may be used for small lesions that are not melanoma. This method can destroy the cancerous cells while minimizing damage to the surrounding uninvolved tissue. After a local anesthetic is given, the surgeon uses a dermal curette to scrape away the cancerous tissue. After curettage is complete, the surgeon places an electric probe on the wound and remnants of the tumor are destroyed by thermal energy.

Wounds created by this treatment heal by second intention, and scarring is usually minimal. Instruct patients in caring for the wound, including cleaning the wound, using prescribed antibacterial drugs, and applying dressings.

Excision is used for biopsy of small lesions. When the diagnosis is melanoma, a sentinel node may be biopsied to determine whether tumor spread has started. If the size and location of the lesion permit, surgical excision with primary closure is the preferred method. If the tumor has already been removed several times or if radiation therapy has damaged the surrounding skin, healing by second intention is indicated. This procedure allows the wound to be monitored for cancer recurrence. Skin grafts and flaps are used to repair large defects if tissue destruction is deep.

Mohs' surgery, a specialized form of excision, is used to treat basal and squamous cell carcinomas. The cancerous tissue is sectioned horizontally in layers, and each layer is examined histologically to determine the presence of residual tumor cells. Although the procedure is long and tedious, cure rates are high and there is less removal of healthy tissue compared with other surgical methods.

Wide excision for deeper melanoma or other skin cancers that are large or invasive often involves removing full-thickness skin in the area of the lesion. Depending on tumor depth, subcutaneous tissues and lymph nodes may also be removed. If the remaining skin is easily moved without creating extensive tension, the wound may be just sutured closed. If the remaining skin is tight or the wound is large, skin grafts may be needed to close the surgical wound (see earlier discussion on pp. 487-488).

Nonsurgical Management

Drug therapy may involve topical or systemic chemotherapy, biotherapy, or targeted therapy. Topical chemotherapy with 5-fluorouracil cream is used for treatment of multiple actinic keratoses or for widespread superficial basal cell carcinoma that would require several surgical procedures to eradicate. Therapy is continued for several weeks, and the treated areas become increasingly tender and inflamed as the lesions crust, ooze, and erode. Prepare the patient for an unsightly appearance during therapy, and reassure him or her that the cosmetic result will be positive.

After treatment is discontinued, cool compresses and topical corticosteroid preparations help decrease inflammation and promote comfort.

Systemic chemotherapeutic agents are used in the treatment of skin cancer except when the prognosis is poor, as in advanced melanoma.

Biotherapy with interferon is now an accepted treatment after surgery for melanomas that are at stage III or higher. The patient is first started on high-dose (20,000,000 units/m²) IV interferon infusions daily for 5 days per week for 4 weeks after the surgical wound is well healed. Maintenance doses of 10,000,000 units/m² are continued three times per week for 1 year. The maintenance doses are given subcutaneously, and the patient must learn to self-inject the drug.

Agents that target lymphocyte control of tumor cell growth may be used for treatment of metastatic melanoma. The approved drug ipilimumab (Yervoy) and the experimental drug tremelimumab target the *CTLA4* (cytotoxic T-lymphocyte–associated antigen 4) receptor and block it, resulting in greater activity of the lymphocyte. This allows the lymphocyte to attack melanoma cells. Because the receptor is present on certain lymphocytes, the side effects of these drugs include significant inflammation in many tissues (Rubin, 2009; Aschenbrenner, 2011).

Radiation therapy for skin cancer is limited to older patients with large, deeply invasive basal cell tumors and to those who are poor risks for surgery. Melanoma is resistant to radiation therapy; however, radiation therapy may be helpful for patients with metastatic disease when used in combination with systemic corticosteroids.

PLASTIC OR RECONSTRUCTIVE SURGERY

Pathophysiology

The two main types of plastic surgery are aesthetic and reconstructive. **Aesthetic plastic surgery** is cosmetic, with the aim of altering a person's physical appearance. This intervention is sought by those who are unsatisfied with their body image. These procedures are considered elective surgery and are not covered by insurance. They can be very expensive and are most often performed among more affluent people. **Reconstructive plastic surgery** is the correction or improvement of functional defects that have occurred as a result of congenital problems (e.g., cleft lip, syndactyly [webbed fingers or toes]) or trauma and scarring (e.g., skin and joint contractures from burn wounds) or from other types of therapy (e.g., mastectomy for breast cancer therapy). These interventions are sought by patients who cannot perform ADLs as a result of an anatomic problem; the cost is often covered by insurance.

In the United States, the decision to undergo plastic surgery is often a response to social and cultural norms about beauty. Patients become self-conscious about scars, facial lesions, disproportionate anatomic features, or, especially, changes in physical features associated with aging. Loss of skin elasticity and changes in fatty tissue distribution are progressive and especially noticeable around the eyes, near the cheeks, and on the neck. Fine facial wrinkles around the eyes and mouth are one of the first signs of aging. These changes are followed by gradual stretching and downward displacement of the soft tissue of the lower two thirds of the face. Similar changes are seen as skin wrinkling and looseness

on the arms, chest, abdomen, buttocks, and thighs. These changes are also seen after dramatic weight loss. Skin lesions associated with chronic sun exposure also may trouble the aging patient.

Other people may want to change a physical detail associated with specific cultural identity. For example, people have changed eyelid shape, nose size and shape, and lip shape to conform to a more “Caucasian” appearance. Still other people have undergone surgery to increase their sense of belonging to a specific ethnic group. For example, African-American women may have aesthetic surgery to increase the size of their buttocks to conform to cultural norms about beauty and sexuality in the African-American community.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

When taking a history from a patient who elects to have plastic surgery, use a nonjudgmental approach and be careful not to assume the reason for surgery on the basis of physical appearance. Often what might appear to be unsightly to you is of little concern to the patient, who wishes to change something else. Observe for any nonverbal communication that might establish the emotional state of the person or reveal feelings of embarrassment or guilt. Encourage the patient to describe the problem, including why it is bothersome and what he or she expects as a result of the change. Ask about his or her health history and recent medical problems, including obesity and trauma, to predict the amount of surgery needed to correct the defect and potential complications.

Physical Assessment/Clinical Manifestations

The patient seeking plastic surgery may have changes in appearance ranging from minor to significant deformity. Depending on the location of the problem, the patient may need to undress before the examination. Ensure privacy because the patient may be embarrassed by the problem.

Begin the physical assessment by closely examining the area of involvement to determine the extent of the deformity or problem. Have the patient assume different normal sitting and standing postures to provide better visibility of nonfacial defects. Document asymmetry of anatomic features, wrinkling or skin redundancy, scars or disfiguring skin marks, and obvious skin lesions.

Psychosocial Assessment

Regardless of whether a person is having reconstructive surgery or cosmetic surgery, body image and sense of self are always involved. These feelings often evoke emotional responses in the person, including shame, anger, resentment, and desperation. A person seeking reconstruction may have felt “different” from other people his or her entire life. A person seeking cosmetic surgery may face ridicule from family or friends about his or her perceived vanity. Use a sensitive, nonjudgmental approach when interacting with the person having or considering plastic surgery. It is important to recognize your own feelings regarding these procedures and to avoid being directive or expressing your own opinions.

Often a patient who asks the nurse “Do you think I need this surgery?” is not comfortable with his or her decision.

Assess the patient for his or her sense of self and self-worth. Note whether he or she makes eye contact with you during the interview. Does the patient make any self-deprecating remarks or use the terms *ugly*, *stupid*, or *not sexy* when referring to himself or herself? If such remarks are made, ask him or her to clarify what is meant. Report concerns to the surgeon.

Address the patient’s expectations of plastic surgery. Often people who seek plastic surgery have unrealistic expectations or are uncertain about what they actually want. For example, the patient with minor deformities who is seeking perfection is sure to be disappointed. The patient who wants an operation mainly to please the spouse or partner is also a poor candidate. His or her psychological outlook before surgery should be positive if results are to be therapeutic.

INTERVENTIONS

Nonsurgical Management

Many techniques to improve skin and general appearance without surgery are available. Some are more invasive than others and have a higher risk for complications. Superficial techniques for skin enhancement include chemical peels, laser resurfacing, and dermabrasion to remove or reduce small scars, fine lines, and other irregular skin surfaces. Dermal filling involves injecting substances to change the contour of a feature or an area. Generally, these fillers replace the collagen lost from the skin through aging. Common fillers include collagen, hyaluronic acids, acrylic hydrogels, and purified human connective tissue (Czerkasij, 2010). Injection with nerve paralyzing agents (e.g., Botulinum Toxin Type A) can improve appearance temporarily by relaxing muscles beneath the skin surface, which smoothes out some wrinkles and grooves.

Surgical Management

Patients considering cosmetic surgery or reconstructive surgery should “shop” for a reputable surgeon who is certified through the American Board of Plastic Surgery. Not all physicians who are “board certified” are actually certified in this specialty. The patient should meet with the physician who will actually perform the surgery and request referrals to previous patients who have already undergone a similar surgery. It is also a good idea for the patient to contact the state medical board to determine whether the surgeon has had complaints lodged against him or her.

Depending on the planned intervention, surgery is performed either in the outpatient setting with the patient under local anesthesia or in the hospital. Most patients scheduled for plastic surgery have had consultations with their surgeon to discuss the planned intervention, possible complications, and postoperative expectations. The types and complications of common cosmetic procedures are listed in Table 27-7.

Many plastic surgeons use digital imaging both as a visual aid when discussing patients’ problems and as a means of documenting before and after surgical intervention. The patient can be shown how the surgery is likely to alter his or her appearance. Pictures taken of patients are confidential. Showing patients pictures of other patients is done only after proper consent is obtained.

Preoperative Care. The most important nursing action before surgery is teaching the patient what to do before and after surgery to prevent complications and increase the chances for a good outcome. All plastic surgery has a risk for complications and failure. When changing the skin and subcutaneous tissue, the skin is loosened from its connections. This causes bleeding, inflammation, and the potential for failure of the tissues to reattach properly. Teach the patient actions to reduce the risk for bleeding and failure of tissue reattachment. These include not smoking or using nicotine in any form because it causes blood vessel constriction and reduces blood flow to the area, delaying attachment and healing. Because of the large amount of blood loss associated with skin (particularly facial) surgery, teach the patient to avoid aspirin and other NSAIDs for several weeks before and after the procedure. Remind patients that bruising and swelling can be extensive and that one or more drains in the surgical area may be used to reduce these problems. Hypertension can change blood flow to the skin of the head and neck. Teach the patient with hypertension the importance of maintaining good blood pressure control by adhering to his or her prescribed therapy.

For any plastic surgery, it is important to prevent excessive swelling or skin movement in the operative area. Remind the patient that certain positions and activities may need to be limited after surgery. Stress the importance of following the surgeon’s instructions in order to have the best outcome.

Immediate preoperative care is focused on collection of any routine laboratory test data required before general anesthesia and preparation of the operative site. In most cases, the procedure for shaving and washing the skin is dictated by the surgeon’s preference.

Patients undergoing facial surgery, specifically **rhytidectomy** (facelift), are often asked to wash their hair several times with antibacterial soap to decrease bacterial flora near the incision site. Instruct patients to remove any makeup and to avoid using face creams before surgery. If a **rhinoplasty** (reconstruction of the nose) is scheduled, explain the need for nasal packing and review mouth-breathing techniques.

Operative Procedures. Reconstructive procedures vary depending on the location, purpose, and extent of reconstruction. Ironically, in performing plastic surgery, the surgeon must make a wound to correct existing skin deformities.

Postoperative Care. General care after surgery focuses on monitoring for typical postoperative complications (see Chapter 18). Pressure dressings may be applied at the time of surgery and left in place for several days to control hemorrhage and edema formation. Check dressings and any nasal packing for bright red bleeding, and monitor changes in vital signs and level of consciousness indicating active hemorrhage.

Repeated swallowing followed by belching after rhinoplasty is a sign of postnasal bleeding and needs to be reported immediately to the surgeon. The patient who has had breast surgery may have drains in place after surgery. Monitor the amount and color of drainage.

Place the patient who has had any facial reconstruction in a semi-Fowler’s position to reduce edema and promote comfort. Use lightweight cold compresses to reduce swelling. Check drains to ensure they are unobstructed. Assess for swelling and bruising every 2 hours. Document assessment

TABLE 27-7 COMMON PLASTIC SURGERY PROCEDURES

DESCRIPTION	INDICATIONS	COMPLICATIONS
Blepharoplasty Excision of bulging fat and redundant skin of the periorbital area with primary closure	Bags under the eyes	Hematoma Ectropion Corneal injury Visual loss (rare) Wound infection (rare)
Breast Augmentation (Augmentation Mammoplasty) Insertion of synthetic breast-shaped implants through a skin incision	Inadequate breast volume or contour	Hematoma or hemorrhage Wound infection (with gram-positive organisms) Phlebitis
Breast Reduction (Reduction Mammoplasty) Excision of excessive breast tissue and skin with primary closure	Hypertrophy of breast tissue caused by elevated hormone levels, endocrine abnormalities, or obesity Weight of large breasts can contribute to back pain	Hematoma or hemorrhage Nipple, areola, and skin flap necrosis Wound infection Fat necrosis Wound dehiscence
Dermabrasion Abrasive removal of the facial epidermis and portion of the dermis followed by healing by second intention	Moderate to severe acne scar Deep wrinkling Multiple actinic keratoses Hyperpigmentation (postinflammatory or after the use of estrogens)	Hypertrophic scarring Altered skin pigmentation Acne flare Wound infection (rare)
Rhinoplasty Removal of excessive cartilage and tissue from the nose with correction of septal defects if indicated	Disproportionate anatomy Post-traumatic nasal deformity Difficulty breathing through the nose	Hematoma or hemorrhage Ecchymosis and edema (temporary) Wound infection (with gram-positive organisms) Septal perforation Minor skin irritation
Rhytidectomy (Facelift) Removal of excess skin and tissue from the face at the level of the hairline followed by primary closure	Excessive wrinkling or sagging of facial skin	Hematoma or hemorrhage Facial nerve damage (temporary or permanent) Wound infection Ecchymosis and edema (temporary) Skin necrosis Hair loss
Liposuction (Suction Lipectomy) Removal of subcutaneous fat from localized areas of accumulation such as the hips, abdomen, neck, and arms	Disproportionate distribution of adipose tissue	Hematoma Severe pain Infection Emboli Sagging of skin (if skin is not elastic enough to contract after fat removal)

findings. Remind patients not to increase pressure in the head and neck region, by:

- Staying in an upright position
- Avoiding facial movement such as chewing, talking, smiling
- Avoiding bending over, blowing the nose, sneezing with the mouth closed
- Not bearing down to have a bowel movement

Support garments are used after breast augmentation surgery to reduce edema and tension on the suture line from the weight of the breast tissue. With abdominal reduction surgery, teach the patient to keep the hips flexed to reduce tension on the suture line and to promote tissue attachment.

Monitor for wound infection and progress toward healing. Of particular concern are any areas of skin necrosis or eschar

formation near the operative site—a complication from excessive tension on the suture line as a result of edema and blood vessel obstruction. [Chart 27-5](#) lists wound monitoring criteria.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

In which position does the nurse place the client immediately after a rhytidectomy to promote venous return and prevent swelling?

- Fowler's
- Lithotomy
- Lateral Sims'
- Trendelenburg

Regardless of the planned procedure, inform the patient to expect edema and discoloration of the operative site. Swelling and bruising alter the facial features and may not resolve for several weeks after surgery. Remind the patient that the true results of surgery will not be visible until healing is complete—usually 6 months to a year or longer after surgery. During this healing time, the patient may become discouraged. Refer him or her to a support group for encouragement (e.g., Cosmetic Surgery and Body Transformation Support Site [www.cosmeticsupport.com]).

OTHER SKIN DISORDERS

Acne

Acne is a red, pustular eruption that affects the sebaceous glands of the skin. It is a common condition that, despite popular belief, is not confined to adolescents. Lesions result from increased sebum production, which is stimulated by androgenic hormones and obstruction of the sebaceous canal outlet. Debris collection promotes bacterial growth and rupture of the gland into the surrounding dermis with inflammation.

Acne is a progressive disorder that manifests as several types of skin lesions, including noninflammatory **comedones** (blackheads and whiteheads), inflammatory papules, pustules, and cysts. These lesions are usually present only on the face and upper trunk.

Control of acne is possible, with spontaneous remission occurring over time. However, severe eruptions or chronic inflammation can lead to extensive scarring.

For patients with superficial lesions, topical agents (retinoic acid, benzoyl peroxide, antibiotic solutions) are used. Systemic antibiotics are indicated for those with cystic inflammatory disease. Patients with severe acne may have improvement after receiving isotretinoin (Accutane, Accutane Roche ♣). Side effects include elevated liver function test results; dry, chapped skin; and depression in some patients. The most important concern, however, is the **teratogenic** (inducement of birth defects) effect of this drug or any systemic retinoic acid. A pregnancy test is required before therapy, and strict birth control measures must be used during therapy.

Lichen Planus

Lichen planus is a common skin disorder of purple, flat-topped papules that itch. Although viral infections and emotional stress may be possible causes, the actual etiology of lichen planus is not known. The course of the disease can be chronic, or it can resolve spontaneously.

Lesions of lichen planus usually occur over the wrists and the inner surfaces of the forearms, but they may be present also on the lower legs, genitalia, and other body areas. Oral lesions may occur alone or with other skin changes. Unlike the skin lesions, oral lesions have a white, lacelike appearance. These lesions usually occur on the oral mucosa and are often confused with thrush.

Treatment is determined by the symptoms. Topical steroids help reduce inflammation, and antihistamines help relieve itching. Systemic steroids may be prescribed when lesions are widespread, but long-term use is avoided because of the side effects.

Pemphigus Vulgaris

Pemphigus vulgaris is a rare, chronic, blistering disease with high morbidity and mortality. It is caused by an autoimmune disorder that occurs most often during middle and old age.

The acute lesions occur on normal-appearing skin or mucous membrane surfaces as fragile, flaccid bullae (large blisters). Breaking the bullae leaves partial-thickness wounds that bleed, weep, and eventually form crusts.

Lesions can occur anywhere. The initial lesions usually occur on the oral mucosa, and later lesions form on the trunk. Spread of the disease is seen with the appearance of new lesions on the face and in skinfold areas while older lesions are in the process of healing. Oral lesions are common and can make chewing and swallowing difficult.

Management of pemphigus vulgaris is aimed at suppressing the immune response that causes the blister formation. Systemic steroids and cytotoxic agents are used to bring about remission. Topical antibiotic creams or ointments are used to reduce bacterial infection of the unhealed lesions.

Toxic Epidermal Necrolysis

Toxic epidermal necrolysis (TEN) is a rare acute drug reaction of the skin resulting in diffuse erythema and large blister formation. Mucous membranes are often involved, and systemic toxicity is evident. The most common causative drugs are chemotherapy agents, sulfonamides, pyrazolones, barbiturates, and antibiotics. Removal of the drug is usually followed by gradual healing in 2 to 3 weeks, with widespread peeling of the epidermis.

This problem can occur at any age and as a result of almost any drug therapy. However, older patients with cancer who are receiving chemotherapy, some targeted therapies, and immunotherapy appear to be at greatest risk (Smith, 2007). Other precipitating factors include bone marrow transplantation and neutropenia-induced infections.

The drug thought to be causing a toxic reaction is discontinued, and therapy is aimed at systemic support and prevention of secondary infection. Patients with TEN are often admitted to burn units, where fluid and electrolyte balance, caloric intake, and hypothermia can be closely monitored. Topical antibacterial agents are used to suppress bacterial growth until healing occurs. Systemic steroids are avoided because of the increased risk for infection.

Stevens-Johnson Syndrome

Stevens-Johnson syndrome is often a drug-induced immunologic skin reaction similar to toxic epidermal necrolysis (TEN). The disorder may be mild with only local skin involvement, or it may be severe and systemic. The skin lesions are widely distributed (including oral and respiratory mucous membranes) and varied in appearance (Fig. 27-17). The patient has a mix of vesicles, erosions, and crusts. With severe involvement, the patient may have respiratory problems, excessive fluid loss, acute kidney injury, and blindness.

Removal of the offending drug is critical. Mild forms of the disorder are usually self-limiting in 10 to 14 days unless the episode was triggered by a bacterial infection. Then, antibiotics are needed (Holcomb, 2007). Severe manifestations require high doses of steroids to suppress the immune and inflammatory reactions. Supportive care may include fluid replacement, mechanical ventilation, and even renal replacement therapy.

FIG. 27-17 Stevens-Johnson syndrome.

Leprosy

Leprosy (Hansen's disease) is a chronic, contagious, systemic mycobacterial infection of the peripheral nervous system with skin involvement. Although uncommon in the United States, the disease remains a problem in many parts of the world. Most cases in the United States are reported in Florida, Louisiana, Texas, New York, California, and Hawaii. The exact mechanism of infection remains unknown. Studies suggest transmission via the airborne route, by insects, or through direct contact with skin lesions. The clinical course of the disease is either progressive or self-limiting, depending on the immune status of the host.

Manifestations of leprosy, including skin changes, are directly related to how resistant the patient is to the mycobacteria:

- Localized (high-immunity) leprosy—one or two isolated, red, anesthetic, hairless plaques that are sometimes scaly
- Generalized (low-immunity) leprosy—widespread, faintly red macules, papules, nodules, and plaques
- Varying degrees of reduced skin sensation of the lesions are caused by peripheral nerve damage

Treatment is available on an outpatient basis to control bacterial growth and reduce physical deformities. The most common treatment is a 6- to 12-month course of multiple drug therapy with dapsone (DDS; Avlosulfon), rifampin (Rifadin, Rimactane), clofazimine (Lamprene), ofloxacin (Floxin), and minocycline (Dynacin, Minocin) ([World Health Organization, 2010](#)). Other agents that also show some effectiveness include levofloxacin (Levaquin), sparfloxacin (Zagam), and clarithromycin (Biaxin).

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing inadequate protection as a result of loss of skin integrity?

- Open skin areas
- Possible presence of drainage
- Sensation changes in or around the area (patient reports pain, itching, or tightness)

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate protection as a result of loss of skin integrity?

Perform and interpret physical assessment, including:

- Assessing the wound for pain, size, depth, drainage, and presence of infection
- Assessing the skin immediately surrounding the wound for redness and swelling
- Monitoring oxygen saturation by pulse oximetry in the affected extremity (if the open area is on an extremity)
- Assessing the patient for risk factors for wound development (pressure, shear, immobility, reduced cognition, poor nutrition, advanced age, incontinence)

- Assessing the rest of the patient's skin (especially over bony prominences, between skinfolds, in the perineal area)

Respond by:

- Documenting wound features
- Cleansing the wound (obtaining cultures, if within agency policy)
- Dressing the wound if drainage is present
- Planning a turning or repositioning schedule
- Teaching UAP or family how to relieve/reduce pressure
- Collaborating with the certified wound care specialist

On what should you REFLECT?

- Observe patient for evidence of restored skin integrity (see [Chapter 26](#)).
- Think about what may have precipitated this episode and what steps could be taken to either prevent a similar episode or identify it earlier.
- Think about what additional resources could improve the nursing response to this situation.

GET READY FOR THE NCLEX® EXAMINATION!**KEY POINTS**

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Assist all patients with limited mobility to change positions at least every 2 hours while awake.
- Evaluate the pressure ulcer risk for all patients on admission and regularly thereafter.
- Be proactive in the use of pressure-relieving devices for any patient who is identified to be at risk for pressure ulcer formation (i.e., requires prolonged bedrest, is an older adult, has some degree of immobility, is incontinent, has some degree of malnutrition, is dehydrated, has decreased sensory perception, or has an altered mental state).
- Wash your hands before and after touching any skin lesions.
- Use Standard Precautions when providing care to a patient who has any areas of nonintact skin.
- Use a lift sheet or mechanical lift to move immobilized older patients rather than pulling or dragging them across bed linens.

Health Promotion and Maintenance

- Encourage all patients to reduce sun exposure and exposure to ultraviolet (UV) light.
- Teach patients how to examine all skin areas on a monthly basis for new lesions and changes to existing lesions. They should keep a record or “body map” of skin lesions.
- Teach patients who have skin scarring from a previous skin injury to examine this area at least monthly for changes related to cancer development or chronic skin conditions.
- Urge all patients to bathe, shampoo the hair, and keep fingernails clean and trimmed on a regular basis.
- Teach all patients the ABCDE method of evaluating a lesion for melanoma.

- Keep the skin of patients who are incontinent clean and dry.
- Ensure that women in their childbearing years who are receiving teratogenic drug therapy for a skin problem understand the effects of this therapy and adhere to strict contraception measures during treatment.

Psychosocial Integrity

- Allow the patient the opportunity to express feelings about a change in body image as a result of changes in the skin, hair, or nails.
- Explain all procedures, restrictions, drugs, and follow-up care to the patient and family.
- Touch the patient who has skin problems to show acceptance.
- Ask the patient who plans to have plastic surgery what he or she expects as a result of the surgery.

Physiological Integrity

- Keep skinfold areas on patients clean and dry.
- Ask any patient who has started taking a newly prescribed drug if he or she has noticed whether any skin changes have occurred since starting the drug.
- Avoid rubbing any area of the skin that has been subjected to pressure.
- Encourage patients with itching to avoid scratching the skin.
- Teach patients to avoid using over-the-counter cortisone preparations on skin lesions until the cause has been identified.
- Teach patients who have a skin infection how to avoid spreading the infection to other parts of their own bodies and to other people.
- Evaluate any open skin area on a patient daily for size, depth, exudate, presence of infection, and indicators of healing.

Care of Patients with Burns

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Apply the principles of asepsis to protect burn patients with open wounds.
2. Manage the patient's environment to prevent infection from auto-contamination and cross-contamination in patients with burn injuries.

Health Promotion and Maintenance

3. Teach everyone fire prevention strategies.
4. Instruct everyone on the correct use and placement of smoke detectors and carbon monoxide detectors.

Psychosocial Integrity

5. Support the patient and family in coping with permanent changes in appearance and function.
6. Encourage the burn patient with wounds and scars to participate in self-care.
7. Assess the patient's and family's use of coping strategies related to burn injury, treatment, possible role changes, and possible outcomes.
8. Allow patients who have lost family members, homes, or jobs time to grieve for these losses.

Physiological Integrity

9. Identify burn patients at risk for inhalation injury.
10. Compare the manifestations of superficial, partial-thickness, and full-thickness burn injuries.

11. Explain the expected manifestations of neural and hormonal compensation during the resuscitation phase of burn injury.
12. Prioritize nursing care for the patient during the resuscitation phase of burn injury.
13. Use laboratory data and clinical manifestations to determine the effectiveness of fluid resuscitation during the resuscitation phase of burn injury.
14. Prioritize nursing care for the patient during the acute phase of burn injury.
15. Coordinate with the registered dietitian to meet the nutritional needs for the patient during the acute phase of burn injury.
16. Evaluate the patient's wound healing during the acute phase of burn injury.
17. Compare pain management strategies for patients in the resuscitation and acute phases of burn injury.
18. Describe the characteristics of infected burn wounds.
19. Use appropriate positioning and range-of-motion interventions for prevention of mobility problems in the patient with burns.
20. Coordinate nursing care for the patient during the rehabilitation phase of burn injury.

Patients who have burn injuries develop many physiologic, metabolic, and psychological changes. Burn injuries can range from a “sunburn” to major injuries involving all layers of the skin. When the skin is injured, inflammation and fluid loss change the function of most body systems. The burn patient needs comprehensive care for weeks to months to survive the injury, reduce complications, and return to his or her best functional status. A multidisciplinary team of health care providers is needed for best care and patient outcomes. Nurses coordinate the activities of the many professionals involved in providing the best care to burn patients.

INTRODUCTION TO THE BURN PROBLEM

Pathophysiology of Burn Injury

The tissue destruction caused by a burn injury leads to many local and systemic problems. Such problems include fluid and protein losses, sepsis, and changes in metabolic, endocrine, respiratory, cardiac, hematologic, and immune functioning. The extent of local and systemic problems is related to age, general health, extent of injury, depth of injury, and the specific body area injured. Even after healing, the burn injury may cause late complications such as contracture formation and scarring. Therefore the prevention of infection and closure of the burn wound are vitally important. A lack of or delay in wound healing is a key factor for all systemic problems and a major cause of disability and death among patients who are burned.

Skin Changes Resulting from Burn Injury

Anatomic Changes. The skin is the largest organ of the body (see Chapter 26). Each of its two major layers, the epidermis and the dermis, has several sublayers. The epidermis, the outer layer of skin, is a layer of stratified epithelial cells about 0.15 mm thick (somewhat thinner in older adults). This layer can grow back after a burn injury because the epidermal cells surrounding sweat and oil glands and hair follicles extend into dermal tissue and regrow to heal partial-thickness wounds. Together, the sweat and oil glands and the hair follicles are the *dermal appendages*. The depth of the dermal appendages varies in different body areas. The sweat and oil glands in the palm of the hand and the sole of the foot, for example, extend deep into the dermis. This allows for healing of deep burns in these areas. The epidermis has no blood vessels. Nutrients to this layer diffuse from the second layer of skin, the dermis.

The dermis is thicker than the epidermis and is made up of collagen, fibrous connective tissue, and elastic fibers. Within the dermis are the blood vessels, sensory nerves, hair follicles, lymph vessels, sebaceous glands, and sweat glands.

When burn injury occurs, skin can regrow as long as parts of the dermis are present. When the entire layer of dermis is burned, all epithelial cells and dermal appendages are destroyed and the skin can no longer restore itself. The subcutaneous tissue lies below the dermis and varies in thickness. The basement membrane, a thin, noncellular protein surface, separates the dermis from the subcutaneous tissue layer. With deep burns, the subcutaneous tissues may be damaged, leaving bones, tendons, and muscles exposed.

Functional Changes. The skin has many functions (see Table 26-1 in Chapter 26). It is a protective barrier against

injury and microbial invasion. Burns break this barrier, greatly increasing the risk for infection.

The skin also helps maintain the delicate fluid and electrolyte balance essential for life. After a burn injury, massive fluid loss occurs through evaporation. Evaporation through burn-injured skin occurs four times as rapidly as through intact skin. The rate of evaporation is in proportion to the total body surface area (TBSA) burned and the depth of injury.

The skin is an excretory organ through sweating. Full-thickness burns destroy the sweat glands, reducing excretory ability.

The sensations of pain, pressure, temperature, and touch are triggered on the skin in normal daily activities, which allows a person to react to changes in the environment. *All burn injuries are painful.* With partial-thickness burns, nerve endings are exposed, increasing sensitivity and pain. With full-thickness burns, nerve endings are completely destroyed. At first these wounds may not transmit sensation except at wound edges when a sharp stimulus is applied. Despite this destruction, patients often have dull or pressure-type of pain in these areas.

Skin exposed to sunlight activates vitamin D. Partial-thickness burns reduce the activation of vitamin D, and this function is lost completely in full-thickness burns.

The internal body temperature remains within a narrow range (about 84.2° to 109.4° F [29° to 43° C]) compared with the wide temperature changes in the external environment. Several processes normally adjust changes in external temperature to maintain the narrow normal range of internal body temperature. Circulating blood both provides and dissipates heat efficiently. When heat is applied to the skin, the temperature of the layer under the dermis rises rapidly. As soon as the heat source is removed, compensatory processes quickly return the area to a normal temperature. If the heat source is not removed or if it is applied at a rate that exceeds the skin's capacity to dissipate it, cells are destroyed.

The skin can tolerate temperatures up to 104° F (40° C) without injury. At temperatures of 158° F (70° C) and above, cell destruction is so rapid that even brief exposure damages the skin and tissue below the skin. Fig. 28-1 shows the relationship between temperature and exposure time for burn injury.

Physical identity is partly determined by the skin's cosmetic quality, which contributes to each person's unique appearance. A patient who sustains a major burn is likely to develop a reduced self-image and other psychosocial problems as a result of a change in appearance.

Depth of Burn Injury. The severity of a burn is determined by how much of the body surface area is involved and the depth of the burn. The degree of tissue damage is related to the agent causing the burn and to the temperature of the heat source, as well as to how long the skin is exposed to it.

Differences in skin thickness in various parts of the body also affect burn depth. In areas where the skin is thin (e.g., eyelids, ears, nose, genitalia, tops of the hands and feet, fingers, and toes), a short exposure to high temperatures causes a deep burn injury. The skin is thinner in older adults (Touhy & Jett, 2010), which increases their risk for greater burn severity, even at lower temperatures of shorter duration.

Burn wounds are classified as superficial-thickness wounds, partial-thickness wounds, full-thickness wounds,

TABLE 28-1 CLASSIFICATION OF BURN DEPTH

CHARACTERISTIC	SUPERFICIAL	SUPERFICIAL PARTIAL-THICKNESS	DEEP PARTIAL- THICKNESS	FULL-THICKNESS	DEEP FULL- THICKNESS
Color	Pink to red	Pink to red	Red to white	Black, brown, yellow, white, red	Black
Edema	Mild	Mild to moderate	Moderate	Severe	Absent
Pain	Yes	Yes	Yes	Yes and no	Absent
Blisters	No	Yes	Rare	No	No
Eschar	No	No	Yes, soft and dry	Yes, hard and inelastic	Yes, hard and inelastic
Healing time	3-6 days	About 2 wk	2-6 wk	Weeks to months	Weeks to months
Grafts required	No	No	Can be used if healing is prolonged	Yes	Yes
Example	Sunburn, flash burns	Scalds, flames, brief contact with hot objects	Scalds; flames; prolonged contact with hot objects, tar, grease, chemicals	Scalds; flames; prolonged contact with hot objects, tar, grease, chemicals, electricity	Flames, electricity, grease, tar, chemicals

FIG. 28-1 Relationship between intensity of heat and duration of exposure. Exposure for prolonged periods causes burns, even with milder temperatures. At more extreme temperatures, tissue damage results after only seconds.

and deep full-thickness wounds. The partial-thickness wounds are further divided into superficial and deep subgroups (McCance et al, 2010). Table 28-1 lists the clinical differences of these burns.

The American Burn Association (ABA) describes burns as minor, moderate, or major depending on the depth, extent, and location of injury (Table 28-2). Fig. 28-2 shows the tissue layers involved with different depths of injury.

Superficial-Thickness Wounds. Of all burn types, superficial-thickness wounds have the least damage because the epidermis is the only part of the skin that is injured. The epithelial cells and basement membrane, needed for total regrowth, remain present.

TABLE 28-2 CLASSIFICATION OF BURN INJURY AND BURN CENTER REFERRAL CRITERIA

CHARACTERISTICS	COMMENTS
Minor Burns Deep partial-thickness burns less than 15% TBSA Full-thickness burns less than 2% TBSA No burns of eyes, ears, face, hands, feet, or perineum No electrical burns No inhalation injury No complicated additional injury Patient is younger than 60 years and has no chronic cardiac, pulmonary, or endocrine disorder	Patients in this category should receive emergency care at the scene and be taken to a hospital emergency department. A special expertise hospital or designated burn center is usually not necessary.
Moderate Burns Deep partial-thickness burns 15%-25% TBSA Full-thickness burns 2%-10% TBSA No burns of eyes, ears, face, hands, feet, or perineum No electrical burns No inhalation injury No complicated additional injury Patient is younger than 60 years and has no chronic cardiac, pulmonary, or endocrine disorder	Patients in this category should receive emergency care at the scene and be transferred either to a special expertise hospital or to a designated burn center.
Major Burns Partial-thickness burns greater than 25% TBSA Full-thickness burns greater than 10% Any burn involving the eyes, ears, face, hands, feet, perineum Electrical injury Inhalation injury Patient is older than 60 years Burn complicated with other injuries (e.g., fractures) Patient has cardiac, pulmonary, or other chronic metabolic disorders	Patients who meet <i>any one</i> of the criteria for a major burn should receive emergency care at the nearest emergency department and then be transferred to a designated burn center as soon as possible.

TBSA, Total body surface area.

FIG. 28-2 The tissues involved in burns of various depths.

Superficial-thickness wounds are caused by prolonged exposure to low-intensity heat (e.g., sunburn) or short (flash) exposure to high-intensity heat. Redness with mild edema, pain, and increased sensitivity to heat occurs as a result. **Desquamation** (peeling of dead skin) occurs for 2 to 3 days after the burn. The area heals rapidly in 3 to 6 days without a scar or other complication.

Partial-Thickness Wounds. A partial-thickness wound involves the entire epidermis and varying depths of the dermis. Depending on the amount of dermal tissue damaged, partial-thickness wounds are further subdivided into superficial partial-thickness and deep partial-thickness injuries.

Superficial partial-thickness wounds are caused by injury to the upper third of the dermis, leaving a good blood supply. These wounds are red and moist and **blanch** (lighten) when pressure is applied (Fig. 28-3). The small vessels bringing blood to this area are injured, resulting in the leakage of large amounts of plasma, which in turn lifts off the heat-destroyed epidermis, causing blister formation. The blisters continue to increase in size after the burn as cell and protein breakdown occur. Small blisters are often left intact if they are not located over a joint. Large blisters usually are opened and debrided to promote healing.

Superficial partial-thickness wounds increase pain sensation. Nerve endings are exposed, and any stimulation (touch or temperature change) causes intense pain. With standard care, these burns heal in 10 to 21 days with no scar but some minor pigment changes may occur.

Deep partial-thickness wounds extend deeper into the skin dermis, and fewer healthy cells remain. Blisters usually do not form because the dead tissue layer is thick, sticks to the underlying dermis, and does not readily lift off the surface. The wound surface is red and dry with white areas in deeper parts (dry because fewer blood vessels are patent). When pressure is applied to the burn, it blanches slowly or not at all (Fig. 28-4). Edema is moderate, and pain is less than with superficial burns because more of the nerve endings have been destroyed.

Blood flow to these areas is reduced by blood vessel constriction. Progression to deeper injury can occur from hypoxia and ischemia. Adequate hydration, nutrients, and oxygen are needed for regrowth of skin cells and prevention of conversion to deeper burns. These wounds can convert to full-thickness wounds when tissue damage increases with infection, hypoxia, or ischemia. Deep partial-thickness

FIG. 28-3 The typical appearance of a superficial partial-thickness burn injury.

wounds generally heal in 3 to 6 weeks, but scar formation results. Surgical intervention with skin grafting can reduce healing time.

Full-Thickness Wounds. A full-thickness wound occurs with destruction of the entire epidermis and dermis, leaving no skin cells to repopulate (Fig. 28-5). This wound does not regrow, and areas not closed by wound contraction (see Chapter 27) require grafting.

The full-thickness burn has a hard, dry, leathery *eschar* that forms from coagulated particles of destroyed dermis. *The eschar is dead tissue; it must slough off or be removed from the wound before healing can occur.* These thick particles often stick to the lower tissue layer by collagen fibers, which make eschar removal difficult. Edema is severe under the eschar in a full-thickness wound. When the injury is **circumferential** (completely surrounds an extremity or the chest), blood flow and chest movement for breathing may be reduced by tight eschar. **Escharotomies** (incisions through the eschar) or **fasciotomies** (incisions through eschar and fascia) may be needed to relieve pressure and allow normal blood flow and breathing (see p. 527 of the Surgical Management discussion in the Preventing Hypovolemic Shock and Inadequate Oxygenation section).

A full-thickness burn wound may be waxy white, deep red, yellow, brown, or black. Thrombosed vessels may be visible beneath the surface of the burn. These dermal blood vessels

are heat coagulated, causing the burned tissue to be **avascular** (without a blood supply). Sensation is reduced or absent in these areas because of nerve ending destruction. Healing time depends on establishing a good blood supply in the injured areas. This process can range from weeks to months.

Deep Full-Thickness Wounds. Deep full-thickness wounds extend beyond the skin into underlying fascia and tissues. These deep injuries damage muscle, bone, and tendons and leave them exposed. These burns occur with flame, electrical, or chemical injuries. The wound is blackened and depressed, and sensation is completely absent (Fig. 28-6). All full-thickness burns need early excision and grafting. Grafting decreases pain and length of stay and hastens recovery. Amputation may be needed when an extremity is involved.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

The nurse assesses the wound of a client burned as a result of stepping into a bathtub filled with very hot water. Which assessment finding of the burned areas on the tops of both feet does the nurse use as a basis to document a probable full-thickness injury?

- A. Most of the wounded area is red.
- B. The client reports that the area hurts when touched.
- C. The area does not blanch when firm pressure is applied.
- D. Thrombosed blood vessels are visible beneath the skin surface.

FIG. 28-4 The typical appearance of a deep partial-thickness burn injury.

FIG. 28-5 The typical appearance of a full-thickness burn injury.

FIG. 28-6 The typical appearance of a deep full-thickness burn injury.

Water is the smallest molecule that can pass through the capillary pores.

Permeability is drastically increased, which allows large molecules such as proteins to pass through the capillary pores easily.

FIG. 28-7 The capillary response to burn injury (early phase). This response is also known as *capillary leak syndrome*.

Vascular Changes Resulting from Burn Injury

Circulatory disruption occurs at the burn site immediately after injury. Blood vessels to the burned skin are occluded, and blood flow is reduced or stopped. Damaged macrophages within the tissues release chemicals that at first cause blood vessel constriction. Blood vessel thrombosis may occur, causing necrosis, which can lead to deeper injuries in these areas.

Fluid shift occurs after initial vasoconstriction as a result of blood vessels near the burn dilating and leaking fluid into the interstitial space (Fig. 28-7). This fluid shift, also known as *third spacing* or *capillary leak syndrome*, is a continuous leak of plasma from the vascular space into the interstitial space. The loss of plasma fluids and proteins decreases blood volume and blood pressure. Leakage of fluid and electrolytes from the vascular space continues, causing extensive edema, even in areas that were not burned. Fluid shift, with excessive weight gain, occurs in the first 12 hours after the burn and can continue for 24 to 36 hours.

The amount of fluid shifted depends on the extent and severity of injury. Capillary leak occurs in both burned and unburned areas when tissue damage is extensive (i.e., more than 20% to 30% total body surface area [TBSA]). Edema develops as plasma and electrolytes escape into the interstitial space. The proteins now in the interstitial space increase the movement of fluids out from the vascular space.

Profound imbalances of fluid, electrolytes, and acid-base occur as a result of the fluid shift and cell damage. These imbalances often include hypovolemia, metabolic acidosis, **hyperkalemia** (high blood potassium level), and **hyponatremia** (low blood sodium level). Hyperkalemia occurs as a result of direct cell injury that releases large amounts of cellular potassium. Sodium is retained by the body as a result of the endocrine response to stress. Aldosterone secretion increases, leading to increased sodium reabsorption by the kidney. This sodium, however, quickly passes into the interstitial spaces of the burned area with the fluid shift. Thus, despite the increased amount of sodium in the body, most of the sodium is trapped in the interstitial space and a sodium deficit occurs in the blood. **Hemoconcentration** (elevated blood osmolarity, hematocrit, and hemoglobin) develops from vascular dehydration. This problem increases blood viscosity, reducing flow through small vessels and increasing tissue hypoxia.

Fluid remobilization starts at about 24 hours after injury, when the capillary leak stops. The diuretic stage begins at

about 48 to 72 hours after the burn injury as capillary membrane integrity returns and edema fluid shifts from the interstitial spaces into the intravascular space. Blood volume increases, leading to increased kidney blood flow and diuresis unless kidney damage has occurred. Body weight returns to normal over the next few days as edema subsides.

During this phase, hyponatremia develops because of increased kidney sodium excretion and the loss of sodium from wounds. **Hypokalemia** (low blood potassium level) results from potassium moving back into the cells and also being excreted in urine. Anemia often develops as a result of hemodilution, but it is generally not severe enough to require blood transfusions. Transfusions are needed if the patient's hematocrit is less than 20% to 25% and the patient has manifestations of hypoxia. Transfusions are given only when absolutely necessary. Protein continues to be lost from the wounds. Metabolic acidosis is possible because of the loss of bicarbonate in the urine and the increased fat metabolism that occurs because of decreased carbohydrate intake.

Cardiac Changes Resulting from Burn Injury

Heart rate increases and cardiac output decreases because of the initial fluid shifts and hypovolemia that occur after a burn injury. Cardiac output may remain low until 18 to 36 hours after the burn injury. Cardiac output increases with fluid resuscitation and reaches normal levels before plasma volume is restored completely. Proper fluid resuscitation and support with oxygen prevent further complications.

Pulmonary Changes Resulting from Burn Injury

Direct injury to the lung from contact with flames rarely occurs. Rather, respiratory problems are caused by superheated air, steam, toxic fumes, or smoke. *Such problems are a major cause of death in patients with burns and are most likely to occur when the burn takes place indoors.* Respiratory failure with burn injuries can result from airway edema during fluid resuscitation, pulmonary capillary leak, chest burns that restrict chest movement, and carbon monoxide poisoning.

Respiratory damage from an inhalation injury can occur in the upper and major airways and the lung tissue (Cancio et al., 2007). The upper airway is affected when inhaled smoke or irritants cause edema and obstruct the trachea. Irritants coming in contact with the upper airway often cause a reflex closure of the vocal cords. This protective reflex reduces the entry of smoke and toxic gases into the lungs. Heat can reach the upper airway, causing an inflammatory

response that leads to edema of the mouth and throat with the potential of airway obstruction.

The chemicals and toxic gases that are produced during combustion cause more airway injury than does the heat. The ciliated membranes lining the trachea normally trap bacteria and foreign materials. Smoke and combustion products slow this activity, which allows foreign particles to enter the bronchi. The lining of the trachea and bronchi may slough 48 to 72 hours after injury, enter the airway, narrow the tracheal lumen, and obstruct the lower airways.

Lung tissue injuries result from toxic irritant damage to the alveoli and capillaries. Leaking capillaries cause alveolar edema. This edema can occur immediately or as late as 1 week after the injury. The fluid that diffuses into the lung tissue spaces contains proteins that form fibrinous membranes and lead to respiratory distress. Progressive pulmonary failure develops, leading to acute pulmonary insufficiency and infection.

Gastrointestinal Changes Resulting from Burn Injury

The fluid shifts and decreased cardiac output that occur after injury divert blood flow to the brain, heart, and liver. As a result, the GI tract has decreased blood flow. Gastric mucosal integrity and motility are impaired. The sympathetic nervous system stress response increases secretion of epinephrine and norepinephrine, which inhibit GI motility and further reduce blood flow to the area. Peristalsis decreases, and a paralytic ileus may develop. Secretions and gases collect in the intestines and stomach, causing abdominal distention.

Curling's ulcer (acute gastroduodenal ulcer that occurs with the stress of severe injury) may develop within 24 hours after a severe burn injury because of reduced GI blood flow and mucosal damage (McCance et al., 2010). The mucus lining the stomach normally is a barrier to the hydrogen ions secreted into the stomach contents. With decreased gastric mucus production, this barrier is disrupted and hydrogen ion production is increased and ulcers may develop as a result. However, this complication is now less common because of the use of H₂ histamine blockers, proton pump inhibitors, drugs that protect GI tissues, and early enteral feeding.

Metabolic Changes Resulting from Burn Injury

A serious burn injury greatly increases metabolism by increasing secretion of catecholamines, antidiuretic hormone, aldosterone, and cortisol. With this hypermetabolism, the patient's oxygen use and calorie needs are high.

The catecholamines activate the stress response. The increased production (and loss) of heat breaks down protein and fat (a process called **catabolism**), rapidly uses glucose and calories, and increases urine nitrogen loss. The heat and water lost from the burn also increase metabolic and catabolic rates, which increase calorie needs. Depending on the extent of injury, the patient's calorie needs double or triple normal energy needs. These increased rates peak 4 to 12 days after the burn and can remain elevated for months until all wounds are closed.

The hypermetabolic condition also increases core body temperature. The patient loses heat through the burned areas because the barrier is lost. Core body temperature increases as a response to the adjustment in temperature regulation by the hypothalamus. A central body temperature control change occurs to adapt to the hypermetabolic state, resulting

in the development of a low-grade fever. This change is a "resetting" of the body's normal temperature-control system to a higher baseline body temperature.

Immunologic Changes Resulting from Burn Injury

Burn injury disrupts or destroys the protective barrier of the skin, increasing the risk for infection. The injury activates the inflammatory response and often suppresses all types of immune functions. Topical and systemic antibiotics, general anesthesia, blood transfusion, and the stress of surgery further reduce immune function.

Compensatory Responses to Burn Injury

Any tissue injury is a stressor and can disrupt homeostasis. Two compensatory (adaptive) responses have immediate benefit: the inflammatory response and the sympathetic nervous system stress response. Together these responses cause changes that result in many of the manifestations seen in the first 2 to 3 days after a burn injury.

Inflammatory compensation can be helpful by triggering healing in the injured tissues. It also is responsible for some of the serious problems that occur with the fluid shift. Inflammatory compensation causes blood vessels to leak fluid into the interstitial space and white blood cells to release chemicals that trigger local tissue reactions. These responses cause the massive fluid shift, edema, and hypovolemia that are seen in the *resuscitation phase* (first 24 to 48 hours) after a burn injury. The extent of the inflammatory response depends on the burn severity. [Chapter 19](#) explains the inflammatory responses in detail.

Inflammatory compensation is immediately helpful to the body when injury occurs. These actions are intended to function on a local and short-term basis. When these actions are widespread or persistent, they can cause severe tissue damage.

Sympathetic nervous system compensation is the stress response that occurs when any physical or psychological stressors are present. Changes caused by sympathetic compensation are most evident in the cardiovascular, respiratory, and GI systems. [Fig. 28-8](#) shows the results of sympathetic nervous system stimulation.

Etiology of Burn Injury

Burn injuries are caused by dry heat (flame), moist heat (scald), contact with hot surfaces, chemicals, electricity, and ionizing radiation. The cause of the injury affects both the prognosis and the treatment.

Dry heat injuries are caused by open flame. The most common flame injuries occur in house fires and explosions. Ignited clothing from an open flame accounts for most of the injuries. Explosions usually result in flash burns because they produce a brief exposure to very high temperatures.

Moist heat (scald) injuries are caused by contact with hot liquids or steam. Scald injuries are more common among older adults than among younger adults. Hot liquid spills usually burn the upper, front areas of the body. Immersion scald injuries usually involve the lower body.

Contact burns occur when hot metal, tar, or grease contacts the skin, often leading to a full-thickness injury. Hot metal injuries occur when a body part contacts a hot surface, such as a space heater or iron. They also can occur in industrial settings from molten metals. Tar and asphalt temperatures usually are greater than 400° F, and deep injuries occur within

seconds when the skin is immersed in or splashed with them. Hot grease injuries from cooking are usually deep because of the high temperature of the grease.

Chemical burns occur as a result of accidents in homes or industry. They can also be the result of a deliberate assault. Injury occurs when chemicals directly contact the skin and epithelial tissues or are ingested. The severity of the injury depends on the duration of contact, the concentration of the chemical, the amount of tissue exposed, and the action of the chemical.

Alkalis found in oven cleaners, fertilizers, drain cleaners, and heavy industrial cleaners damage the tissues by causing the skin and its proteins to liquefy. This allows for deeper spread of the chemical and more severe burns. Acids found in bathroom cleaners, rust removers, chemicals for swimming pools, and industrial drain cleaners damage tissue by coagulating cells and skin proteins, which can limit the depth of tissue damage. Organic compounds are found in chemical disinfectants and gasoline and cause damage because they are fat soluble and are easily absorbed through the skin. Once absorbed, they have toxic effects on the kidneys and liver.

Electrical injuries are burns occurring when an electrical current enters the body (Fig. 28-9). These injuries have been called the “grand masquerader” of burns because the surface injuries may look small but the associated internal injuries can be huge. Tissue injury from electrical trauma results from electrical energy being converted to heat energy. The extent

of injury depends on the type of current, the pathway of flow, the local tissue resistance, and the duration of contact. The skin is the most resistant organ; the greatest resistance is in the epidermis of the skin. At high voltages, the difference in tissue resistance is not important. Although various underlying tissues have different resistance to current flow, once skin resistance is overcome, the body acts as a conductor and current flows throughout the involved body part. Bone has a very high resistance because of its density. Current will flow along the surface of the bone, and the heat generated damages the attached muscle. As a result, deep muscle injury may be present even when superficial muscles appear normal or uninjured.

The longer the electricity is in contact with the body, the greater the damage. The duration of contact is increased by tetanic contractions of the strong flexor muscles in the forearm, which can prevent the person from releasing the electrical source.

It is difficult to know the exact path a current takes in the body. The course of flow is defined by the locations of the “contact sites,” which are the entrance and exit wounds (Fig. 28-10). At first, the wounds may not be obvious. The path of the injury may involve many internal organs between the two contact sites.

Burn injuries from electricity can occur in one of three ways: *thermal burns*, *flash burns*, or *true electrical injury*. Thermal burns occur when clothes ignite from heat or flames

FIG. 28-8 The physiologic actions of the sympathetic nervous system compensatory responses to burn injury (early phase).

produced by electrical sparks. External burn injuries can occur when the electrical current jumps, or “arcs,” between two body surfaces. These injuries usually are severe and deep. True electrical injury occurs when direct contact is made with an electrical source. Internal damage results, and the injuries can be devastating. Damage starts on the inside and goes out; deep-tissue destruction may not be apparent immediately after injury. Organs in the path of the current may become ischemic and necrotic.

Radiation injuries occur when people are exposed to large doses of radioactive material. The most common type of tissue injury from radiation exposure occurs with therapeutic

radiation. This injury is usually minor and rarely causes extensive skin damage.

Radiation exposure is more serious in industrial settings where radioactive energy is produced or radioactive isotopes are used. Injury severity depends on the type of radiation, distance from the source, duration of exposure, absorbed dose, and depth of penetration into the body. Chapter 24 discusses potential tissue damage from alpha, beta, and gamma radiation.

Incidence/Prevalence of Burn Injury

Fires and burns are the fifth most common cause of unintentional injury deaths in the United States and the third leading cause of fatal home injuries (American Burn Association, 2010). Although the number of fatalities and injuries caused by residential fires has declined gradually over the past several decades, many residential fire-related deaths remain preventable and continue to pose a significant public health problem.

An estimated 4000 fire and burn deaths occur each year from all sources of burn injury (American Burn Association, 2010). Most deaths occur at the scene of the incident or during transport.

The number of deaths from burn injuries decreases with appropriate intervention. Factors that increase the risk for death include age older than 60 years, a burn greater than 40% TBSA, and the presence of an inhalation injury. When a patient has all three of these factors, the risk for death is very high. Better outcomes from burn injuries occur because of vigorous fluid resuscitation, early burn wound excision, improved critical care monitoring, early enteral nutrition, antibiotics, and the use of specialized burn centers.

HEALTH PROMOTION AND MAINTENANCE

Minor burns are common, and prevention involves planning and awareness. Teach all people to assess how hot the water is before bathing, showering, or immersing a body part in it. Hot water tanks should be set below 140° F. Reinforce the use of potholders when taking food from conventional or microwave ovens. Stress the importance of never adding a flammable substance (e.g., gasoline, kerosene, alcohol, lighter fluid, charcoal starter) to an open flame. Suggest the use of sunscreen agents and protective clothing to avoid sunburn.

House fires also are common and lead to severe burns and death. Teach people to reduce the risk for house fires by never smoking in bed, avoiding smoking when drinking alcohol or

FIG. 28-9 The mechanism of electrical injury: currents passing through the body follow the path of least resistance to the ground.

FIG. 28-10 Electrical contact sites. **A**, Possible entrance site. **B**, Possible exit site.

taking drugs that induce sleep, and keeping matches and lighters out of the reach of children or anyone who is cognitively impaired. If space heaters must be used, stress the importance of keeping clothing, bedding, and other flammable objects away from them. Remind people to keep the screens and doors closed on the fronts of fireplaces and to have chimneys swept each year to prevent creosote buildup. Also remind patients using home oxygen not to smoke or have open flames in a room where oxygen is in use (Edelman et al., 2008).

Leaving a burning building is critical to prevent injury or death. Teach all people to use home smoke detectors and carbon monoxide detectors and to ensure that the detectors are in good working order. The number of detectors needed depends on the size of the home. Recommendations are that each bedroom has a separate smoke detector, there should be at least one detector in the hallway of each story, and at least one detector is needed for the kitchen, each stairwell, and each home entrance. Teach everyone to develop a planned escape route with alternatives for when a main route is blocked by fire. Reinforce that no one should ever re-enter a burning building to retrieve belongings.

RESUSCITATION PHASE OF BURN INJURY

Overview

Events within the first hour after injury can make the difference between life and death for the patient with a burn injury. Immediate care focuses on maintaining an open airway, ensuring adequate breathing and circulation, limiting the extent of injury, and maintaining the function of vital organs. [Chart 28-1](#) outlines the emergency management of a burn injury.

The **resuscitation phase** is the first phase of a burn injury. It begins at the onset of injury and continues for about 24 to 48 hours. During this phase, the injury is evaluated and the immediate problems of fluid loss, edema, and reduced blood flow are assessed. The priorities for management during this period are to (1) secure the airway, (2) support circulation by fluid replacement, (3) keep the patient comfortable with analgesics, (4) prevent infection through careful wound care, (5) maintain body temperature, and (6) provide emotional support.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Knowledge of circumstances surrounding the burn injury is valuable in the management of a burn victim. If possible, obtain information directly from the patient. If this is not possible, ask family members or witnesses to the event. Ask about the circumstances of the injury, the time and place of injury, and the source and cause of injury. Ask detailed questions about how the burn occurred and the events occurring from the time of injury until help arrived. Also obtain demographic data, health history (including pre-existing illness), drug use, any additional injuries, and pain information (Brown-Guttovz, 2011).

CHART 28-1 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Emergency Management of Burns

General Management for All Types of Burns

- Assess for airway patency.
- Administer oxygen as needed.
- Cover the patient with a blanket.
- Keep the patient on NPO status.
- Elevate the extremities if no fractures are obvious.
- Obtain vital signs.
- Initiate an IV line, and begin fluid replacement.
- Administer tetanus toxoid for prophylaxis.
- Perform a head-to-toe assessment.

Specific Management

Flame Burns

- Smother the flames.
- Remove smoldering clothing and all metal objects.

Chemical Burns

- If dry chemicals are present on skin or clothing, DO NOT WET THEM.
- Brush off any dry chemicals present on the skin or clothing.
- Remove the patient's clothing.
- Ascertain the type of chemical causing the burn.
- Do not attempt to neutralize the chemical unless it has been positively identified and the appropriate neutralizing agent is available.

Electrical Burns

- At the scene, separate the patient from the electrical current.
- Smother any flames that are present.
- Initiate cardiopulmonary resuscitation.
- Obtain an electrocardiogram (ECG).

Radiation Burns

- Remove the patient from the radiation source.
- If the patient has been exposed to radiation from an unsealed source, remove his or her clothing (using tongs or lead protective gloves).
- If the patient has radioactive particles on the skin, send him or her to the nearest designated radiation decontamination center.
- Help the patient bathe or shower.

Demographic data include age, weight, and height. The rate of serious complications and death from burn injuries is increased among adults older than 50 years. [Chart 28-2](#) lists the age-related differences in older adults' responses to a burn injury. The patient's preburn weight is used to calculate fluid rates, energy requirements, and drug doses. This weight is the *dry weight*, because it represents the patient's weight before edema begins to form. Calculations based on a weight obtained after fluid replacement is started are not accurate because of water-induced weight gain. Height is important in determining total body surface area (TBSA), which is used to calculate nutritional needs.

A health history, including any pre-existing illnesses, must be known for appropriate treatment. Obtain specific information about the patient's history of cardiac or kidney problems, chronic alcoholism, substance abuse, and diabetes mellitus; any of these problems influence fluid resuscitation. The physiologic stress of a burn can make a mild disease process develop more symptoms or worsen an active process. Obtain a drug history that includes allergies, current drugs,

CHART 28-2 NURSING FOCUS ON THE OLDER ADULT

Age-Related Changes Increasing Complications from Burn Injury

AGE-RELATED CHANGES	COMPLICATIONS AND NURSING CONSIDERATIONS
Thinner skin, sensory impairment, decreased mobility	Sensory impairment and decreased mobility increase the risk for burn injury. Thinner skin increases the depth of injury even when the exposure to the cause of injury is of shorter duration.
Slower healing time	Longer time with open areas results in a greater risk for infection and metabolic derangements.
More likely to have cardiac impairments	Limits the aggressiveness of fluid resuscitation. Increases the risk for shock and acute kidney injury (AKI).
Reduced inflammatory and immune responses	Increases the risk for infection and sepsis. Patient may not have a fever when infection is present.
Reduced thoracic and pulmonary compliance	Increased risk for atelectasis, hypoxia, and other pulmonary complications.
More likely to have pre-existing medical conditions such as diabetes mellitus, kidney impairment, or pulmonary impairment	Any of these disorders compromise vital organ function and can interfere with fluid resuscitation efforts or other treatments.

and immunization status from the patient or family. Determine the dose and time the last drug was taken. Ask whether the patient smokes or drinks alcohol daily; these factors influence treatment and responses.

Other injuries may occur at the time of the burn. The most common causes of additional injuries are falls and motor vehicle crashes. Such injuries increase the risk for complications or death. Determine whether additional injuries such as fractures, chest injuries, and abdominal trauma are causing pain or discomfort.

Physical Assessment/Clinical Manifestations

Physical assessment findings in the resuscitation phase differ greatly from findings later in the course of the injury. Use a systematic approach to ensure that no problem is missed. Assessment of the respiratory system is most critical to prevent life-threatening complications.

Respiratory Assessment. Patients with major burn injuries and those with inhalation injury are at risk for respiratory problems. Respiratory manifestations common with a burn injury are listed in Table 28-3. *Thus continuous airway assessment is a nursing priority* (Brown-Guttovz, 2011).

Direct Airway Injury. The degree of inhalation damage depends on the fire source, temperature, environment, and types of toxic gases generated. Ask about the source of the fire, duration of exposure, and whether the fire was in an enclosed space. Inspect the mouth, nose, and pharynx. Burns

TABLE 28-3 FACTORS DETERMINING INHALATION INJURY OR AIRWAY OBSTRUCTION

- Patients who were injured in a closed space
- Patients with extensive burns or with burns of the face
- Intra-oral charcoal, especially on teeth and gums
- Patients who were unconscious at the time of injury
- Patients with singed scalp hair, nasal hairs, eyelids, or eyelashes
- Patients who are coughing up carbonaceous sputum
- Changes in voice such as hoarseness or brassy cough
- Use of accessory muscles or stridor
- Poor oxygenation or ventilation
- Edema, erythema, and ulceration of airway mucosa
- Wheezing, bronchospasm

of the lips, face, ears, neck, eyelids, eyebrows, and eyelashes are strong indicators that an inhalation injury may be present. Burns inside the mouth and singed nasal hairs also indicate possible inhalation injury. Black particles of carbon in the nose, mouth, and sputum and edema of the nasal septum indicate smoke inhalation, as does a “smoky” smell to the patient’s breath.

A change in respiratory pattern may indicate a pulmonary injury. The patient may:

- Become progressively hoarse
- Develop a brassy cough
- Drool or have difficulty swallowing
- Produce sounds on exhalation that include audible wheezes, crowing, and stridor

Any of these changes may mean the patient is about to lose his or her airway.

! NURSING SAFETY PRIORITY

Critical Rescue

For a burn patient in the resuscitation phase who is hoarse, has a brassy cough, drools or has difficulty swallowing, or produces an audible breath sound on exhalation, immediately apply oxygen and notify the Rapid Response Team.

Upper airway edema and inhalation injury are most common in the trachea and mainstem bronchi. Auscultation of these areas may reveal wheezes, which indicate partial obstruction. *Patients with severe inhalation injuries may have such rapid obstruction that, within a short time, they cannot force air through the narrowed airways. As a result, the wheezing sounds disappear. This finding indicates impending airway obstruction and demands immediate intubation.* Many patients are intubated when an inhalation injury is suspected rather than waiting until obstruction makes endotracheal or nasotracheal intubation difficult or impossible.

TABLE 28-4 PHYSIOLOGIC EFFECTS OF CARBON MONOXIDE POISONING

CARBON MONOXIDE LEVEL	PHYSIOLOGIC EFFECTS
1%-10% (normal)	Increased threshold to visual stimuli Increased blood flow to vital organs
11%-20% (mild poisoning)	Headache Decreased cerebral function Decreased visual acuity Slight breathlessness
21%-40% (moderate poisoning)	Headache Tinnitus Nausea Drowsiness Vertigo Altered mental state Confusion Stupor Irritability Decreased blood pressure, increased and irregular heart rate Depressed ST segment on ECG and dysrhythmias Pale to reddish purple skin
41%-60% (severe poisoning)	Coma Convulsions Cardiopulmonary instability
61%-80% (fatal poisoning)	Death

ECG, Electrocardiogram.

Carbon Monoxide Poisoning. Carbon monoxide (CO) is one of the leading causes of death from a fire. It is a colorless, odorless, tasteless gas released in the process of combustion. Inhalation injury is a risk for carbon monoxide poisoning.

CO is rapidly transported across the lung membrane and binds tightly to hemoglobin in place of oxygen to form carboxyhemoglobin (CoHb). CO also causes the oxyhemoglobin dissociation curve to shift to the left, which impairs oxygen unloading at the tissue level. This shift results in reduced oxygen delivery because 98% of the oxygen supplied to the tissues comes bound to hemoglobin. Even though the oxygen-carrying capacity of the hemoglobin is reduced, the blood gas value of partial pressure of arterial oxygen (Pao₂) is normal (Laing, 2010). The vasodilating action of carbon monoxide causes the “cherry red” color (or at least the absence of cyanosis) in these patients. Manifestations vary with the concentration of CoHb. Table 28-4 lists the effects of carbon monoxide poisoning.

Thermal (Heat) Injury. Except for steam inhalation, aspiration of scalding liquid, or explosion of flammable gases under pressure, thermal burns to the respiratory tract are usually limited to the upper airway above the glottis (nasopharynx, oropharynx, and larynx). *Heat damage of the pharynx is often severe enough to produce edema and upper airway obstruction, especially epiglottitis. The problem can occur any time during resuscitation. In the unresuscitated patient, supraglottic edema may be delayed because of the dehydration that occurs with hypovolemia. During fluid resuscitation, however, the tissues rehydrate and then swell. When it is known that the upper airways were exposed to heat, intubation may be performed as an early intervention before obstruction occurs.*

! NURSING SAFETY PRIORITY

Action Alert

When intubation has not been performed in a patient whose upper airways were exposed to heat or toxic gases, continually assess the upper airway for recognition of edema and obstruction.

Inhaled steam can injure the lower respiratory tract because water holds heat and the airways down to the major bronchioles can be damaged. Ulcerations, redness, and edema of the mouth and epiglottis are the first manifestations, with rapid swelling leading to upper airway obstruction. Stridor, hoarseness, and shortness of breath result.

Smoke Poisoning. Smoke poisoning, or chemical injury from the inhalation of combustion by-products, is a common type of inhalation injury. Toxic by-products, especially cyanide, are produced when plastics or home furnishings are burned. Cyanide binds to cell energy-making components, thereby inhibiting cell metabolism and cell function.

Pulmonary Fluid Overload. Pulmonary edema can occur even when the lung tissues have not been damaged directly. Other damaged tissues release such large amounts of histamine and other inflammatory mediators causing capillary leak that even lung capillaries leak fluid into the pulmonary tissue spaces.

Circulatory overload from fluid resuscitation may cause left-sided congestive heart failure. This problem creates high pressure within pulmonary blood vessels that pushes fluid into the lung tissue spaces. Excess lung tissue fluid makes gas exchange difficult. *The patient is short of breath and has dyspnea in the supine position. Crackles are heard on auscultation.*

! NURSING SAFETY PRIORITY

Critical Rescue

When symptoms of pulmonary edema are present, elevate the head of the bed to at least 45 degrees, apply humidified oxygen, and notify the burn team or the Rapid Response Team.

External Factors. Patients with burn injuries also may have breathing problems from external factors. The most common external factor affecting breathing is tight eschar from deep circumferential chest burns. The eschar either restricts chest movement or compresses structures in the neck and throat so that airflow is impaired. Inspect the patient's chest hourly for ease of respiration, amount of chest movement, rate of breathing, and effort. If the patient is being mechanically ventilated, increased airway pressures may indicate the need for escharotomies. Use continuous pulse oximetry to assess breathing effectiveness in maintaining blood oxygen levels.

Cardiovascular Assessment. Changes in the cardiovascular system begin immediately after the burn injury and include shock. *Hypovolemia shock is a common cause of death in the resuscitation phase in patients with serious injuries. See Chapter 39 for discussion of shock.*

At first, cardiac manifestations are from hypovolemia and decreased cardiac output. Monitor the degree of edema, and assess cardiac status by measuring central and peripheral pulses, blood pressure, capillary refill, and pulse oximetry. Noninvasive blood pressure readings are inaccurate in patients with large burns involving the upper extremities, and invasive

blood pressure monitoring may be needed. At first, the patient has tachycardia, decreased blood pressure, and decreased peripheral pulses. Peripheral capillary refill is slow or absent as tissue blood flow decreases. With fluid resuscitation, peripheral edema increases, as does the patient's body weight.

Electrocardiographic (ECG) changes can indicate damage to the heart as a result of electrical burn injuries or stress that induces a myocardial infarction. Obtain baseline ECG tracings at the time of admission, and continue the ECG monitoring throughout the resuscitation phase. Compare current ECG tracings with the initial tracings to assess whether the patient is experiencing new-onset conduction abnormalities from the burn injury or the fluid resuscitation.

Kidney/Urinary Assessment. Changes in kidney function with burn injury are related to decreased blood flow and to cellular debris. During the fluid shift, blood flow to the kidney may not be adequate for glomerular filtration. As a result, urine output is greatly decreased compared with IV fluid intake. The urine is very concentrated and has a high specific gravity.

Other substances may be present in the blood that flows through the kidney. Destroyed red blood cells release hemoglobin and potassium. When muscle damage occurs from a major burn or electrical injury, a large oxygen-carrying protein called *myoglobin* is released from damaged muscle and circulates to the kidney. Most damaged cells release proteins that form uric acid. All of these large molecules in the blood may precipitate in the kidney tubular system. A “sludge” then forms that blocks kidney blood and urine flow and may cause kidney failure.

Assess kidney function by accurately measuring urine output hourly and comparing this value with fluid intake. Urine output is decreased during the first 24 hours of the resuscitation phase. Fluid resuscitation is provided at the rate needed to maintain urine output at 30 to 50 mL or 0.5 mL/kg/hr. Assess response to fluid resuscitation by measuring urine specific gravity, blood urea nitrogen (BUN), serum creatinine, and serum sodium levels in addition to hourly urine output. Examine the urine for color, odor, and the presence of particles or foam.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

Which assessment does the nurse perform first on the client just admitted after an electrical injury with contact sites on the left hand and left foot?

- A. Core body temperature
- B. Electrocardiography
- C. Depth of burn injury
- D. Urine output

Skin Assessment. Assess the skin to determine the size and depth of burn injury. The size of the injury is first estimated in comparison with the *total body surface area (TBSA)*. For example, a burn that involves 40% of the TBSA is a 40% burn. The size of the injury is important not only for diagnosis and prognosis but also for calculating drug doses, fluid replacement volumes, and caloric needs.

Inspect the skin to identify injured areas and changes in color and appearance. Except with electrical burns, this initial size assessment usually can be made accurately with specific assessment tools and charts.

FIG. 28-11 The rule of nines for estimating burn percentage.

The most rapid method for calculating the size of a burn injury in adult patients whose weights are in normal proportion to their heights is the *rule of nines* (Fig. 28-11). With this method, the body is divided into areas that are multiples of 9%. Although useful at the site of injury and in emergency departments, overestimation of the TBSA involved can easily occur. More complex evaluations using other methods are made in the burn unit.

Because specific treatments are related to the depth of the burn injury, initial assessment of the skin includes estimations of burn depth. Criteria for depth of injury are based on appearance and associated characteristics (see [Depth of Burn Injury](#) section, pp. 512-515).

Bedside evaluation of burn depth is only an estimate. Other methods, such as thermography, the use of vital dyes, indocyanine green (ICG) video angiography, and laser

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

The client who tripped while carrying an open kettle of hot water received scald burns to the entire chest, the entire anterior section of the right arm, the right half of the abdomen, and the anterior portion of the right leg from the groin to the knee. At what percentage of total body surface area does the nurse calculate the injury using the rule of nines?

- A. 22% to 23%
- B. 30% to 31%
- C. 39% to 40%
- D. 48% to 49%

Doppler imaging (LDI) more precisely measure the amount of tissue perfusion of the injured tissue. ICG and LDI are the most accurate of the three methods. Laser Doppler imaging is used more frequently because it is relatively accurate, less invasive, and faster than the other methods.

Gastrointestinal Assessment. Although the GI tract usually is not directly injured (except with chemical ingestion), changes in function occur in all burn patients. The decreased blood flow and sympathetic stimulation reduce GI motility and promote development of a paralytic ileus. Auscultate the abdomen to assess bowel sounds. Bowel sounds are commonly reduced or absent in a patient with severe burns. Other manifestations indicating paralytic ileus include nausea, vomiting, and abdominal distention. Patients with burns of 25% TBSA or who are intubated generally require a nasogastric (NG) tube inserted to prevent aspiration and remove gastric secretions. Assess the tube for placement and patency after insertion. Because of the potential for ulcer formation in the GI tract, examine each stool and vomitus for gross blood or other material that indicates partially digested blood (“coffee ground”—appearing crumbs). Test for the presence of occult blood on any vomit or stool.

Laboratory Assessment

Changes in laboratory test values are found in different phases of postburn recovery and reflect tissue damage or compensatory responses. However, other changes in specific laboratory findings may suggest complications.

During the resuscitation phase and before the start of fluid resuscitation, blood analysis reflects the fluid shift and direct tissue damage. Baseline laboratory test values and early postburn expected changes are listed in [Chart 28-3](#).

Changes in the total white blood cell (WBC) count and differential reflect immune function and inflammatory responses to the burn injury. The burn patient’s total WBC count, especially the neutrophil percentage, first rises and then drops rapidly, with a “left shift” (see [Chapter 19](#)) as the immune system becomes unable to sustain its defenses. If sepsis occurs, the total WBC count may be as low as 2000 cells/mm³.

Other laboratory tests that provide useful information about the burn patient’s status include urine electrolyte assays, urine cultures, liver enzyme studies, and clotting studies. Drug and alcohol screens are obtained if drug or alcohol intoxication is suspected.

CULTURAL AWARENESS

For African-American patients, a sickle cell preparation is performed if sickle status is unknown. The trauma of a burn injury can trigger a sickle cell crisis in patients who have the disease and in those who carry the trait.

Imaging Assessment

Standard x-rays and scans do not provide direct assessment data about the burn wound. These assessments are not performed unless other trauma is suspected.

Other Diagnostic Assessment

Specific diagnostic studies are performed when deep organ trauma is suspected. Such studies include IV renograms, computed tomography (CT), ultrasonography, bronchoscopy, and magnetic resonance imaging (MRI). When burn injuries involve the eye, an ophthalmic evaluation detects

CHART 28-3 LABORATORY PROFILE

Burn Assessment During the Resuscitation Phase

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS
Serum Studies		
Hemoglobin	12-16 g/dL (women) 14-18 g/dL (men)	Elevated as a result of fluid volume loss
Hematocrit	37%-47% (women) 42%-52% (men)	Elevated as a result of fluid volume loss
Urea nitrogen	10-20 mg/dL	Elevated as a result of fluid volume loss
Glucose	70-105 mg/dL	Elevated as a result of the stress response and altered uptake across injured tissues
Electrolytes		
Sodium	136-145 mEq/L (mmol/L)	Decreased; sodium is trapped in edema fluid and lost through plasma leakage
Potassium	3.5-5.0 mEq/L (mmol/L)	Elevated as a result of disruption of the sodium-potassium pump, tissue destruction, and red blood cell hemolysis
Chloride	98-106 mEq/L (mmol/L)	Elevated as a result of fluid volume loss and reabsorption of chloride in urine
Arterial Blood Gas Studies		
PaO ₂	80-100 mm Hg	Slightly decreased
PaCO ₂	35-45 mm Hg	Slightly increased from respiratory injury
pH	7.35-7.45	Low as a result of metabolic acidosis
Carboxyhemoglobin	0%-10%	Elevated as a result of inhalation of smoke and carbon monoxide
Other		
Total protein	6.4-8.3 g/dL	Low; protein exudate is lost through the wound
Albumin	3.5-5.0 g/dL	Low; protein is lost through the wound and through vascular membranes because of increased permeability

corneal damage (see Chapters 48 and 49 for specific eye and vision evaluation procedures).

ANALYSIS

A burned patient has dramatic changes not only in the directly damaged tissues but also in many other body systems.

The priority problems for the patient with burn injuries in the resuscitation phase who have sustained a burn injury greater than 25% of the TBSA are:

1. Potential for inadequate oxygenation related to upper airway edema, pulmonary edema, airway obstruction, or pneumonia
2. Hypovolemic shock related to increase in capillary permeability, active fluid volume loss, electrolyte imbalance, and inadequate fluid resuscitation
3. Potential for organ ischemia (brain, heart, kidney, gastrointestinal) related to hypovolemia and hypotension
4. Acute and Chronic Pain related to tissue injury, damaged or exposed nerve endings, débridement, dressing changes, invasive procedures, and donor sites
5. Potential for acute respiratory distress syndrome (ARDS) related to inhalation injury

PLANNING AND IMPLEMENTATION

Supporting Oxygenation

Planning: Expected Outcomes. With proper intervention, the patient is expected to maintain a patent airway and have adequate oxygenation. Indicators include that the patient should have either normal or nearly normal oxygen saturation, P_{aO_2} , P_{aCO_2} , and arterial pH.

Interventions. Nursing and medical interventions are used to support normal pulmonary function and prevent pulmonary problems such as pulmonary edema, which can result from lung injury or from fluid overload and heart failure. (Even young, healthy people can develop fluid overload and heart failure.) Specific plans for pulmonary management depend on the cause of the breathing problem and the status of the respiratory tract. *Thus a priority nursing intervention is monitoring the patient's respiratory status.*

Nonsurgical Management. Interventions include airway maintenance, promotion of ventilation, monitoring gas exchange, oxygen therapy, drug therapy, positioning, and deep breathing.

Airway maintenance begins at the burn scene in an unconscious patient and may involve only a chin-lift or a head-tilt maneuver. *Remember that upper airway edema becomes pronounced 8 to 12 hours after the beginning of fluid resuscitation. These patients often require nasal or oral intubation if crowing, stridor, or dyspnea is present.*

A bronchoscopy is performed to examine the vocal cords and airways of patients at risk for obstruction. Patients with severe smoke inhalation or poisoning may require a bronchoscopy on admission and routinely thereafter for examination of the respiratory tract, deep suctioning of the lungs, and removal of sloughing necrotic tissue. Assess the endotracheal tube hourly to ensure patency and location in intubated patients.

Other causes of airway obstruction are excessive secretions and sloughed tissue from damaged lungs. Suction as indicated based on clinical assessment. Vigorous endotracheal or

nasotracheal tube suctioning is performed after chest physiotherapy and aerosol treatments. Patients report that deep endotracheal suctioning is extremely painful. Therefore suctioning the endotracheal tube often requires increased analgesia or sedation.

Promoting ventilation includes ensuring that skeletal muscle movement of the chest is adequate for ventilation. Chest movement can be restricted by eschar and by tight dressings that cover the neck, chest, and abdomen. Observe the patient for ease of respiratory movements, and loosen tight dressings as needed to assist with ventilation.

Monitor for gas exchange by using laboratory tests (e.g., arterial blood gas, carboxyhemoglobin levels) and by assessing for cyanosis, disorientation, and increased pulse rate. Other data to monitor in critically ill patients include chest x-ray findings, pulmonary artery catheter pressures, and central venous pressure measurement.

Cyanide poisoning may occur in patients burned in house fires. An elevated plasma lactate level is one indicator of cyanide toxicity in patients who do not have severe burns.

Oxygen therapy by giving humidified oxygen by facemask, cannula, or hood is used to manage any breathing impairment in the burn patient. Arterial oxygenation less than 60 mm Hg is an indication for intubation and mechanical ventilation. Keep emergency airway equipment at or near the patient's bedside. This equipment includes oxygen, masks, cannulas, manual resuscitation bags, laryngoscope, endotracheal tubes, and equipment for tracheostomy. Chapter 34 addresses specific nursing actions for patients during mechanical ventilation.

Drug therapy with antibiotics is used when pneumonia or other pulmonary infections impair breathing. Drug selection is based on known culture and sensitivity reports or on the specific organisms common to that burn unit.

Patients with pulmonary edema and any degree of heart failure may receive digoxin or other agents to improve left ventricular function and prevent or treat pulmonary edema. Diuretics, a mainstay of therapy for pulmonary edema from other causes, may or may not be used in the resuscitation phase, depending on the patient's blood volume and kidney function.

When a patient's activity during mechanical ventilation severely compromises respiratory mechanics, it may be necessary to use a paralytic drug, such as atracurium (Tracrium) or vecuronium (Norcuron). Paralytic drugs remove all breathing control from the patient, making mechanical ventilation easier. *These drugs do not prevent the patient from seeing and hearing or from experiencing fear, pain, and loss of control. Any patient receiving neuromuscular blockade drugs must also receive drugs for sedation, analgesia, and antianxiety unless clinically contraindicated.*

! NURSING SAFETY PRIORITY

Critical Rescue

Ensure that all alarms are operative on ventilators, and check patients who are receiving neuromuscular blockade frequently, because they cannot call for help if they become extubated accidentally.

Positioning and deep breathing can improve breathing and oxygenation. Turn the patient frequently, and assist him or her out of bed to a chair as much as possible. Teach the

patient to use coughing and deep-breathing exercises. Urge him or her to use incentive spirometry hourly while awake. Chest physiotherapy may be helpful to mobilize lung secretions.

Surgical Management. A tracheotomy may be needed when long-term intubation is expected. This procedure increases the risk for infection in burn patients even more than in nonburned patients. Emergency tracheotomies are performed when an airway becomes occluded and oral or nasal intubation cannot be achieved.

Other surgical procedures for improving the burn patient's oxygenation include inserting chest tubes and performing an escharotomy. Chest tubes are used to re-expand the lung when a pneumothorax or hemothorax has occurred (see Chapter 34). Tight eschar on the neck, chest, or abdomen can restrict respiratory movement. Escharotomies (described on p. 527) can relieve this restriction and permit greater respiratory movement.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

The client with burns to the head, neck, and upper body from a house fire starts drooling uncontrollably about 8 hours after the injury. What is the nurse's best first action?

- A. Ensure that the client remains NPO.
- B. Notify the Rapid Response Team.
- C. Slow the IV infusion rate.
- D. Raise the head of the bed.

Preventing Hypovolemic Shock and Inadequate Oxygenation

Planning: Expected Outcomes. With appropriate intervention, the patient is expected to have blood pressure and tissue oxygenation restored to normal. Indicators include these vital signs and assessment parameters:

- Blood pressure at or near the patient's normal range
- Palpable peripheral pulses (or heard with Doppler) in all extremities
- Oxygen saturation, partial pressure of arterial oxygen (P_{aO_2}), partial pressure of arterial carbon dioxide (P_{aCO_2}), and arterial pH at or near the normal ranges

Interventions. Interventions are aimed at increasing blood fluid volume, supporting compensatory mechanisms, and preventing complications. Nonsurgical management is often sufficient for achieving these aims. Surgical management is required most often for full-thickness burns.

Nonsurgical Management. Fluid volume and tissue blood flow are restored through IV fluid therapy and drug therapy. Priority nursing interventions are carrying out fluid resuscitation and monitoring for indications of effectiveness or complications.

Rapid infusion of IV fluids, known as *fluid resuscitation*, is needed to maintain sufficient blood volume for normal cardiac output, mean arterial pressure, and tissue oxygenation. Chart 28-4 lists best practices for fluid resuscitation. Many formulas for calculating fluid requirements exist. Table 28-5 lists those commonly used for the therapy of adult patients. Although the types and amounts of electrolytes, crystalloids, and colloids vary, the purpose of any formula is to prevent shock by maintaining circulating blood fluid volume. The optimal formula and infusion schedules remain controversial.

CHART 28-4 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Fluid Resuscitation of the Burn Patient

- Initiate and maintain at least one large-bore IV in an area of intact skin (if possible).
- Coordinate with physicians to determine the appropriate fluid type and total volume to be infused during the first 24 hours postburn.
- Administer one half of the total 24-hour prescribed volume within the first 8 hours postburn and the remaining volume over the next 16 hours.
- Assess IV access site, infusion rate, and infused volume at least hourly.
- Monitor these vital signs at least hourly:
 - Blood pressure
 - Pulse rate
 - Respiratory rate
 - Breath sounds
 - Voice quality (if not intubated)
 - Oxygen saturation
 - End-tidal carbon dioxide levels
- Assess urine output at least hourly:
 - Volume
 - Specific gravity
 - Color
 - Character
 - Presence of protein
- Assess for fluid overload:
 - Formation of dependent edema
 - Engorged neck veins
 - Rapid, thready pulse
 - Presence of lung crackles or wheezes on auscultation
- Measure additional body fluid output hourly

TABLE 28-5 COMPOSITION OF COMMON BURN FLUID RESUSCITATION FORMULAS

FORMULA	SOLUTION AND AMOUNT FOR THE FIRST 24 HOURS
Parkland (Baxter)	Crystalloid only (lactated Ringer's) 4 mL/kg/% TBSA burn
Modified Parkland	Crystalloid only (lactated Ringer's) 4 mL/kg/% TBSA burn + 15 mL/m ² of TBSA
Modified Brooke	Protenate or 5% albumin in 0.9% saline Lactated Ringer's without dextrose 0.5 mL to 1.5 mL/kg/% TBSA burn

TBSA, Total body surface area.

Resuscitation for a severe burn requires large fluid loads in a short time to maintain blood flow to vital organs. All common formulas recommend that half of the calculated fluid volume for 24 hours be given in the first 8 hours after injury. The other half is given over the next 16 hours for a total of 24 hours. Fluid boluses are avoided because they increase capillary pressure and worsen edema. In the second 24-hour period after a burn injury, the volume and content of the IV fluids are based on the patient's specific fluid and electrolyte imbalances and his or her response to treatment. This resuscitation involves hourly infusion volumes that are greatly in excess of the 125 mL to 150 mL per hour common infusion rates (Pham et al., 2008).

Fluid replacement formulas are calculated from the time of injury and not from the time of arrival at the hospital. For example, if a burn injury occurred at 8 AM but the patient was

not admitted to the hospital until 10 AM, the first 8-hour period would be completed at 4 PM, or 8 hours after the injury. Thus if resuscitation was delayed by 2 hours until admission to the hospital, calculated fluids would need to be given over the next 6-hour period rather than an 8-hour period. Burn resuscitation formulas are guides. The patient's response to therapy determines exact fluid requirements.

The management of extensive burns requires a large-bore central venous catheter so that massive fluid loads can be given. Peripheral lines are less useful because they become dislodged or fluid flow is cut off when massive peripheral edema compresses the IV catheter and the vein.

Monitoring patient responses is important to determine the adequacy of resuscitation for hydration and blood perfusion of the brain, heart, and kidneys. Urine output is the most common and most sensitive noninvasive assessment parameter for cardiac output and tissue perfusion. *Regardless of the total amount of fluid calculated as needed to meet the fluid requirements of the patient, the amount of fluid given depends on how much IV fluid per hour is needed to maintain the hourly urine output at 0.5 mL/kg (about 30 mL/hr).* Adjustment of the IV fluid rate on the basis of urine output plus serum electrolyte values is known as the **titration** of fluid. In burns larger than 35% TBSA, the use of urine output and vital signs to guide resuscitation may not be adequate. Invasive monitoring of cardiac and pulmonary function is needed to ensure optimal fluid resuscitation.

Burn patients can develop severe hypovolemic shock and need invasive cardiac monitoring. Vital parameters such as central venous pressure, pulmonary artery pressures, and cardiac output are obtained on an hourly to continuous basis.

Monitor the ECG activity of patients who have sustained large burns. Nonburn-related dysrhythmias, such as atrial fibrillation, are often present in older patients. Compare current ECG findings with those obtained on admission.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

The client with 45% burns has a hematocrit of 52% 10 hours after the burn injury and 6 hours after fluid resuscitation was started. What is the nurse's best action?

- Assess the client's blood pressure and urine output.
- Notify the physician or the Rapid Response Team.
- Document the report as the only action.
- Increase the IV infusion rate.

Drug therapy for shock prevention in burn patients is different from that for the heart failure patient. A common mistake in treatment is giving diuretics to increase urine output rather than changing the amount and rate of fluid infused. *Diuretics do not increase cardiac output; they actually decrease circulating volume and cardiac output by pulling fluid from the circulating blood volume to enhance diuresis.* This effect reduces blood flow to other vital organs (especially the heart, lungs, and brain) and greatly increases the risk for severe hypovolemic shock. Therefore diuretics are not generally used to improve urine output for burn patients. An exception is the patient with a burn injury caused by electrical energy. In electrical burns, muscle and deep-tissue damage release large protein molecules (myoglobin), which precipitate in and obstruct the renal tubules. Although the diuretic **mannitol** (Osmitol) is often used in this situation, it should

always be given after adequate urine output has been established.

CONSIDERATIONS FOR OLDER ADULTS

In older patients, especially those with cardiac disease, a complicating factor in fluid resuscitation may be heart failure or myocardial infarction. Drugs that increase cardiac output (e.g., dopamine [Intropin]) or that strengthen the force of myocardial contraction (e.g., digoxin [Lanoxin]) may be used along with fluid therapy.

Surgical Management. The surgical procedure for the treatment of inadequate tissue perfusion is **escharotomy**. An incision through the burn eschar relieves pressure caused by the constricting force of fluid buildup under circumferential burns on the extremity or chest and improves circulation. If the pressure is not relieved, arterial compression can occur with a loss of blood flow to the extremity leading to ischemia and possible necrosis. Incisions are made along the length of the extremity and extend into the subcutaneous tissue (Figs. 28-6 and 28-12). This procedure relieves the tourniquet effect of the eschar. If tissue pressure remains elevated after escharotomy, a **fasciotomy** (a deeper incision extending through the fascia) may be needed.

Escharotomies are often performed in a treatment room. No anesthesia is needed for escharotomy because nerve endings have been destroyed by the burn injury, but sedation and analgesia are given to reduce anxiety. Assure the patient that he or she will be made as comfortable as possible during the procedure. Remove the dressings, and thoroughly cleanse the areas to be incised. After the procedure, apply topical antimicrobial drugs and dressings to the area. Carefully monitor escharotomy sites for bleeding. Fasciotomies should be performed in an operating room with the patient under general anesthesia.

Managing Pain

The pain with burn injuries is both chronic and acute. Many factors contribute to burn pain and may be altered to reduce pain perception. Pain from the actual injury is worse when painful procedures are performed. Many nursing procedures needed by burn patients increase pain. Accurate assessment of the patient's pain before and during procedures is an essential part of pain management.

Planning: Expected Outcomes. The pain level of a patient with a burn injury is expected to be alleviated or reduced. Indicators include that the patient should rarely demonstrate these behaviors:

- Reporting pain
- Moaning and crying
- Making facial expressions of pain
- Losing his or her appetite

Interventions. Pain management is tailored to the patient's tolerance for pain, coping mechanisms, and physical status. *The priority nursing actions include continually assessing the patient's pain level, using appropriate pain-reducing strategies, and preventing complications.*

Nonsurgical Management. Interventions for the patient having pain include drug therapy, complementary therapy measures, and environmental manipulation.

Drug therapy usually requires opioid analgesics (e.g., morphine sulfate, hydromorphone [Dilaudid], fentanyl) and non-opioid analgesics. Although these drugs may provide

FIG. 28-12 Escharotomy to release circumferential burn eschar and improve circulation to a distal extremity. **A**, Tight circumferential eschar restricting swelling as edema forms in the tissue beneath the eschar. Edema compresses blood vessels, which inhibits blood flow to the distal extremity. **B**, An escharotomy incision allows outward swelling of edematous tissues. The restricted blood flow to the distal extremity is relieved. **C**, An anterior axillary incision is made bilaterally to relieve respiratory distress.

adequate pain relief when no procedures are being performed, they rarely offer more than moderate relief during painful procedures. In addition, they depress respiratory function and reduce intestinal motility. Thus nonpharmacologic interventions also are needed for the burn patient.

During the resuscitation postburn phase, the IV route is used for giving opioid drugs because of problems with absorption from the muscle and stomach. When these agents are given IM or subcutaneously, they remain in the tissue spaces and do not relieve pain. In addition, when edema is present, all the doses are rapidly absorbed at once when the fluid shift is resolving. This delayed but rapid absorption can result in lethal blood levels of analgesics.

! NURSING SAFETY PRIORITY

Drug Alert

Opioid drugs for pain are given only by the intravenous route during the resuscitation phase.

Anesthetic agents, such as ketamine (Ketalar), pentobarbital sodium (Nembutal, Novopentobarb), and nitrous oxide, also reduce pain. Use strict protocols when giving these agents to prevent serious complications.

Complementary and alternative therapy measures include relaxation techniques, meditative breathing, guided imagery, music therapy, massage, and healing or therapeutic touch. Hypnosis and autohypnosis can be used by alert, cooperative patients under the direction of trained therapists. Therapeutic touch, acupuncture, and acupressure are used to a limited extent for burn patients; the results are variable. Active music interventions for distraction have been useful in reducing patients' perceptions of pain and anxiety (Tan et al., 2010) (see the Evidence-Based Practice box on p. 529). Additional nontraditional and complementary therapy types of pain intervention are detailed in [Chapter 2](#).

Environmental changes, such as providing a quiet environment, using nonpainful tactile stimulation, and increasing the patient's control, can increase comfort. Sleep deprivation

increases patients' discomfort. Increasing sleep or rest time in a quiet environment helps reduce the adverse effects of sleep deprivation, replenishes body hormone stores, helps prevent critical care unit psychosis, and restores the diurnal effects of endorphins. Coordinate with the health care team to ensure that procedures are performed during the patient's waking hours.

Tactile stimulation can reduce pain. Help the patient change positions every 2 hours to reduce pressure on any specific area, improve circulation to painful areas, and ease pain. Massage nonburn areas to reduce pain transmission and stimulate endorphin release. Apply heat and maintain warm room temperatures to prevent shivering.

To reduce anxiety and increase feelings of confidence and independence, encourage the patient to participate in pain control measures. For example, make a contract with him or her that specifies how long a painful procedure will last. This helps patients deal with the pain for that particular period. Patient-controlled analgesia (PCA) also reduces pain. Important issues and techniques for the best use of PCA include giving an initial bolus of 5 to 10 mg of morphine (or equivalent drug), increasing the PCA dose as needed to achieve pain relief, and planning for a change in dosing regimens at night (e.g., giving a bolus dose at bedtime). See [Chapter 5](#) for a detailed discussion of combination drug therapy for pain management.

? NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

A burned client newly arrived from an accident scene is prescribed 4 mg of morphine sulfate intravenously. What is the most important reason the nurse administers the analgesic to this client by the intravenous (IV) route?

- The drug will be effective more quickly than if given IM or subcutaneously.
- It is less likely to interfere with the client's breathing and oxygenation.
- The danger of an overdose during fluid remobilization is reduced.
- The client has delayed gastric emptying.

EVIDENCE-BASED PRACTICE

Music Hath Charms ...

Tan, X., Yowler, C., Super, D., & Fratiannie, R. (2010). The efficacy of music therapy protocols for decreasing pain, anxiety, and muscle tension levels during burn dressing changes: A prospective randomized crossover trial. *Journal of Burn Care & Research*, 31(4), 590-597.

Burn pain is intensified during manipulation of the burn wound during dressing changes. Although drug therapy with opioids and other pharmacologic agents is used during these acutely painful procedures, it provides only moderate relief. Many narrative and case studies have indicated that music therapy coupled with drug therapy improves pain management during débridement and dressing changes; however, these studies often did not include control groups, objective measures, or random assignment.

The purpose of the current study was to determine the effectiveness of music therapy interventions in reducing patients' pain, anxiety, and muscle tension levels during burn dressing changes. Twenty-nine burn patients were recruited into the study and served as their own controls using a randomly assigned crossover design. On one day, they participated in a music therapy intervention before, during, and after dressing changes. On another day, the patients did not participate in an active music therapy intervention. Half of the subjects received the intervention on the first observation day and no intervention on the second observation day. The other half received no intervention the first observation day and received the music intervention on the second observation day. Data were collected for pain, anxiety, and muscle tension at seven points for each patient at each of the two observation periods. The interactions were videotaped. Patients self-rated pain and anxiety. Muscle tension was objectively rated by three research nurses independently viewing the videos and using the Muscle Tension Inventory Scale. The inter-rater reliability for these nurses using this scale was measured at >0.6, an excellent category of agreement.

No significant differences in pain, anxiety, and muscle tension were found between the two treatment days before the dressing changes. All patients reported reduced pain and anxiety on the days with the music intervention during and after dressing changes (pain and anxiety reduction reached statistical significance). Similarly, muscle tension was reduced significantly during and after dressing changes on the music intervention days compared with non-intervention days.

Level of Evidence: 2

This study was well designed with random assignment to crossover timing of the intervention. The addition of an objective measurement of muscle tension added strength to the design. An interim analysis was performed early in the study to establish adequacy of sample size (29 subjects provided power at 80% and the chance of a type I error at .05).

Commentary: Implications for Practice and Research

Several differences in this study enhanced its outcome and credibility compared with previous reports of music therapy effectiveness. One of the most important aspects of this music intervention is that it was an active process, not just the addition of music played passively during the dressing changes. The active process consisted of having patients work with a music therapist in selecting the music type, having "live" music, and having patients sing along or "fill-in" song gaps. Thus the distraction effect away from painful stimuli was high.

A major implication of these results is to test alternate methods of active distraction to supplement or complement drug therapy for pain and anxiety reduction during acutely painful but necessary procedures. Not all patients are equally likely to respond to a music intervention; however, applying this research method to test other active distraction interventions can lead to an increase in the available options.

Surgical Management. Early surgical excision of the burn wound is used in many burn centers (see the [Surgical Excision](#) section on p. 533). Early excision under anesthesia reduces the pain from daily débridement at the bedside or during hydrotherapy.

**DECISION-MAKING CHALLENGE****Patient-Centered Care; Safety**

The patient is a 60-year-old, 148-lb (70-kg) woman admitted directly to the burn center after sustaining an injury from a house fire. She fell asleep while smoking in bed, and the blankets ignited. At the scene, she was given oxygen with a 100% non-rebreather mask. Emergency medical services (EMS) reports from the scene that she is confused and irritable, her blood pressure is decreased, and her heart rate is irregular. She has partial-thickness burns on her entire face and neck. She also has circumferential full-thickness burns to her anterior and posterior chest, abdomen, bilateral upper extremities, and hands. The roughly estimated TBSA burn is 54%. On admission, she is disoriented and has stridor and shortness of breath. Further assessment reveals singed scalp hair, eyebrows, and nasal hairs. A 20-gauge IV line is present in the right antecubital space.

1. Is this patient at risk for an inhalation injury? Support your response.
2. Do you need to perform further assessment of the airway? If yes, what would you expect to find on your assessment that would indicate airway obstruction or inhalation injury?
3. Once the patient has an adequate airway and level of consciousness, what intervention should be implemented next?
4. How would you determine the amount of fluid required for this patient using the rule of nines and the Parkland formula?
5. What parameters would indicate to you that the patient is being adequately resuscitated?

Preventing Acute Respiratory Distress Syndrome

Planning: Expected Outcome. The patient with a burn injury is expected to:

- Not experience acute respiratory distress
- Have arterial blood gases (ABGs) within normal limits
- Maintain normal lung compliance.

Interventions. Patients who develop acute respiratory distress syndrome (ARDS) from burn injuries require thorough assessments and interventions. Interventions focus on increasing lung compliance and improving Pao₂ (partial pressure of arterial oxygen) levels. The priority nursing care actions are coordinating respiratory therapy strategies and monitoring the patient's response to these interventions.

In collaboration with the physician and respiratory therapist, give positive end-expiratory pressure (PEEP) to augment the decreased lung volume by providing a continuous positive pressure in the airways and alveoli. This procedure enhances the diffusion of oxygen across the alveolar-capillary membrane. PEEP can be combined with intermittent mandatory volume (IMV) to enhance its effectiveness.

Assess and document the patient's response so that needed ventilator changes can be made. *Document and immediately report any signs of respiratory distress or change in respiratory patterns to the burn team and the respiratory therapist.* Monitor pulse oximetry and ABG levels to assess changes in respiratory status.

Neuromuscular blocking drugs (atracurium) can be used in patients receiving mechanical ventilation to reduce oxygen consumption (see the discussion of specific nursing care in the [Supporting Oxygenation](#) section, pp. 525-526).

DECISION-MAKING CHALLENGE

Patient-Centered Care; Teamwork and Collaboration

The patient who sustained a 58% TBSA burn injury described on p. 529 is started on fluid resuscitation using the Parkland formula as a guide. She has a Foley catheter in place and now has wine-colored urine. At this time, you are no longer able to palpate her radial pulses. The patient was intubated on arrival to the hospital. Six hours into her resuscitation she has a decrease in her oxygenation saturation and the peak airway pressure alarm on the ventilator keeps sounding.

1. What is the cause of the discolored urine, and what interventions may be prescribed?
2. What are the potential causes for oxygen desaturation and for elevation of peak airway pressures? What is your next intervention?
3. What are the potential causes for a decrease in radial pulses?
4. The patient requires escharotomies to both her extremities and trunk. What steps would you take to prepare the patient for this procedure? What postprocedure care would you perform?

ACUTE PHASE OF BURN INJURY

Overview

The acute phase of burn injury begins about 36 to 48 hours after injury and lasts until wound closure is complete. During this phase, a multidisciplinary approach to care is needed. The nurse coordinates care that is directed toward continued assessment and maintenance of the cardiovascular and respiratory systems, as well as toward GI and nutritional status, burn wound care, pain control, and psychosocial interventions.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Physical Assessment/Clinical Manifestations

Cardiopulmonary Assessment. In the acute phase of burn injury, the priority nursing interventions are to assess the cardiovascular and respiratory systems to maintain these systems and to identify or prevent complications. At this time, the patient may develop pneumonia that can result in respiratory failure requiring mechanical ventilation. Although cardiovascular problems related to the fluid shift should be resolved, the patient is at risk for infection and sepsis, which affect cardiovascular function. The interventions used in the resuscitation phase also may be needed for these new problems.

Neuroendocrine Assessment. The increased metabolic demands placed on the body after a severe burn injury can severely deplete nutritional stores. Weigh the patient daily without dressings or splints, and compare it with his or her preburn weight. A 2% loss of body weight indicates a mild deficit. A 10% or more weight loss is important and requires the evaluation and modification of calorie intake. For very accurate calorie requirements, indirect calorimetry may be used. This method determines kilocalories of energy expenditure by measuring oxygen consumption (VO_2) and carbon dioxide production (VCO_2). Measurements are taken while the patient is at rest—usually at least 30 minutes after the most recent dressing changes or other stressful procedures.

TABLE 28-6 LOCAL AND SYSTEMIC SIGNS OF INFECTION

Local Signs

- Conversion of a partial-thickness injury to a full-thickness injury
- Ulceration of healthy skin at the burn site
- Erythematous, nodular lesions in uninvolved skin and vesicular lesions in healed skin
- Edema of healthy skin surrounding the burn wound
- Excessive burn wound drainage
- Pale, boggy, dry, or crusted granulation tissue
- Sloughing of grafts
- Wound breakdown after closure
- Odor

Systemic Signs

- Altered level of consciousness
- Changes in vital signs (tachycardia, tachypnea, temperature instability, hypotension)
- Increased fluid requirements for maintenance of a normal urine output
- Hemodynamic instability
- Oliguria
- GI dysfunction (diarrhea, vomiting, abdominal distention, paralytic ileus)
- Hyperglycemia
- Thrombocytopenia
- Change in total white blood cell count (above normal or below normal)
- Metabolic acidosis
- Hypoxemia

Indirect calorimetry often is performed shortly after admission to a burn center and at least once each week until the wounds are closed.

Immune Assessment. The patient with a burn injury is at risk for infection because of open wounds and reduced immune function. *Burn wound sepsis is a serious complication of burn injury, and infection is the leading cause of death during the acute phase of recovery.* Continually assess the patient for signs of local and systemic infections (Table 28-6), including changes in wound appearance, changes in neurologic and GI function, and subtle changes in vital signs. Monitor for manifestations of gram-positive, gram-negative, and fungal infections (Table 28-7). Enforce meticulous handwashing by all health care personnel.

NURSING SAFETY PRIORITY

Action Alert

Use aseptic technique in caring for wounds and during invasive monitoring to prevent infections.

Musculoskeletal Assessment. Patients with a burn injury are at risk for musculoskeletal problems as a result of other injuries, immobility, healing processes, and treatment. The musculoskeletal status is first evaluated on admission to the hospital or burn center and throughout the acute phase of injury. Assess active and passive range of motion for all joints, including the neck. Give special attention to joints within the burn area. Ranges and limitations are documented for future reference.

TABLE 28-7 SIGNS AND SYMPTOMS OF SEPSIS CAUSED BY DIFFERENT ORGANISMS

SIGN/ SYMPTOM	GRAM- POSITIVE	GRAM- NEGATIVE	FUNGAL
Onset	Insidious, 2-6 days	Rapid, 12-36 hr	Delayed
Cognition	Severe disorientation and lethargy	Mild disorientation	Mild disorientation
Ileus	Severe	Severe	Mild
Diarrhea	Rare	Severe	Occasional
Temperature	Fever	Hypothermia	Fever
Hypotension	Late	Early	Late
White blood cell count	Neutrophilia	Neutropenia	Neutrophilia
Platelets	Normal	Low	Low

ANALYSIS

During the acute phase of the burn injury, the patient has resolution of some earlier problems, may have initial problems that extend into the acute phase, and may develop new problems. Priority problems for patients with burn injuries greater than 25% TBSA in the acute phase of recovery are:

1. Wound care management related to burn injury, skin grafting procedures, and immobilization
2. Potential for infection related to open burn wounds, the presence of multiple invasive catheters, reduced immune function, and malnutrition
3. Excessive weight loss related to increased metabolic rate, reduced calorie intake, and increased urinary nitrogen losses
4. Reduced mobility related to open burn wounds, pain, and scars and contractures
5. Reduced self-image related to trauma, changes in physical appearance and lifestyle, and alterations in sensory and motor function

PLANNING AND IMPLEMENTATION

Managing Wound Care

Planning: Expected Outcomes. With appropriate intervention, the patient with a burn injury is expected to have no wound extension and have wounds healed. Indicators include that the patient:

- Has presence of granulation, re-epithelialization, and scar tissue formation
- Has decreased wound size
- Has no new wounds

Interventions. Interventions focus on preserving the integrity of nonburned skin, enhancing wound healing of burned skin, and preventing complications.

Nonsurgical Management. Nonsurgical burn wound management involves removing exudates and necrotic tissue, cleaning the area, stimulating granulation and revascularization, and applying dressings. Restoring skin, whether by natural healing or grafting, starts with the removal of eschar and other cellular debris from the burn wound. This removal is called **débridement**. Nonsurgical treatment allows debris removal through mechanical and enzymatic actions that

separate eschar over time. The purpose is to have the wound prepare itself for grafting and wound closure by a natural process. *Priority nursing interventions include assessing the wound, providing wound care, and preventing infection and other complications.*

Mechanical Débridement. Burn wounds are débrided and cleaned one or two times each day during **hydrotherapy** (the application of water for treatment). Nurses, unlicensed assistive personnel (UAP), and physical therapists perform hydrotherapy daily to débride and examine the wounds. Hydrotherapy is most often performed by showering the patient on a specially designed shower table, or washing only small areas of the wound at the bedside. Showering enhances wound inspection and allows water temperature to be kept constant. Immersion of the patient in a tub or whirlpool is not often performed for hydrotherapy because it increases the risk for infection by auto-contamination and cross-contamination.

Nurses and skilled technicians use forceps and scissors to remove loose, nonviable tissue during hydrotherapy. At most burn units, small blisters are left intact because they are a protective barrier that promotes wound healing. Larger blisters are opened. Washcloths or gauze sponges are used to débride soft, “cheesy” eschar. During hydrotherapy, wash burn areas thoroughly and gently with mild soap or detergent and water. Then rinse these areas with room-temperature water.

Enzymatic Débridement. Enzymatic débridement can occur naturally by autolysis or artificially by the application of exogenous agents. **Autolysis** is the disintegration of tissue by the action of the patient’s own cellular enzymes. This process is seldom used in North America for larger burns because it is slow and results in a prolonged hospital stay, increasing the risk for infection.

Topical enzyme agents, such as collagenase (Santyl), are used for rapid wound débridement. When these agents are applied directly to the burn wound in a once-a-day dressing change, the enzymes digest collagen in necrotic tissues. They require a moist environment within a specific pH range to be active. Polysporin powder is often used with this topical agent to prevent infection.

Dressing the Burn Wound. After burn wounds are cleaned and débrided, topical antibiotics are reapplied to prevent infection (see pp. 533-534 in the **Minimizing Infection** section). Some type of dressing is then applied to the burn wound. Burn dressings include standard wound dressings, biologic dressings, synthetic dressings, and artificial skin.

Standard Wound Dressings. Standard wound dressings are multiple layers of gauze applied over the topical agents on the burn wound. The number of gauze layers depends on:

- Depth of the injury
- Amount of drainage expected
- Area injured
- Patient’s mobility
- Frequency of dressing changes

The gauze layers are held in place with roller-type gauze bandages applied in a distal to proximal direction or with circular net fabrics. Cover gauze dressings on the patient’s extremities with elastic wraps, especially if the patient is ambulatory. Dressings are generally changed and reapplied every 8 to 24 hours after thoroughly cleaning the areas.

Biologic Dressings. Biologic dressings are often used for temporary wound coverage and closure. These dressings are

skin or membranes obtained from human tissue donors (homograft or allograft) or animals (heterograft or xenograft). When applied over open wounds, a biologic dressing rapidly adheres and promotes healing or prepares the wound for permanent skin graft coverage.

Biologic materials are used in healing partial-thickness and granulating full-thickness wounds that are clean and free of eschar. Table 28-8 lists the advantages and disadvantages of biologic dressings. The type of biologic dressing selected depends on the type of wound to be covered and the availability of the material.

Homografts, also called *allografts*, are human skin obtained from a cadaver and provided through a skin bank. They are fresh or frozen; frozen skin is thawed in a warm bath of sterile normal saline before application. Disadvantages to the use of homografts are the high costs (\$750 to \$1500 per square foot) and the risk for transmitting a blood-borne infection.

Heterografts, also called *xenografts*, are skin obtained from another species. Pigskin is the most common heterograft and is compatible with human skin. Pigskin is assessed daily for adherence and need for replacement.

Amniotic membrane is another form of biologic dressing used on burn wounds. Its large size, low cost, and availability have helped with its success. In full-thickness injuries, the amniotic membrane adheres to the wound. With partial-thickness areas, the amniotic membrane is effective as a dressing until epithelial cell regrowth occurs. The membrane requires frequent changes because it does not develop a blood supply and it disintegrates in about 48 hours.

Cultured skin can be grown from a small specimen of epidermal cells from an unburned area of the patient's body. The cells are grown in a laboratory to produce cell sheets that can be grafted on the patient to generate a permanent skin surface. The length of time for culturing and growing the skin

is prolonged, and the cell sheets are fragile. Take care when applying these sheets to ensure adherence and prevent sloughing. This process is very costly.

Artificial skin is an alternative approach to closure of the burn wound. This substance has two layers, a Silastic epidermis and a porous dermis made from beef collagen and shark cartilage. After the artificial skin is applied to a clean, excised wound surface, fibroblasts move into the collagen portion and create a structure similar to normal dermis. The artificial dermis slowly dissolves and is replaced with blood vessels and connective tissue (*neodermis*). The neodermis supports a standard autograft placed over it when the Silastic layer is removed.

Biosynthetic Wound Dressings. Biosynthetic wound dressings are a combination of biosynthetic and synthetic materials. Biobrane is commonly used and effective in the treatment of clean superficial partial-thickness burns such as scalds, as a covering for meshed autografts, and as a donor site dressing. It is made up of a nylon fabric that is partially embedded into a silicone film. Collagen is incorporated into both the silicone and the nylon components. The nylon fabric comes into contact with the wound surface and adheres to it until epithelialization has occurred. The porous silicone film allows exudates to pass through.

Synthetic Dressings. Synthetic dressings are made of solid silicone and plastic membranes (e.g., polyvinyl chloride and polyurethane). They are applied directly to the surface of a clean or surgically prepared wound and remain in place until they fall off or are removed. Many of these dressings are transparent or translucent, and the wound can be inspected without removing the dressing. Pain is reduced at the site because these agents also prevent contact of the wound's nerve endings with air. These dressings also are used to cover donor sites where skin was obtained for autografting.

Transparent film is the dressing commonly used for the care of donor site wounds. This dressing type promotes faster healing with low infection rates, minimal pain, and reduced cost.

TABLE 28-8 BIOLOGIC DRESSINGS

Uses

- Débridement of untidy wounds after separation of eschar
- Promotion of re-epithelialization of deep partial-thickness wounds
- Temporary coverage after excision of the burn wound
- Protection of granulation tissue between autografts
- Test graft before autografting

Advantages

- Early adherence to the wound
- Reduction of evaporative heat loss
- Reduction of evaporate water loss
- Prevention of dehydration of granulation tissue
- Reduction of exudate protein losses
- Reduction of pain
- Assistance in wound débridement
- Enhancement of healing with partial-thickness injuries
- Protection of exposed neovascular tissue
- Inhibition of bacterial proliferation

Disadvantages

- Early lysis resulting in bacterial proliferation
- Expensive
- Rejection responses
- Not readily available
- Storage (some may require refrigeration or freezing)
- Possible transmission of diseases, such as hepatitis

NCLEX EXAMINATION CHALLENGE

Psychosocial Integrity

The burn client asks the nurse not to remove the loosened bits of skin and tissue during the dressing change, saying "The more skin you take off, the longer it will take me to heal." What is the nurse's best response?

- "Do you want some pain medication before I begin?"
- "The only things I am removing are blocks of bacteria growth, not skin."
- "Don't worry, I have worked the burn unit for years and know what I am doing."
- "This tissue is no longer living and as long as it is present, real healing cannot start."

Surgical Management. Surgical management of burn wounds involves excision and wound covering. Surgical excision is performed early in the postburn period. Grafting may be performed throughout the acute phase as burn wounds are made ready and donor sites are available. Early grafting reduces the time patients are at risk for infection and sepsis. Wound covering by autografting involves taking healthy skin from an area of the patient's intact skin and transplanting it to an excised burn wound.

FIG. 28-13 The typical appearance of meshed autografts. **A**, Appearance of meshed autograft at application. **B**, Appearance of meshed autograft after healing.

Surgical Excision. Surgical excision is the most common treatment for full-thickness and deep partial-thickness wounds. The patient is taken to the operating room within the first 5 days after injury and again as needed until all wounds are closed permanently.

The burn wound is excised by either a tangential or a fascial excision technique. In the *tangential technique*, the surgeon removes very thin layers of the necrotic burn surface until bleeding tissue is encountered. Bleeding indicates that a bed of healthy dermis or subcutaneous fat has been reached.

In the *fascial technique*, the surgeon cuts away the burn wound to the level of superficial fascia. Fascial excision usually is performed only for very deep and extensive burns. Blood loss is minimal, and grafting is usually successful.

Wound Covering. Permanent skin coverage for large full-thickness injuries occurs by applying an autograft. Skin for an autograft is taken from the patient's body. The surgeon removes a piece of skin from a remote unburned area of the body and transplants it to cover the burn wound. Skin grafts are generally of split thickness (0.015 inch), and a partial-thickness injury is formed at the site of surgical removal (the donor site). Grafts are placed either on a clean granulated bed or over an area from which dead tissue has just been removed.

The available donor sites for larger burns are small. Patients with larger burns may have only 5% to 20% of the skin surface available to use for covering the 80% to 95% burned area. Coverage is accomplished by:

- Repeated removal of skin from the same donor site, with time allowed between harvests for healing
- Meshing the split-thickness skin grafts (Fig. 28-13) to allow a small graft to cover a larger area. Healing time is slower for a meshed graft because the skin must fill in open meshed areas (interstices), as well as attach to the granulation bed

Minimizing Infection

Burn wound infection occurs through **auto-contamination**, in which the patient's own normal flora overgrows and invades other body areas, especially the GI tract; and **cross-contamination**, in which organisms from other people or environments are transferred to the patient.

Planning: Expected Outcomes. The patient is expected to remain free from infection by cross-contamination and not develop sepsis. Indicators include that the patient will exhibit only mild or none of these manifestations:

- Foul-smelling discharge
- Fever
- Blood culture colonization
- Wound site colonization
- White blood cell count elevation

Interventions. Interventions focus on preventing infection and removing infected tissue.

Nonsurgical Management. Priority nursing interventions include using principles of asepsis to prevent infection transmission, providing a safe environment, and monitoring for early detection of infection. Drug therapy, isolation therapy, and environmental management are strategies for preventing and managing infection.

Drug Therapy for Infection Prevention. Burn wound conditions promote the growth of *Clostridium tetani*, and all burn patients are at risk for this dangerous infection. Tetanus toxoid, 0.5 mL given IM, enhances immunity to *C. tetani*. This agent is routinely given when the patient is admitted to the hospital. Administration of tetanus immune globulin (human) (Hyper-Tet) is recommended when the patient's history of tetanus immunization is not known.

The use of topical antimicrobial drugs is an important intervention for infection prevention in burn wounds. The expected outcome of this therapy is to reduce bacterial growth in the wound and prevent sepsis.

Topical antibiotics are applied by either the *open* or the *closed* technique. With the open technique, use either aseptic or clean methods to apply the agent directly to the burn wound without further dressing the wound. Clean the wound every 8 to 24 hours, and apply fresh antimicrobial agents each time. With the more common closed technique, dress the burn wound after applying the topical agents.

Two of the more commonly used agents are silver sulfadiazine (Silvadene, Flamazine) and mafenide acetate (Sulfamylon). Topical antimicrobial drugs are not applied to freshly grafted areas because they may inhibit cell growth. Chart 28-5 lists the features of many topical antimicrobial agents.

CHART 28-5 COMMON EXAMPLES OF DRUG THERAPY

Burns

AGENT	DESCRIPTION	ACTION	ADVANTAGES	DISADVANTAGES	INTERVENTIONS
Silver sulfadiazine (Silvadene, Thermazene)	Nontoxic salt of silver sulfadiazine in water-based cream	Binds to bacterial cell membranes and interferes with DNA synthesis	Does not cause hypochloremia, hyponatremia, electrolyte imbalance, or kidney disease Painless Wide-spectrum antimicrobial action against gram-positive and gram-negative organisms Long shelf life Delays eschar separation to a lesser degree than do many other topical drugs	Absorbed into eschar less than other drugs May cause rash, pruritus, burning, and leukopenia Not consistently effective for burns covering 60% of the body Not effective against <i>Pseudomonas</i>	Watch for signs of infection, such as souppiness of wound area. Watch for allergic reaction causing a drop in white blood cell count. Do not use if reaction to sulfonamide has occurred. Use on deep partial-thickness or full-thickness wounds.
Collagenase (Santyl) with Polysporin powder	Topical enzymatic debridging agent with 250 collagenase units/g of white petroleum	Digests collagen in necrotic tissue	Painless Daily dressing changes Side effects are rare Quick débridement action Easy to apply Not harmful to healthy tissue Specific only to nonviable tissue	Expensive	Apply once a day. Use on deep partial-thickness wound with eschar. Monitor wounds for infection. May be used with barrier dressing such as Xeroform.
Mafenide acetate (Sulfamylon)	Soft, white, non-staining, water-based cream Available in solution	Bacteriostatic action against many gram-positive and gram-negative organisms	Effective against <i>Pseudomonas</i> Long shelf life Excellent for treating electrical burns Penetrates thick eschar May use as a solution to wet down grafts or wounds	May lead to infection May cause metabolic acidosis, hyperpnea, and rash When applied, may cause pain that lasts 30-40 minutes	Premedicate for pain before application. Monitor blood gas and serum electrolyte levels. Monitor for infection.
Nitrofurazone (Furacin)	Cream, solution, or water-soluble ointment, or foam	Wide-spectrum anti-bacterial	Effective against <i>Staphylococcus aureus</i> and some antibiotic-resistant organisms Causes neither pain nor maceration	May cause contact dermatitis (rare) Messy to apply in cream form May cause renal problems if used in extensive burns	Observe carefully for signs of allergic reaction and evidence of superinfection.
Gentamicin sulfate (Garamycin, Gentamar)	Available as a cream or solution for topical use	Antibiotic action against organisms resistant to other drugs	Effective against <i>Pseudomonas</i> Does not cause pain	May have ototoxic (ear) and nephrotoxic (kidney) effects May result in resistance by certain organisms	Use with caution in patients with decreased kidney function. Monitor serum and urine creatinine clearance before and during treatment.
Polymyxin B-bacitracin (AK-Poly-Bac, Polysporin)	Topical cream	Wide-spectrum antimicrobial	Painless Effective against many gram-positive and gram-negative organisms Can be used on face Can be placed on healed grafts to lubricate	May cause urticaria, burning, and inflammation Does not penetrate eschar	Apply every 2-8 hr to keep areas moist.

Acticoat	Two layers on a silver-coated, high-density, polyethylene mesh, enclosing a single layer of an apertured non-woven fabric of rayon and polyester	Releases antimicrobial silver ions when moistened with sterile water	Effective against a wide range of gram-negative and gram-positive bacteria Decrease in pain due to decrease in number of dressing changes required Effective against some strains of yeast and fungi May be left in place up to 3 days	Needs to be wet down with sterile water Expensive May cause elevated serum silver levels, elevated liver function tests, and transient gray facial discoloration	Do not use with oil-based products or other topical antimicrobials. Contraindicated in patients with known hypersensitivity to any of the components of the product. May dry out and adhere to the wound surface; soak off to remove.
PolyMem	Hydrophilic pink polyurethane foam sheet bonded to a semipermeable polyurethane film; foam contains a non-ionic surfactant that is activated by moisture	Contains a mild, nontoxic, non-ionic, tissue-friendly cleansing agent that is activated by moisture, drainage, and/or exudate and is gradually released into the wound bed Reduces interfacial tension between healthy tissue and debris, loosens eschar and necrotic tissue, and supports autolytic débridement	May be left on for 7 days Provides liquid barrier and allows for gas exchange Provides wound comfort Cost-effective due to using less materials and number of dressings required	Expensive Contains no antimicrobial properties	Change earlier than 7 days if exudate is visible through outer dressing. Watch for signs of infection. Use on partial-thickness wounds. Must be covered with secondary dressing. May be used on donor sites.
Aquacel Ag	Made from sodium carboxymethylcellulose containing 1.2% ionic silver	Releases ionic silver in a controlled manner as wound exudate is absorbed into the dressing Supports wound healing by providing a moist wound healing environment Dressing absorbs and interacts with wound exudate to form a soft, hydrophilic, gas-permeable gel that traps bacteria and conforms to the contours of the wound while providing a micro-environment	Antimicrobial effect against wide range of organisms including MRSA, VRE May be left on up to 14 days Decreased pain due to decrease in number of dressing changes	Expensive May interfere with movement when used over joints	Use on partial-thickness wounds. Must be covered with secondary dressing. Do not use for patients who are sensitive or have allergic reaction to dressing or its components. Moisten with sterile water or saline to ease removal. Do not use with oil-based products.
Mepilex Ag	Antimicrobial soft silicone foam	Absorbs exudates and maintains moist environment Begins inactivating wound pathogens within 30 minutes of application to wound	Effective sustained release of silver up to 7 days Broad antimicrobial protection including MRSA Decreased pain due to decrease in number of dressings Easy removal from wound	Expensive	Do not use on patients with known hypersensitivity to silver. Do not use together with oxidizing agents such as hydrogen peroxide. May be used in partial- and full-thickness burns. Must apply secondary dressing. May be used with skin grafts and donor sites.

MRSA, Methicillin-resistant *Staphylococcus aureus*; VRE, vancomycin-resistant *Enterococcus*.

Drug Therapy for Treatment of Infection. Systemic antibiotics are used when burn patients have symptoms of an actual infection, including septicemia. Broad-spectrum antibiotics are given until the results of blood cultures and sensitivity status are available. At that time, antibiotics that are effective against the specific organism(s) causing the infection are used. Because of increased metabolism, burn patients may require a higher dose of these drugs to maintain effective blood levels. For some antimicrobials, serial peak and trough blood levels are monitored to determine the efficacy of treatment and evaluate potential ear and kidney toxicity.

Providing a Safe Environment. Providing a safe environment can include isolation therapy. More commonly, it involves coordinating all members of the health care team in the use of asepsis and monitoring for early recognition of actual infection.

Isolation therapy is used in some burn centers with the belief that it reduces cross-contamination, although this practice is controversial. Some burn centers practice no isolation, whereas others use near-total sterile conditions. All isolation methods use proper and consistent handwashing as the most effective technique for preventing infection transmission.

Use of asepsis requires all health care personnel to wear gloves during all contact with open wounds. The use of sterile versus clean gloves for routine wound care varies by agency and is a matter of debate. Regardless of sterility, change gloves when handling wounds on different areas of the body and between handling old and new dressings.

The equipment on burn units is not shared among patients. Disposable items (e.g., pillows, syringes, dishes) are used as much as possible. Assign any equipment used in daily routine care (e.g., thermometers, blood pressure cuffs, stethoscopes) to each patient for the duration of his or her stay. Daily cleaning of the equipment and general housekeeping are essential for infection control. All single-item unit equipment must be cleaned after use on one patient and before use on another. Because *Pseudomonas* has been found in plants, the presence of plants and flowers is prohibited. Some burn units do not permit patients to eat raw foods (e.g., salads, fruit, pepper) to reduce exposure to organisms. Rugs and upholstered articles are difficult to clean and may harbor organisms; their use is also restricted.

Visitors are restricted when the patient is immunosuppressed. Ill people, small children, and other patients should not come into direct contact with the burn patient. Some burn units recommend that all visitors wear protective clothing (gowns, gloves, masks, and shoe and hair covers) in the burn patient's room, but no data support the effectiveness of this approach.

Early detection involves careful monitoring of the burn wounds at each dressing change. Examine the wounds for these signs of infection:

- Pervasive odor
- Color changes—focal, dark red, brown discoloration in the eschar
- Change in texture
- Purulent drainage
- Exudate
- Sloughing grafts
- Redness at the wound edges extending to nonburned skin

Laboratory cultures and biopsies are recommended. Quantitative biopsies of the eschar and granulation tissue are

performed routinely and as needed to monitor the growth of organisms. These tests are the gold standard for wound monitoring.

Surgical Management. Infected burn wounds with colony counts of or approaching 10^5 colonies per gram of tissue may be life threatening, even with antibiotic therapy. Surgical excision of the burn wound may be necessary to control these infections.

Minimizing Weight Loss

Planning: Expected Outcomes. The patient is expected to maintain adequate nutrient intake for meeting the body's calorie needs. Indicators include that the patient should have mild or no deviations from the normal ranges for:

- Weight/height ratio
- Food intake
- Hematocrit and hemoglobin
- Serum albumin
- Blood glucose

Interventions. Interventions include calculating the patient's calorie needs and providing an adequate daily source of calories and nutrients that the patient can ingest and metabolize. Coordinate with a registered dietitian to meet the expected outcomes regarding the patient's nutritional status. Therapy begins with calculating the patient's current daily calorie needs. Several formulas and charts are used for this calculation. Nutritional requirements for a patient with a large burn area can exceed 5000 kcal/day (Prelack et al., 2007). In addition to a high-calorie intake, the burn patient requires a diet high in protein for wound healing. Work with the dietitian and the patient to plan additions to standard nutritional patterns.

Oral diet therapy may be delayed for several days after the injury until the GI tract is motile. Nasoduodenal tube feedings are often started soon after admission. Beginning enteral feedings early helps decrease weight loss, gut atrophy, bacterial translocation, and sepsis. These feedings often are started within 4 hours of beginning fluid resuscitation. This type of supplement prevents nutritional deficits in severely burned patients.

Encourage patients who can eat solid foods to ingest as many calories as possible. Consider the patient's preferences with diet planning and food selection. Encourage patients to request food whenever they feel they can eat, not just according to the hospital's standard meal schedule. Offer frequent high-calorie, high-protein supplemental feedings. Keep an accurate calorie count for foods and beverages that are actually ingested by the patient.

Patients who cannot swallow but who have adequate gastric motility may meet calorie and nutrition needs through enteral tube feedings (see [Chapter 63](#)). Parenteral nutrition may be given IV when the GI tract is not functional or when the patient's nutritional needs cannot be met by oral and enteral feeding. This method is used as a last resort because it is invasive and can lead to infectious and metabolic complications.

Maintaining Mobility

Planning: Expected Outcomes. The patient with a burn injury is expected to maintain or regain an optimal ability to move purposefully. Indicators include that the patient should have minimal limitations in these actions:

- Muscle movement
- Joint movement

CHART 28-6 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Positioning to Prevent Contractures

Affected Body Part	Position of Function	Intervention
Head and neck	Hyperextension	No pillow. Place a towel roll under the patient's neck or shoulder. Neck splint.
Posterior neck	Flexion	Have patient turn the head from side to side.
Upper chest and chest	Shoulder retraction	Place patient in supine position. Place a folded towel under the spine, between the scapulae.
Lateral trunk	Flexion to uninvolved side	Place patient supine with arm on the affected side up over the head.
Anterior shoulder	Abduction and external rotation	Maintain the upper arm at 90 degrees of abduction from the lateral aspect of the trunk.
Posterior shoulder	Slight flexion and interior rotation	Keep the arm slightly behind the midline.
Axilla	Abduction with 10- to 15-degree forward flexion and external rotation	Support the abducted arm with suspension from IV pole or bedside table. Axilla splint.
Elbow	Extension and supination	Keep the joint in the extended position.
Wrist	30 to 45 degrees of extension	Use a splint.
Fingers		
MP joints	70 to 90 degrees of flexion	Use a splint.
PIP and DIP joints	Extension	Use a splint.
Ankle	90 degrees of dorsiflexion	Use a padded footboard or splint with heels free of pressure.
Legs	15 to 20 degrees of abduction	Place small pillow between legs.
Hip	Extension and neutral rotation	Place patient supine with lower extremity extended. Use trochanter roll. Use foam wedge along lateral aspect of thigh.

DIP, Distal interphalangeal; MP, metatarsophalangeal; PIP, proximal interphalangeal.

- Walking
- Body positioning performance

Interventions. Interventions focus on maintaining the patient's preburn range of joint motion and preventing contracture formation.

Nonsurgical Management. Nonsurgical management includes the nursing interventions of positioning, range-of-motion exercises, ambulation, and pressure dressings.

Positioning is critical for patients with burn injuries because the position of comfort for the patient is often one of joint flexion, which leads to contracture development. Maintain the patient in a neutral body position with minimal flexion. Best practices for preventing contractures are listed in [Chart 28-6](#). Splints and other devices may help the patient maintain good positioning. These devices usually are used on the hands, elbows, knees, neck, and axillae.

Range-of-motion exercises are performed actively at least three times a day. If the patient cannot move a joint actively, perform passive range-of-motion exercises. Give burned hands special attention. Urge the patient to perform active range-of-motion exercises for the hand, thumb, and fingers every hour while he or she is awake.

Ambulation is started as soon as possible after the fluid shifts have resolved. Patients with attached equipment (IV catheters, nasogastric tubes, ECG leads, extensive dressings) can ambulate with preparation and assistance. This activity is performed two or three times a day and progresses in length each time. Ambulation inhibits bone density loss, strengthens muscles, stimulates immune function, promotes ventilation, and prevents many complications.

Pressure dressings are applied after grafts heal to help prevent contractures and tight hypertrophic scars, which can

FIG. 28-14 A patient wearing a compression garment over dressings.

inhibit mobility. These dressings also inhibit venous stasis and edema in areas with decreased lymph flow. Pressure dressings may be elastic wraps or specially designed, custom-fitted, elasticized clothing that provides continuous pressure. [Fig. 28-14](#) shows such a garment. For best effectiveness, pressure garments must be worn at least 23 hours a day, every day, until

the scar tissue is mature (12 to 24 months). These garments can be uncomfortable with itchiness and increased warmth. Reinforce to the patient and family that wearing pressure garments is beneficial in saving mobility and reducing scarring.

Surgical Management. Surgical management restores mobility rather than prevents immobility. Surgical release of contractures is commonly performed in the neck, axilla, elbow flexion areas, and hand. Specific surgical procedures vary for each patient.

Nursing responsibilities include interventions to prevent contractures from re-forming, as well as the care of new grafts and suture lines. Constantly reinforce the need for the patient to adhere to exercise and splinting regimens to prevent the recurrence of joint immobility.

Supporting a Positive Self-Image

Planning: Expected Outcomes. After intervention, the patient with a burn injury is expected to have a positive perception of his or her own appearance, body functions, and self-worth. Indicators include that the patient should consistently demonstrate these behaviors:

- Willingness to touch the affected body part
- Adjustment to changes in body function
- Willingness to use strategies to enhance appearance and function
- Successful progression through the grieving process
- Use of support systems

Interventions. Nonsurgical and surgical interventions can assist patients who have body image and self-image problems as a result of burn injury.

Nonsurgical Management. Understanding the stages of grief is helpful for the patient, family, and health care professionals. Assess which stage of grief the patient is currently experiencing, and help interpret his or her behaviors. The patient often is unaware of or is confused by his or her feelings. Reassure the patient that feelings of grief, loss, anxiety, anger, fear, and guilt are normal. The patient may be grieving the loss of body parts, appearance, role identity, and social identity. Coordinate with other health care team members (e.g., psychologist, psychiatrist, social worker, clergy or religious leader) in addressing these problems.

Accept the physical and psychological features of the patient. Present patients and families with realistic expected outcomes for the patient's functional capacity and physical appearance. Provide information sessions and counseling for the family to identify patterns of support. Facilitate the patient's use of these systems and the development of new support systems. Make referrals to support groups. To identify the effectiveness of such assistance and possible gaps in support, evaluate support resources throughout the course of recovery.

Engaging in decision making and independent activities fosters feelings of self-worth, which are closely linked to self-image. Plan and encourage the patient's active participation in self-care activities. Assist family members to understand that it is more beneficial for the patient to perform these activities than to have them performed by someone else. Urge families to include the patient in family decision making to the same degree that he or she participated in this process before the injury.

Surgical Management. Reconstructive and cosmetic surgery can be performed many years after the burn injury.

Restoring function and improving appearance through surgical techniques often increase the patient's feelings of self-worth and promote a positive self-image. Many patients have unrealistic expectations of reconstructive surgery and envision an appearance identical or equal in quality to the preburn state. Teach the patient and family about expected cosmetic outcomes.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Teamwork and Collaboration

A 60-year-old who sustained a 58% TBSA flame burn had topical silver sulfadiazine (Silvadene) applied to her wounds. On the fifth postburn day, she becomes febrile and has an elevated WBC count with a left shift. When you change her dressing, you notice malodor coming from her wound.

1. What is the likely cause of the fever and leukocytosis?
2. What other assessment data would indicate sepsis?
3. What interventions are taken by the health care team to prevent wound infection and sepsis in the burn patient?

REHABILITATIVE PHASE OF BURN INJURY

Overview

Although rehabilitation efforts are started at the time of admission, the technical rehabilitative phase begins with wound closure and ends when the patient returns to his or her highest level of functioning. The emphasis is on the psychosocial adjustment of the patient, the prevention of scars and contractures, and the resumption of preburn activity, including resuming work, family, and social roles. This phase may take years or even last a lifetime as patients adjust to permanent limitations.

PATIENT-CENTERED COLLABORATIVE CARE

Although attention is placed first on the physical interventions for the burn injury, psychological care is equally important. Provide psychosocial support to the patient and family throughout hospitalization but more extensively in the rehabilitative phase.

Information from the patient and family aids in the assessment and diagnosis of psychological problems and allows treatment to be instituted. Explore the patient's feelings about the burn injury. It is extremely difficult for patients to concentrate on the many tasks before them when obstacles such as guilt and grief are in the forefront.

Ask the patient or family member whether there is a history of psychological problems. To assist with a future plan of care, assess and document the type of coping mechanisms the patient has used successfully during times of stress. Also assess the patient's family unit and the family members' history of interaction. Identify cultural and ethnic factors, and consider these when planning psychosocial interventions.

Throughout the hospitalization, the patient progresses through a variety of stages and exhibits many feelings, including denial, regression, and anger. Accurately assess the patient's feelings during each stage so appropriate plans of care can be developed and carried out.

TABLE 28-9 NEEDS TO ADDRESS BEFORE DISCHARGE OF THE PATIENT WITH BURNS

• Early patient assessment • Financial assessment • Evaluation of family resources • Weekly discharge planning meeting • Psychological referral • Patient and family teaching (home care) • Designation of principal learners (specific family members or significant others who will help with care) • Development of teaching plan • Training for wound care	• Rehabilitation referral • Home assessment (on-site visit) • Medical equipment • Public health nursing referral • Evaluation of community resources • Visit to referral agency • Re-entry programs for school or work environment • Long-term care placement • Environmental interventions • Auditory testing • Speech therapy • Prosthetic rehabilitation
--	--

Community-Based Care

Discharge planning for the patient with a burn injury begins at admission to the hospital or burn center. The multidisciplinary team meets regularly to plan for discharge. In helping the patient reach mutually established discharge outcomes, the team evaluates the progress of each discipline. Table 28-9 lists common discharge needs of the patient with burns.

Psychosocial Preparation

During the recovery period and for some time after discharge from the hospital, patients with severe burn injuries are likely to have psychological problems that require intervention. Such problems include post-traumatic stress disorder, sexual dysfunction, and severe depression. Assistance is coordinated with the patient, family, and health care team. Psychosocial assistance is best provided by a professional counselor with experience in helping burn patients.

One specific area to address with the patient is the reaction of others to the sight of healing wounds and disfiguring scars. Patients with facial burns are especially subjected to stares and other reactions from the public. Visits from friends and short public appearances before discharge may help the patient begin adjusting to this problem. Community reintegration programs can assist the psychosocial and physical recovery of the patient with serious burns.

NCLEX EXAMINATION CHALLENGE

Psychosocial Integrity

Which statement made by the client who experienced burns to the head and neck indicates positive adjustment to the injury?

- "I am planning on cutting the grass in the mornings when the sun isn't as strong."
- "I am working with my family so they can do all of the chores I used to do."
- "I hope the home care nurse can change my dressings so that I do not have to look at my wounds."
- "My wife and I have decided to go to movies instead of baseball games so that people can't see me."

Home Care Management

The patient with severe burns is discharged from the acute care setting when serious complications are resolved and

minimal wound areas remain open. During the first weeks at home, the patient usually needs at least daily wound care, physical therapy, nutritional support, symptom management, and drug therapy.

Although the patient usually views going home in a positive light, the problems of physical care and the psychological stresses from changes in appearance, role, function, and lifestyle may overwhelm the patient and family. Successful discharge depends on extensive planning and preparation of the patient, family, and home environment through education and the involvement of appropriate support agencies and services.

Preparation for discharge includes assessment of the family and home care situation from physical and social perspectives. Consider the needs of the patient when evaluating the home for cleanliness; access to bathing facilities, electricity, and running water; stairways; number of occupants; temperature control; and safety. If the burn injuries occurred in a house fire, a new residence may need to be established.

Teaching for Self-Management

Education about burn care and living with the consequences of burn injuries begins when the patient is admitted to the hospital or burn center. A weekly plan for patient education is outlined; a positive outcome is progression toward independence for the patient and family. Critical for this outcome is teaching patients and family members to perform such care tasks as dressing changes. Allow patients and family members to first observe dressing changes, then to assist in performing the changes, and finally to change the dressings independently under your supervision.

Before discharge, all people who will be involved in the patient's home care participate in discharge planning and teaching sessions. In addition to details about dressing changes, explain:

- Signs and symptoms of infection
- Drug regimens
- Proper use of prosthetic and positioning devices
- Correct application and care of pressure garments
- Comfort measures to reduce pruritus
- Dates for follow-up appointments

Health Care Resources

The health care team evaluates the family in terms of capacity and willingness to assist in providing care to the patient after discharge. A visiting nurse or case manager referral can assist the family with care problems arising at home. In addition, the visiting nurse can help the family determine what special equipment, supplies, or services will be needed. The frequency of home visits depends on the patient's condition and the ability of family members to function as care providers. *It is imperative that the visiting nurse have extensive experience in providing burn care.* The home care nurse may need a brief visit to the patient while in the hospital and may need to observe burn wound care.

The home care of a patient after a serious burn often involves daily physical therapy and rehabilitation sessions at special centers. Address and resolve transportation problems before the patient is discharged. In some instances, the burn center has arrangements for transportation. Some community volunteer agencies provide transportation by private car.

When rehabilitation is prolonged, the patient may be discharged to a rehabilitation facility. Consult with the rehabilitation team, and provide copies of the care and teaching plans used with the patient.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Teamwork and Collaboration

A 60-year-old patient who sustained a flame injury and smoke inhalation injury has had several surgical procedures for skin grafting. She also had a tracheostomy and amputation of her fingers of her right hand (she is right-hand dominant). She has been in the Burn Center for 2 months and is now in her third week on a rehabilitation floor. Although she has survived and her family is very grateful, you notice the patient does not participate in her therapy and has a loss of appetite. She sits in the chair most of the day staring out the window. Your assessment reveals that she is depressed.

1. Are these symptoms the patient is experiencing part of the complex systemic response to burn injuries? If so, is this expected at this time? Why or why not?
2. What resources or referrals would be most appropriate for this patient at this time?

EVALUATION: OUTCOMES

Evaluate the care of the patient with a burn injury on the basis of the identified priority patient problems. The expected outcomes include that the patient should:

- Maintain adequate oxygenation and circulation to all vital organs
- Maintain a patent airway
- Have cardiac output restored to normal
- Have pain alleviated or reduced
- Experience no further loss of skin integrity
- Have wounds healed without complications
- Remain free from infection by cross-contamination
- Not experience sepsis
- Maintain an adequate nutrient intake for meeting the body's calorie needs
- Regain and maintain an optimal ability to move purposefully
- Have a positive perception of his or her own appearance and body functions

Specific indicators for these outcomes are listed for each priority patient problem in the Planning and Implementation section (see earlier).

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use strict aseptic technique when caring for patients who have open burn wounds.
- Check ventilator alarm settings hourly for patients who are receiving paralytic drugs during mechanical ventilation.

Health Promotion and Maintenance

- Encourage all people to have and maintain home smoke and carbon monoxide detectors.
- Warn patients who smoke about not smoking in bed and not smoking when taking any substance that induces sedation (drugs or alcohol).
- Instruct patients who have reduced sensation in hands or feet to use a bath thermometer to check water temperature before bathing.
- Teach patients to avoid exposing burned skin to the sun or to temperature extremes.

Psychosocial Integrity

- Allow patients time to grieve over a change in body image.
- Reassure patients that pain will be managed effectively.
- Explain all procedures to the patient.

- Give analgesics, sedatives, and antianxiety drugs to patients receiving paralytic drugs during mechanical ventilation.
- Encourage the patient to actively participate in pain control measures.
- Encourage the patient to look at and touch burned areas.

Physiological Integrity

- Assess the burn patient's airway and adequacy of breathing before assessing any other body system.
- Keep an endotracheal kit or tracheostomy kit at the bedside of any patient with facial burns, burns inside the mouth, singed nasal hairs, or a "smoky" smell to the breath.
- Notify the Rapid Response Team immediately if the patient with an inhalation injury becomes more breathless or audible wheezes disappear.
- Give half of the fluid volume calculated for the first 24 hours after burn injury in the first 8 hours postburn.
- Give prescribed opioid analgesics by the IV route during the resuscitation phase of burn recovery.
- Position patients to prevent contractures and promote joint function.
- Assist patients to ambulate several times each day as soon as the fluid shifts have resolved.
- Encourage patients to use the prescribed splints and pressure garments to prevent joint immobility.

CONCEPT OVERVIEW

Oxygenation and Tissue Perfusion

All cells and tissues need oxygen to live and function. Some cells, such as brain cells and heart muscle cells, are very dependent on oxygen. Without oxygen, brain cells stop functioning and die in about 5 to 10 minutes. Other cells, such as skin cells, can live and function for many hours with low oxygen levels or even without oxygen. Skeletal muscle cells can survive for hours with low levels of oxygen but cannot function for very long without it.

The source of the oxygen for all body cells is the air we breathe into our lungs. Delivery of oxygen to the cells and tissues requires the pumping mechanism of the heart and the oxygen-carrying mechanism of the hemoglobin in red blood cells. In health, the need of body tissues for oxygen is balanced by the body's oxygen intake and delivery systems (Fig. 1).

When oxygen needs increase, such as during mild to moderate exercise, oxygen intake through the respiratory system increases to compensate (or adjust) and keep oxygen delivery to the tissues in balance with their oxygen need (Fig. 2).

When oxygen need increases as a result of heavy exercise or an illness in which metabolism is increased (and the person has a fever), all oxygen intake and delivery systems must adjust by increasing their activity to match the increased oxygen need. When this compensation is perfect, the increased rate and depth of respiration, along with the increased heart rate and blood pressure, keep oxygen intake and delivery in balance with oxygen need (Fig. 3).

FIG. 3

Some health problems reduce the body's ability to compensate when oxygen need is greater than basic (basal) levels. For example, in a person who has asthma, the lungs may be able to take in enough oxygen to meet basic oxygen needs but cannot adjust or compensate when a greater oxygen intake is needed, such as during mild to moderate exercise (Fig. 4).

In this situation, the heart needs to compensate *more* to increase delivery of the set amount of oxygen taken in (Fig. 5).

In another situation, when the person has a cardiac problem and the heart rate alone cannot increase oxygen delivery during mild to moderate exercise (Fig. 6), his or her respiratory rate would have to increase more than usual to keep oxygen delivery in balance with oxygen need.

What happens when any part of the oxygen intake or delivery systems has a problem that interferes with ensuring that the cells have enough oxygen? Consider a person with pneumonia who has great difficulty with oxygen intake to the point that the body's basic oxygen need is not met. Even though the oxygen need is at a basic level, the need is unbalanced compared with oxygen intake and delivery. The person's compensation mechanisms are working (respiratory rate is increased, heart rate is increased) but are not completely effective. How could balance be restored? Interventions are needed to support the body's compensation efforts to restore balance.

The best way is to eliminate the pneumonia, which could take days even with proper drug therapy. Other ways involve (1) reducing oxygen need to the lowest possible level by having the patient rest and (2) improving oxygen intake by increasing the percentage of oxygen in the air that he or she breathes (oxygen therapy) (Fig. 7).

LEARNING OUTCOMES

Health Promotion and Maintenance

1. Encourage all people to use masks and adequate ventilation when engaging in activities that expose them to inhalation irritants and toxins.

Psychosocial Integrity

2. Teach patients and family members about what to expect during tests and procedures to assess respiratory function and respiratory disease.

Physiological Integrity

3. Assess the patient's endurance in performing ADLs.
4. Use concepts of anatomy and appropriate psychomotor skills to apply respiratory assessment techniques correctly.

5. Perform a clinical respiratory assessment, including health history, genetic risk, physical assessment, and psychosocial assessment.
6. Distinguish between normal and abnormal (adventitious) breath sounds.
7. Explain the respiratory changes associated with aging.
8. Calculate the pack-year smoking history for the patient who smokes or who has ever smoked cigarettes.
9. Interpret arterial blood gas values to assess the patient's respiratory status.
10. Explain nursing care needs for the patient after bronchoscopy or open lung biopsy.

All cells need oxygen (O_2) to live and perform their specific jobs. Oxygen intake depends on the respiratory system (Fig. 29-1). The respiratory system is important for *oxygenation and tissue perfusion* because the source of the oxygen for all body cells is the air we breathe. This system includes the upper airways, lungs, lower airways, and alveolar air sacs. Air with oxygen enters the nose and mouth and moves through the airways or respiratory tubes (trachea, bronchi, bronchioles) and into the air sacs (alveoli) of the lungs. Once in the air sacs, the oxygen from the air moves into the blood so that it can be carried to all tissues and organs. Carbon dioxide (CO_2), the waste gas created in the tissues, moves from the

blood into the lungs so it can be exhaled. All systems depend on adequate oxygen intake for tissue perfusion with oxygen. Any respiratory problem affects total body health and well-being.

Lung and breathing problems are common and are the fifth leading cause of death in North America (McCance et al., 2010). Some respiratory problems are chronic, and the patient has physical and lifestyle limitations. Many acute health problems, medical therapies, and surgeries adversely affect respiratory function temporarily or permanently.

ANATOMY AND PHYSIOLOGY REVIEW

The purposes of breathing are (1) to provide *oxygen for tissue perfusion* so that cells have enough oxygen to metabolize and generate energy and (2) to remove carbon dioxide, the waste product of metabolism. The respiratory system also influences acid-base balance, speech, sense of smell, fluid balance, and temperature control. The lungs are also an excretory organ because they can also break down some toxins and eliminate them from the body during exhalation.

Upper Respiratory Tract

The upper airways consist of the nose, the sinuses, the pharynx, and the larynx (Fig. 29-2).

Nose and Sinuses

The nose is the organ of smell, with receptors from cranial nerve I (*olfactory*) located in the upper areas. This organ is rigid and contains two passages separated by the septum. The upper nose is composed of bone; the lower two thirds is composed of cartilage, allowing some movement. The septum

FIG. 29-1 Role of the respiratory system in oxygenation and tissue perfusion. RBCs, Red blood cells.

FIG. 29-2 Structures of the upper respiratory tract.

and interior walls of the nasal cavity are lined with mucous membranes that have a rich blood supply. The **anterior nares** (external openings into the nasal cavities) are lined with skin and hair, which help keep particles or organisms from entering the lungs. The posterior nares are openings from the nasal cavity into the throat.

The **turbinates** are three bones that protrude into the nasal cavities from the internal portion of the nose (see Fig. 29-2). Turbinates increase the total surface area for filtering, heating, and humidifying inspired air before it passes into the nasopharynx. Inspired air entering the nose is first filtered in the nares. Particles not filtered out in the nares are trapped in the mucous layer. These particles are moved by **cilia** (hair-like projections) to the throat, where they are either swallowed or expectorated. Inspired air is humidified by the mucous membrane and is warmed by heat from the vascular network.

The **paranasal sinuses** are air-filled cavities within the bones that surround the nasal passages (Fig. 29-3). Lined with ciliated membrane, the purposes of the sinuses are to provide resonance during speech and to decrease the weight of the skull.

Pharynx

The pharynx, or throat, is a passageway for both the respiratory and digestive tracts. It is located behind the oral and nasal cavities. The throat is divided into the nasopharynx, the oropharynx, and the laryngopharynx (see Fig. 29-2).

The nasopharynx is located behind the nose, above the soft palate. It contains the adenoids and the opening of the eustachian tube. The **eustachian tubes** connect the nasopharynx with the middle ears and open during swallowing to equalize pressure within the middle ear.

The oropharynx is located behind the mouth, below the nasopharynx. It extends from the soft palate to the base of the tongue and is used for breathing and swallowing. The **palatine tonsils**, which are part of the immune system, are located on the side borders of the oropharynx. They guard the body against invading organisms.

The **laryngopharynx** is the area located behind the larynx, extending from the base of the tongue to the esophagus. It is

the critical dividing point where foods and fluids are separated from air. At this point, the passageway divides into the larynx and the esophagus.

Larynx

The **larynx** is the “voice box” and is located above the trachea, just below the throat at the base of the tongue. It is controlled by the recurrent laryngeal nerves. The larynx is composed of several cartilages (Fig. 29-4). The **thyroid cartilage** is the largest and is commonly called the “Adam’s apple.” The **cricoid cartilage**, which contains the vocal cords, lies below the thyroid cartilage. The **cricothyroid membrane** is located below the level of the vocal cords and joins the thyroid and cricoid cartilages. This site is used in an emergency for access to the lower airways. In this procedure, called a **cricothyroidotomy**, an opening is made between the thyroid and cricoid cartilage and results in a tracheostomy. The two **arytenoid cartilages** work with the thyroid cartilage in vocal cord movement.

Inside the larynx are two pairs of vocal cords: the false vocal cords and the true vocal cords. The **glottis** is the opening between the true vocal cords (Fig. 29-5). The **epiglottis** is a leaf-shaped, elastic structure that is attached along one edge to the top of the larynx. Its hingelike action prevents food from entering the trachea (aspiration) by closing over the glottis during swallowing. The epiglottis opens during breathing and coughing.

FIG. 29-4 Structures of the larynx.

FIG. 29-3 The paranasal sinuses.

FIG. 29-5 Detail of the glottis (two vocal folds and the intervening space, the rima glottidis).

FIG. 29-6 Structures of the lower respiratory tract.

Lower Respiratory Tract

Airways

The lower airways are the trachea; two mainstem bronchi; lobar, segmental, and subsegmental bronchi; bronchioles; alveolar ducts; and alveoli (Fig. 29-6). The lower respiratory tract (*tracheobronchial tree*) is an inverted treelike structure consisting of muscle, cartilage, and elastic tissues. This system of branching tubes, which decrease in size from the trachea to the respiratory bronchioles, allows gases to move to and from the lungs. Gas exchange takes place in the lung tissue between the alveoli and the lung capillaries, not in the airways.

The *trachea* (windpipe) is located in front of the esophagus. It begins at the lower edge of the cricoid cartilage of the larynx and extends to the level of the fourth or fifth thoracic vertebra. The trachea branches into the right and left mainstem bronchi at a junction called the **carina**. The trachea contains 6 to 10 C-shaped rings of cartilage. The open portion of the C is the back portion of the trachea and contains smooth muscle that is shared with the esophagus.

The *mainstem bronchi*, or primary bronchi, begin at the carina. The bronchus is similar in structure to the trachea. The right bronchus is slightly wider, shorter, and more vertical than the left bronchus. Because of these differences, the right bronchus can be accidentally intubated when an endotracheal tube is passed. Also, when a foreign object is aspirated from the throat, it usually enters the right bronchus.

The mainstem bronchi branch into the secondary (lobar) bronchi that enter each of the five lobes of the two lungs. Each lobar bronchus branches into progressively smaller divisions. The cartilage of these lobar bronchi is ring-shaped and resists

collapse. The bronchi are lined with a ciliated, mucus-secreting membrane. The cilia move mucus up and away from the lower airway to the trachea, where the mucus is either spit out or swallowed.

The *bronchioles* branch from the secondary bronchi and divide into smaller and smaller tubes, which are the terminal and respiratory bronchioles (Fig. 29-7). These tubes have a small diameter, have no cartilage, and depend entirely on the elastic recoil of the lung to remain open.

Alveolar ducts with alveoli attached branch from the respiratory bronchioles and resemble a bunch of grapes. Alveolar sacs arise from these ducts. The alveolar sacs contain groups of alveoli, which are the basic units of gas exchange (see Fig. 29-7). A pair of healthy adult lungs has about 290 million alveoli, which are surrounded by lung capillaries. These numerous small alveoli share common walls, making a large surface area for gas exchange. In a healthy adult, this surface area is about the size of a tennis court. **Acinus** is a term for the structural unit consisting of a respiratory bronchiole, an alveolar duct, and an alveolar sac.

The alveolar walls have cells called *type II pneumocytes* that secrete **surfactant**, a fatty protein that reduces surface tension in the alveoli. Without surfactant, **atelectasis** (alveolar collapse) occurs. In atelectasis, gas exchange is reduced because alveolar surface area is reduced.

Lungs

The lungs are elastic, cone-shaped organs located in the pleural cavity in the chest. The apex (top) of each lung extends above the clavicle; the base (bottom) of each lung lies just above the diaphragm. The lungs are composed of millions of

FIG. 29-7 The terminal bronchioles and the acinus.

alveoli and their related ducts, bronchioles, and bronchi. The right lung, which is larger than the left, is divided into three lobes: upper, middle, and lower. The left lung, which is narrower and smaller than the right lung, is divided into only two lobes. About 60% to 65% of lung function occurs in the right lung. Any problem with the right lung interferes with *oxygenation* to a greater degree than a problem in the left lung.

The **pleura** is a continuous smooth membrane composed of two surfaces that totally enclose the lungs. The parietal pleura lines the inside of the chest cavity and the upper surface of the diaphragm. The visceral pleura covers the lung surfaces. These two surfaces are lubricated by a thin fluid produced by the cells lining the pleura. This fluid allows the surfaces to glide across each other smoothly and painlessly during breathing.

Blood flow in the lungs occurs through two separate systems: bronchial and pulmonary. The bronchial system carries the blood needed to meet the metabolic demands of the lungs. The bronchial arteries, which branch from the thoracic aorta, are part of the systemic circulation and do not participate in gas exchange.

The pulmonary circulation is a highly vascular capillary network. Oxygen-poor blood travels from the right ventricle of the heart into the pulmonary artery, which eventually branches into arterioles that form capillary networks. These capillaries are meshed around and through the alveoli—the site of gas exchange (see Fig. 29-7). Freshly oxygenated blood travels from the capillaries to the pulmonary veins and then to the left atrium. From the left atrium, oxygenated blood flows into the left ventricle, where it is pumped throughout the systemic circulation.

Accessory Muscles of Respiration

Breathing occurs through changes in the size of and pressure within the chest cavity. Contraction and relaxation of specific chest muscles (and the diaphragm) cause changes in the size and pressure of the chest cavity. Accessory muscles that help in this process include the scalene muscles, which lift the first two ribs; the sternocleidomastoid muscles, which raise the

FIG. 29-8 The oxygen-hemoglobin dissociation curve. P_{50} , the partial pressure of O_2 at which hemoglobin is 50% saturated; PO_2 , oxygen partial pressure.

sternum; and the trapezius and pectoralis muscles, which fix the shoulders. At times, various back and abdominal muscles are used when the work of breathing is increased.

Oxygen Delivery and the Oxygen-Hemoglobin Dissociation Curve

Oxygen delivery to the tissues requires the binding of oxygen to hemoglobin in red blood cells. Each molecule of hemoglobin can bind four oxygen molecules, which fills or *saturates* all of its binding sites. In the healthy person, each red blood cell normally has hundreds of thousands of hemoglobin molecules. When blood passes through the lung alveoli, where oxygen concentration is the greatest, oxygen diffuses from the alveoli into red blood cells and binds to all those hemoglobin molecules. This oxygen-rich blood then goes to the left side of the heart and is pumped out into systemic circulation. In tissues away from the source of oxygen, hemoglobin unloads (**dissociates**) the oxygen molecules and delivers them to the tissues. Fig. 29-8 shows the oxygen-hemoglobin dissociation curve.

Tissue oxygen delivery through dissociation or unloading from hemoglobin is based on tissues' need for oxygen. The curve in Fig. 29-8 shows that the rate of this unloading changes depending on how much oxygen is already in the tissues. When blood perfuses tissues in which the oxygen levels are high, as indicated in the upper right-hand corner of the figure, hemoglobin binds oxygen very tightly and little oxygen is unloaded or dissociated from the hemoglobin into the tissues. This prevents oxygen delivery from being wasted by unloading it where it is not needed. When blood perfuses tissues in which oxygen levels are very low, as indicated in the lower left-hand corner of Fig. 29-8, hemoglobin binds oxygen less tightly and will rapidly and easily unload its remaining oxygen to provide these tissues with needed oxygen. So, how rapidly and easily hemoglobin dissociates oxygen to the tissues changes depending on oxygen need. The S-shaped

curve indicates that it is harder for oxygen to dissociate from hemoglobin in tissues that are well-oxygenated and much easier in tissues that are “starving” for oxygen.

The curve in Fig. 29-8 indicates that, on average, 50% of hemoglobin molecules have completely dissociated their oxygen molecules when blood perfuses tissues that have an oxygen tension (concentration) of 26 mm Hg. This is considered a “normal” point at which 50% of hemoglobin molecules are no longer saturated with oxygen.

When the need for oxygen is greater in tissues, this curve shifts to the *right*, which means the hemoglobin will dissociate oxygen faster even when the tissue oxygen tension levels are greater than 26 mm Hg. Conditions that shift the curve to the right are those that result from higher tissue metabolism (increased tissue temperature, increased tissue carbon dioxide concentration, increased tissue concentration of glucose breakdown products, and decreased tissue pH [acidosis]). This means it is easier for hemoglobin to unload oxygen to these tissues because they need it to support the higher metabolism. This is actually a tissue protective mechanism that increases oxygen delivery to the tissues that need it most.

On the other hand, when tissues have less need of oxygen because they are metabolizing more slowly than usual, the oxygen-hemoglobin dissociation curve shifts to the *left*, which means that the hemoglobin dissociates less easily. The tissue oxygen tension level has to be *lower* for hemoglobin to unload oxygen. Tissue conditions that cause a shift to the left include decreased tissue temperatures, decreased carbon dioxide levels, decreased amounts of glucose breakdown products, and a higher tissue pH (alkalosis). This also is a tissue protective mechanism to prevent wasting oxygen delivery to tissues that are not using the oxygen they already have.

One clinical example of how these actions are helpful is one in which a person is having a myocardial infarction (heart attack). Blood flow to the area is reduced and the heart muscle is metabolizing under hypoxic conditions, which create more carbon dioxide in the tissue and acidosis. As a result, the hemoglobin that does reach this hypoxic tissue unloads more oxygen at a faster rate to prevent ischemia and cardiac muscle cell death. What if this person believes he or she is having indigestion, which can have similar symptoms of chest discomfort, and tries to correct the problem by taking in large amounts of bicarbonate-based antacids? This ingestion increases the pH in the blood and all tissues, shifting the oxygen-hemoglobin dissociation curve to the left. As a result, the hypoxic cardiac muscle cells receive even less oxygen and more of them die.

Respiratory Changes Associated With Aging

The respiratory changes that occur with aging are described in Chart 29-1. Many additional respiratory changes in older patients result from heredity and a lifetime of exposure to environmental pollutants (e.g., cigarette smoke, bacteria, industrial fumes and irritants).

Respiratory disease is a major cause of illness and chronic disability in older patients. Although respiratory function normally declines with age, there is usually no problem keeping pace with the demands of ordinary activity. The sedentary older adult, however, often feels breathless during exercise (Touhy & Jett, 2010).

It is difficult to determine which respiratory changes in older adults are related to normal aging and which changes are caused by respiratory disease or exposure to pollutants.

Age-related changes in the muscles and the cardiac and vascular system also may cause abnormal breathing, even if the lungs are normal.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

How does atelectasis reduce gas exchange?

- A. Airway obstruction
- B. Reduced alveolar surface area
- C. Failure of pulmonary circulation to fully perfuse lung tissue
- D. Increased bronchial secretions filling the alveoli with fluid rather than with air

ASSESSMENT METHODS

Patient History

Obtaining accurate information from the patient is important for identifying the type and severity of breathing problems. Chart 29-2 lists questions to ask patients (based on Gordon's Functional Health Patterns) to assess the impact of pulmonary function.

Age, gender, and race can affect the physical and diagnostic findings related to breathing. Many of the diagnostic studies for respiratory disorders (e.g., pulmonary function tests) use these data for determining predicted normal values.

WOMEN'S HEALTH CONSIDERATIONS

Women, especially smokers, have greater bronchial responsiveness (i.e., bronchial hyperreactivity) and larger airways than men. This factor increases the risk for a more rapid decline in lung function as a woman ages, especially in women who were or are smokers.

CULTURAL AWARENESS

Compared with whites, black people and others with dark skin usually show a lower oxygen saturation (3% to 5% lower) as measured by pulse oximetry; this results from deeper coloration of the nail bed and does not reflect true oxygen status.

Explore the home, community, and workplace for environmental factors that could cause or worsen lung disease. Occupational lung diseases include pneumoconiosis, which results from the inhalation of dust (e.g., coal dust, stone dust, silicone dust); toxic lung injury; and hypersensitivity disease (e.g., hypersensitivity to latex). Work history includes the exact dates of employment and a brief job description. Exposure to industrial dusts of any type or to the chemicals found in smoke and fumes may cause breathing disorders. Bakers, coal miners, stone masons, cotton handlers, woodworkers, welders, potters, plastic and rubber manufacturers, printers, asbestos workers, farm workers, and steel foundry workers are at risk for breathing problems. Use this opportunity to teach patients about the use of masks and adequate ventilation to protect the respiratory system from inhalation irritants.

Ask about home conditions, such as the type of heat used (e.g., gas heater, wood-burning stove, fireplace, kerosene heater). Determine exposure to irritants (e.g., fumes, chemicals, animals, birds, air pollutants). Ask about hobbies such as painting, working with ceramics, building model airplanes, refinishing furniture, or woodworking, which may expose the patient to harmful chemicals. Teach patients to wear masks

CHART 29-1 NURSING FOCUS ON THE OLDER ADULT

Changes in the Respiratory System Related to Aging

PHYSIOLOGIC CHANGE	NURSING INTERVENTIONS	RATIONALES
Alveoli Alveolar surface area decreases. Diffusion capacity decreases. Elastic recoil decreases. Bronchioles and alveolar ducts dilate. Ability to cough decreases. Airways close early.	Encourage vigorous pulmonary hygiene (i.e., encourage patient to turn, cough, and deep breathe), and to use incentive spirometry, especially if he or she is confined to bed or has had surgery. Encourage upright position.	Potential for mechanical or infectious respiratory complications is increased in these situations. The upright position minimizes ventilation-perfusion mismatching.
Lungs Residual volume increases. Vital capacity decreases. Efficiency of oxygen and carbon dioxide exchange decreases. Elasticity decreases.	Include inspection, palpation, percussion, and auscultation in lung assessments. Help patient actively maintain health and fitness. Assess patient's respirations for abnormal breathing patterns. Encourage frequent oral hygiene.	Inspection, palpation, percussion, and auscultation are needed to detect normal age-related changes. Health and fitness help keep losses in respiratory functioning to a minimum. Periodic breathing patterns (e.g., Cheyne-Stokes) can occur. Oral hygiene aids in the removal of secretions.
Pharynx and Larynx Muscles atrophy. Vocal cords become slack. Laryngeal muscles lose elasticity, and airways lose cartilage.	Have face-to-face conversations with patient when possible.	Patient's voice may be soft and difficult to understand.
Pulmonary Vasculature Vascular resistance to blood flow through pulmonary vascular system increases. Pulmonary capillary blood volume decreases. Risk for hypoxia increases.	Assess patient's level of consciousness and cognition.	Patient can become confused during acute respiratory conditions.
Exercise Tolerance Body's response to hypoxia and hypercarbia decreases.	Assess for subtle manifestations of hypoxia.	Early assessment helps prevent complications.
Muscle Strength Respiratory muscle strength, especially the diaphragm and the intercostals, decreases.	Encourage pulmonary hygiene, and help patient actively maintain health and fitness.	Regular pulmonary hygiene and overall fitness help maintain maximal functioning of the respiratory system and prevent illness.
Susceptibility to Infection Effectiveness of the cilia decreases. Immunoglobulin A decreases. Alveolar macrophages are altered.	Encourage pulmonary hygiene, and help patient actively maintain health and fitness.	Regular pulmonary hygiene and overall fitness help maintain maximal functioning of the respiratory system and prevent illness.
Chest Wall Anteroposterior diameter increases. Thorax becomes shorter. Progressive kyphoscoliosis occurs. Chest wall compliance (elasticity) decreases. Mobility may decrease. Osteoporosis is possible.	Discuss the normal changes of aging. Discuss the need for increased rest periods during exercise. Encourage adequate calcium intake (especially during a woman's premenopause phase).	Patients may be anxious because they must work harder to breathe. Older patients have less tolerance for exercise. Calcium intake helps prevent osteoporosis by building bone in younger patients.

during these exposures and to ensure the area is well ventilated.

Ask patients about their respiratory history (Table 29-1), including smoking history, drug use, travel, and area of residence.

Smoking history includes the use of cigarettes, cigars, pipe tobacco, and marijuana and other controlled substances. Ask whether any of these substances are used now or in the past. Assess whether the patient has passive exposure to smoke in

the home or workplace. If the patient smokes, ask for how long, how many packs a day, and whether he or she has quit smoking (and how long ago). Document the smoking history in **pack-years** (number of packs smoked per day multiplied by number of years the patient has smoked).

Smoking induces changes in the airways that lead to some airway obstruction. As a result, smokers have a more rapid age-related decline in pulmonary function than do nonsmokers. The pulmonary function of patients who have quit

CHART 29-2 RESPIRATORY ASSESSMENT

Using Gordon's Functional Health Patterns

Health Perception—Health Management Pattern

- How has your general health been?
- Have you had any colds this past year?
- Have you missed work or school because of respiratory illness this past year?
- Do you use cigarettes? For how many years? How many packs per day?

Activity-Exercise Pattern

- Do you feel you have sufficient energy to perform tasks or routines that are required of you?
- Do you feel you have sufficient energy to do what you would like to do?
- Do you exercise? How often? For how long each time? What type(s) of exercise do you perform?
- What activities do you perform in your spare time?
- What is your ability to perform these tasks?

AIDS, Acquired immune deficiency syndrome; BCG, bacille Calmette-Guérin; HIV, human immune deficiency virus.

smoking for 2 or more years appears to decline less rapidly than in those who continue to smoke.

Drug use, both prescribed drugs and illicit drugs, can affect lung function. Some drugs affect the lungs when taken systemically. Ask about drugs taken for breathing problems and

about drugs taken for other conditions. For example, a cough can be a side effect of some antihypertensive drugs (angiotensin-converting enzyme [ACE] inhibitors). Determine which over-the-counter drugs (e.g., cough syrups, antihistamines, decongestants, inhalants, nasal sprays) the patient is using. Also assess the use of complementary and alternative therapies. Ask about past drug use and the reason it was discontinued. For example, the patient may have used many bronchodilator inhalers but may prefer one particular drug for relieving breathlessness. Some drugs for other conditions can cause permanent changes in lung function. For example, patients may have pulmonary fibrosis if they received bleomycin (Blenoxane) as chemotherapy for cancer or amiodarone (Cordarone) for cardiac problems (Roberts, 2010). Illicit drugs, such as marijuana or cocaine, are often inhaled and can affect lung function.

Allergies to substances such as foods, dust, molds, pollen, bee stings, trees, grass, animal dander and saliva, or drugs can affect breathing. Ask the patient to describe specific allergic responses. For example, does he or she wheeze, have trouble breathing, cough, sneeze, or have rhinitis after exposure to the allergen? Has he or she ever been treated for an allergic response? If the patient has received treatment for allergies, ask about what caused the need for treatment, the type of treatment, and the response to treatment.

! NURSING SAFETY PRIORITY

Action Alert

Document any known allergies and the specific type of allergic response in a prominent place in the patient's medical record.

Travel and geographic area of residence may be relevant for possible exposure to certain diseases. For example, *histoplasmosis*, a fungal disease caused by inhalation of contaminated dust, is found in the central part of the United States and Canada. *Coccidioidomycosis*, another fungal disease, is found mostly in the western and southwestern parts of the United States, in Mexico, and in portions of Central America, as is *Hantavirus*.

Nutrition Status

Assess the patient's diet history and nutrition status to determine allergic reactions to certain foods or preservatives. Manifestations range from rhinitis, chest tightness, weakness, **dyspnea** (shortness of breath), urticaria, and severe wheezing to loss of consciousness. Ask about usual food intake and whether any breathing problems occur with eating.

Family History and Genetic Risk

Obtain a family history to assess for respiratory disorders that have a genetic component, such as cystic fibrosis, some lung cancers, and emphysema (Workman & Winkelman, 2008). Patients with asthma often have a family history of allergy. Ask about a history of infectious disease, such as tuberculosis, because family members may have similar environmental or occupational exposures.

Current Health Problems

Whether the breathing problem is acute or chronic, the current health problem usually includes cough, sputum production, chest pain, and shortness of breath at rest or on exertion. Explore the present illness in chronologic order.

Ask specifically about the onset of the problem, how long it lasts, the location of the problem, how often it occurs, whether the problem has become worse over time, what symptoms occur with it, which actions or interventions provide relief and which ones make it worse, and what treatments have been used.

Cough is a sign of lung disease. Ask the patient how long the cough has been present and whether it occurs at a specific time of day (e.g., on awakening in the morning) or in relation to any physical activity. Ask whether the cough produces sputum or is dry, tickling, or hacking.

Sputum production is an important symptom associated with coughing. Check the duration, color, consistency, odor, and amount of sputum. Sputum may be clear, white, tan, gray, or, if infection is present, yellow or green.

Describe the consistency of sputum as thin, thick, watery, or frothy. Smokers with chronic bronchitis have mucoid sputum. Excessive pink, frothy sputum is common with pulmonary edema. Bacterial pneumonia often produces rust-colored sputum, and foul-smelling sputum often occurs with a lung abscess. **Hemoptysis** (blood in the sputum) is most often seen in patients with chronic bronchitis or lung cancer. Patients with tuberculosis, pulmonary infarction, bronchial adenoma, or lung abscess may have grossly bloody sputum.

Ask the patient to quantify sputum by describing its volume in terms such as teaspoon, tablespoon, and cups or fractions of cups. Normally, the bronchial tree can produce up to 3 ounces (90 mL) of sputum per day.

Chest pain can occur with other health problems as well as with lung problems. A detailed description of chest pain helps distinguish whether it is caused by pleural, musculoskeletal, cardiac, or GI problems. Ask the patient whether the pain is continuous or made worse by coughing, deep breathing, or swallowing. Cardiac pain is usually intense and “crushing.” It may also radiate to the arm, shoulder, or neck. Pulmonary pain varies depending on the cause. Pain that feels like something is “rubbing” inside is more common with pulmonary pain. The pain may appear only on deep inhalation or be present at the end of inhalation and the end of exhalation. Pulmonary pain is not made worse by touching or pressing over the area.

Dyspnea (difficulty in breathing or breathlessness) is a subjective perception and varies among patients. A patient’s feeling of dyspnea may not be consistent with the severity of the problem. Determine the type of onset (slow or abrupt); the duration (number of hours, time of day); relieving factors (position changes, drug use, activity cessation); and whether wheezing, crackles, or stridor occurs with the breathlessness.

Try to quantify dyspnea by asking whether this symptom interferes with ADLs and, if so, how severely. For example, is the patient breathless while dressing, showering, shaving, or eating? Does dyspnea occur after walking one block or climbing one flight of stairs? **Table 29-2** classifies dyspnea with changes in ADL performance.

Ask about **paroxysmal nocturnal dyspnea (PND)**, which is intermittent dyspnea during sleep, and about **orthopnea**, which is a shortness of breath that occurs when lying down but is relieved by sitting up. These two conditions often occur with chronic lung disease and left-sided heart failure. In PND, the patient has a sudden onset of breathing difficulty that is severe enough to awaken him or her.

TABLE 29-2 CORRELATION OF DYSPNEA CLASSIFICATION WITH PERFORMANCE OF ADLS

CLASSIFICATION	ADLS KEY
Class I: No significant restrictions in normal activity. Employable. Dyspnea occurs only on more-than-normal or strenuous exertion.	4: No breathlessness, normal.
Class II: Independent in essential ADLs but restricted in some other activities. Dyspneic on climbing stairs or on walking on an incline but not on level walking. Employable only for sedentary job or under special circumstances.	3: Satisfactory, mild breathlessness. Complete performance is possible without pause or assistance but not entirely normal.
Class III: Dyspnea commonly occurs during usual activities, such as showering or dressing, but the patient can manage without assistance from others. Not dyspneic at rest; can walk for more than a city block at own pace but cannot keep up with others of own age. May stop to catch breath partway up a flight of stairs. Is probably not employable in any occupation.	2: Fair, moderate breathlessness. Must stop during activity. Complete performance is possible without assistance, but performance may be too debilitating or time consuming.
Class IV: Dyspnea produces dependence on help in some essential ADLs such as dressing and bathing. Not usually dyspneic at rest. Dyspneic on minimal exertion; must pause on climbing one flight, walking more than 100 yards, or dressing. Often restricted to home if lives alone. Has minimal or no activities outside of home.	1: Poor, marked breathlessness. Incomplete performance; assistance is necessary.
Class V: Entirely restricted to home and often limited to bed or chair. Dyspneic at rest. Dependent on help for most needs.	0: Performance not indicated or recommended; too difficult.

ADLs, Activities of daily living.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

The 60-year-old client’s smoking history includes smoking 2 packs of cigarettes per day since the age of 15 until the age of 40, and then smoking 3 packs per day to the present. How does the nurse document this smoking history?

- A. 45 pack-years
- B. 80 pack-years
- C. 90 pack-years
- D. 110 pack-years

Physical Assessment

Assessment of the Nose and Sinuses

Inspect the patient’s external nose for deformities or tumors, and inspect the nares for symmetry of size and shape. To observe the interior nose, ask the patient to tilt the head back for a penlight examination. Use a nasal speculum and nasopharyngeal mirror for a more thorough inspection of the nasal cavity.

Inspect for color, swelling, drainage, and bleeding. The mucous membrane of the nose normally appears redder than the oral mucosa, but it is pale, engorged, and bluish gray in patients with allergic rhinitis. Check the nasal septum for

bleeding, perforation, or deviation. Septal deviation is common and appears as an S shape, tilting toward one side or the other. A perforated septum is present if the light shines through the perforation into the opposite side; this condition is often found in cocaine users. Nasal polyps, a common cause of obstruction, are pale, shiny, gelatinous lumps or “bags” attached to the turbinates. Block one naris at a time to check whether air moves through the unblocked side easily.

Assessment of the Pharynx, Trachea, and Larynx

Assessment of the pharynx begins with inspection of the mouth. To examine the posterior pharynx, use a tongue depressor to press down one side of the tongue at a time (to avoid stimulating the gag reflex). As the patient says “ah,” observe the rise and fall of the soft palate and uvula and inspect for color and symmetry, drainage, edema or ulceration, and enlarged or inflamed tonsils.

Inspect the neck for symmetry, alignment, masses, swelling, bruises, and the use of accessory neck muscles in breathing. Palpate lymph nodes for size, shape, mobility, consistency, and tenderness. Tender nodes that are movable suggest inflammation. Malignant nodes are often hard and do not move with palpation.

Gently palpate the trachea for position, mobility, tenderness, and masses. The trachea should be in the midline. Many lung disorders cause the trachea to deviate from the midline. Tension pneumothorax, large pleural effusion, mediastinal mass, and neck tumors push the trachea *away* from the affected area. Pneumonectomy, fibrosis, and atelectasis pull it *toward* the affected area. Decreased tracheal mobility may occur with cancer or fibrosis of the mediastinum.

The larynx is usually examined by a specialist with a laryngoscope. An abnormal voice, especially hoarseness, may be heard when there are problems of the larynx.

Assessment of the Lungs and Thorax

Inspection. Inspect the front and back of the thorax with the patient sitting up. Normal landmarks of the chest front (anterior) and back (posterior) are shown in Fig. 29-9. The patient should be undressed to the waist and draped for privacy and warmth. Observe the chest, and compare one side with the other. Work from the top (apex) and move downward toward the base, going from side to side, while inspecting for discoloration, scars, lesions, masses, and spinal curvatures. Assessing from side to side allows you to compare the assessment findings for each lung at the same level.

Observe the rate, rhythm, and depth of inspirations as well as the symmetry of chest movement. Impaired movement or unequal expansion may indicate disease. Observe the type of breathing (e.g., pursed-lip or diaphragmatic breathing) and the use of accessory muscles.

Examine the shape of the patient’s chest, and compare the anteroposterior (AP or front-to-back) diameter with the lateral (side-to-side) diameter. This ratio normally is about 1:1.5 depending on body build. The ratio increases to 1:1 in patients with emphysema, which results in the typical barrel-chest appearance.

Normally the ribs slope downward. Patients with air trapping in the lungs caused by emphysema have ribs that are more horizontal. Observe or palpate the distance between the ribs (*intercostal space*). This distance is usually one fingerbreadth (2 centimeters). The distance increases in disorders that cause air trapping, such as emphysema. Observe for retraction of muscle between the ribs and at the sternal notch. Retractions are areas that get sucked inward when the patient inhales. This does not occur during normal respiratory effort. Retractions may occur when the patient is working hard to inhale around an obstruction.

FIG. 29-9 Anterior and posterior chest landmarks.

Palpation. Palpate the chest after inspection to assess respiratory movement symmetry and observable abnormalities. Palpation also can help identify areas of tenderness and check vocal or tactile **fremitus** (vibration).

Assess chest expansion by placing your thumbs on the patient's spine at the level of the ninth ribs and extending the fingers sideways around the rib cage. As the patient inhales, both sides of the chest should move upward and outward together in one symmetric movement and move your thumbs apart. On exhalation, the thumbs should come back together as they return to the midline. Use this technique on the anterior chest for patients who cannot sit up or change positions. Decreased movement on one side (unequal expansion) may be a result of pain, trauma, or air in the pleural cavity. Respiratory lag or slowed movement on one side occurs with a pulmonary mass, pleural fibrosis, atelectasis, pneumonia, or a lung abscess.

Palpate any abnormalities found on inspection (e.g., masses, lesions, bruises, swelling). Also palpate for tenderness, particularly if the patient has reported pain. **Crepitus** (air trapped in and under the skin, also known as *subcutaneous emphysema*) is felt as a crackling sensation beneath the fingertips. Document this finding when it occurs around a wound site or a tracheostomy site or if a pneumothorax is suspected.

Tactile (vocal) fremitus is a vibration of the chest wall produced when the patient speaks. This vibration can be felt on the chest wall. Fremitus is decreased if the transmission of sound waves from the larynx to the chest wall is slowed. This problem can occur when the pleural space is filled with air (pneumothorax) or fluid (**pleural effusion**) or when the bronchus is obstructed. Fremitus is increased with pneumonia and abscesses because they increase the density of the thorax and enhance transmission of the vibrations.

Percussion. Use percussion to assess for pulmonary resonance, the boundaries of organs, and diaphragmatic excursion. Percussion involves tapping the chest wall, which sets the underlying tissues into motion and produces audible sounds (Fig. 29-10).

Percussion produces five different notes (Table 29-3). These sounds help determine the density of the underlying structures (i.e., whether the lung tissue contains air or fluid or is solid).

Auscultation. Auscultation includes listening with a stethoscope for normal breath sounds, adventitious sounds,

and voice sounds. This technique provides information about the flow of air through the tracheobronchial tree and helps identify fluid, mucus, or obstruction in the respiratory system (Bradley, 2007).

Begin auscultation with the patient sitting in an upright position. With the stethoscope pressed firmly against the chest wall (clothing can distort or muffle sounds), instruct the patient to breathe slowly and deeply through an open mouth. (Breathing through the nose sets up turbulent sounds that are transmitted to the lungs.) Use a systematic approach, beginning at the lung apices and moving from side to side down through the intercostal spaces to the lung bases (Fig. 29-11). This side-to-side method allows you to compare one lung with the other at the same level. Avoid listening over bony structures. Listen to a full respiratory cycle, noting the quality and intensity of the breath sounds.

Normal breath sounds are produced as air vibrates while moving through the passages from the larynx to the alveoli. Breath sounds are identified by their location, intensity, pitch, and duration within the respiratory cycle (e.g., early or late inspiration and expiration). Normal breath sounds are known as “bronchial” or “tubular” (harsh hollow sounds heard over the trachea and mainstem bronchi), “bronchovesicular” (heard over the branching bronchi), and “vesicular” (soft

FIG. 29-10 Percussion technique.

TABLE 29-3 CHARACTERISTIC FEATURES OF THE FIVE PERCUSSION NOTES

NOTE	PITCH	INTENSITY	QUALITY	DURATION	FINDINGS
Resonance	Low	Moderate to loud	Hollow	Long	Resonance is characteristic of normal lung tissue.
Hyperresonance	Higher than resonance	Very loud	Booming	Longer than resonance	Hyperresonance indicates the presence of trapped air, so it is commonly heard over an emphysematous or asthmatic lung and occasionally over a pneumothorax.
Flatness	High	Soft	Extreme dullness	Short	An example location is the sternum. Flatness percussed over the lung fields may indicate a massive pleural effusion.
Dullness	Medium	Medium	Thudlike	Medium	An example location is over the liver and the kidneys. Dullness can be percussed over an atelectatic lung or a consolidated lung.
Tympany	High	Loud	Musical, drumlike	Short	Examples are the cheek filled with air and the abdomen distended with air. Over the lung, a tympanic note usually indicates a large pneumothorax.

FIG. 29-11 Sequence for percussion and auscultation.

TABLE 29-4 CHARACTERISTICS OF NORMAL BREATH SOUNDS					
	PITCH	AMPLITUDE	DURATION	QUALITY	NORMAL LOCATION
Bronchial (tubular, tracheal) 	High	Loud	Inspiration < expiration	Harsh, hollow, tubular, blowing	Trachea and larynx
Bronchovesicular 	Moderate	Moderate	Inspiration = expiration	Mixed	Over major bronchi where fewer alveoli are located; posterior, between scapulae (especially on right); anterior, around upper sternum in first and second intercostal spaces
Vesicular 	Low	Soft	Inspiration > expiration	Rustling, like the sound of the wind in the trees	Over peripheral lung fields where air flows through smaller bronchioles and alveoli

From Jarvis, C. (2012). *Physical examination and health assessment* (6th ed.). St. Louis: Saunders.

rustling sound heard in the periphery over small bronchioles) (Table 29-4). Describe these sounds as *normal*, *increased*, *diminished*, or *absent*.

When bronchial breath sounds are heard at the lung edges, they are abnormal. This increased sound occurs when the bronchial sounds are transmitted to an area of increased density, such as in patients with atelectasis, tumor, or pneumonia. When heard in an abnormal location, bronchovesicular breath sounds may indicate normal aging or an abnormality such as pulmonary consolidation and chronic airway disease.

Adventitious sounds are additional breath sounds superimposed on normal sounds, and they indicate pathologic changes in the lung. Table 29-5 describes adventitious sounds: crackle, wheeze, rhonchus, and pleural friction rub. Adventitious sounds vary in pitch, intensity, duration, and the phase of the respiratory cycle in which they occur. Document exactly what you hear on auscultation.

Voice sounds (vocal resonance) through the normally air-filled lung produce a muffled, unclear sound because sound vibrations travel poorly through air. These sounds become louder and more distinct when the sound travels through a

solid tissue or liquid. The presence of pneumonia, atelectasis, pleural effusion, tumor, or abscess causes increased vocal resonance.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

In performing a chest assessment, the nurse observes or determines all of the following findings on a 70-year-old client. Which finding indicates to the nurse that the client may have an increased residual lung volume?

- A. Exhalation is twice as long as inhalation.
- B. Breath sounds are absent at the lung edges.
- C. The intercostal spaces measure 4 centimeters.
- D. Vibrations can be felt on the chest wall when the client speaks.

Other Indicators of Respiratory Adequacy

Assess other indicators of respiratory adequacy, because gas exchange affects all body systems. Some indicators (e.g., cyanosis) indicate immediate oxygenation problems. Other changes (e.g., clubbing, weight loss) reflect long-term oxygenation problems.

Skin and mucous membrane changes, such as pallor or cyanosis, may indicate *inadequate oxygenation*. Assess the nail beds and the mucous membranes of the oral cavity. Examine the fingers for clubbing (see Fig. 32-12), which indicates long-term hypoxia.

General appearance includes muscle development and general body build. Long-term respiratory problems lead to weight loss and a loss of general muscle mass (McCance et

al., 2010). Arms and legs may appear thin or poorly muscled. Neck and chest muscles may be hypertrophied, especially in the patient with chronic obstructive pulmonary disease (COPD).

Endurance decreases whenever breathing is inadequate for gas exchange (McCance et al., 2010). Observe how easily the patient moves and whether he or she is short of breath while resting or becomes short of breath when walking 10 to 20 steps. As the patient speaks, note how often he or she pauses for breath between words.

Psychosocial Assessment

Breathing difficulty from any cause often induces anxiety. The patient may be anxious because of reduced oxygen to the brain or because the sensation of not getting enough air is a frightening experience. The thought of having a serious respiratory problem, such as lung cancer, can also induce anxiety. Encourage the patient to express his or her feelings and fears about manifestations and their possible meaning.

Assess those aspects of the patient's lifestyle that either can affect respiratory function or are affected by it. Some respiratory problems may become worse with stress. Ask about current life stresses and usual coping mechanisms.

Chronic respiratory disease may cause changes in family roles or relationships, social isolation, financial problems, and unemployment or disability. Discuss coping mechanisms to assess the patient's reaction to these stressors and identify strengths. For example, the patient may react to stress with dependence on family members, withdrawal, or failure to adhere to interventions. Assist the patient in determining

TABLE 29-5 CHARACTERISTIC FEATURES OF ADVENTITIOUS BREATH SOUNDS

ADVENTITIOUS SOUND	OCCURRENCE IN THE RESPIRATORY CYCLE	CHARACTER	ASSOCIATION
Discontinuous			
Fine crackles	Either early or late inspiration	Popping, discontinuous sounds caused by air moving into previously deflated airways; sounds like hair being rolled between fingers near the ear “Velcro” sounds late in inspiration usually associated with restrictive disorders	Asbestosis
Fine rales			Atelectasis
High-pitched rales			Interstitial fibrosis Bronchitis Pneumonia Chronic pulmonary diseases
Coarse crackles	More common on expiration but may be present early in inspiration	Lower-pitched, coarse, discontinuous rattling sounds caused by fluid or secretions in large airways; likely to change with coughing or suctioning	Bronchitis
Low-pitched crackles			Pneumonia Tumors Pulmonary edema
Continuous			
Wheeze	Audible during either inspiration, expiration, or both	Squeaky, musical, continuous sounds associated with air rushing through narrowed airways; may be heard without a stethoscope Arise from the small airways Usually do not clear with coughing	Inflammation Bronchospasm Edema Secretions Pulmonary vessel engorgement (as in cardiac “asthma”)
Rhonchus (rhonchi)	Audible during both inspiration and expiration but commonly more prominent on expiration	Lower-pitched, coarse, continuous snoring sounds Arise from the large airways	Thick, tenacious secretions Sputum production Obstruction by foreign body Tumors
Pleural Friction Rub	Heard during both inspiration and expiration, generally at the end of inspiration and the beginning of expiration	Loud, rough, grating, scratching sounds caused by the inflamed surfaces of the pleura rubbing together; often associated with pain on deep inspirations Heard in lateral lung fields	Pleurisy Tuberculosis Pulmonary infarction Pneumonia Lung cancer

available support systems to help cope with changes resulting from breathing problems.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Teamwork and Collaboration

The patient is a 74-year-old woman who is 5 days postoperative from a right total hip arthroplasty. Her past medical history includes an 80-pack-year smoking history, COPD, and atrial fibrillation. She reports that she is short of breath. Your physical examination reveals diminished breath sounds and dullness on percussion over her right lower lobe. Her oxygen saturation (SpO_2) is 87% on 2 liters of oxygen per nasal cannula.

1. What are some possible new-onset health problems associated with these findings?
2. Who should you contact and why?
3. What age-related changes are important to consider?
4. What additional referrals might be appropriate for this patient?

Diagnostic Assessment

Laboratory Assessment

Several laboratory tests (Chart 29-3) are useful in assessing respiratory problems. A red blood cell (RBC) count provides data about the transport of oxygen. Hemoglobin, found in RBCs, transports oxygen to the tissues. A deficiency of hemoglobin could cause hypoxemia.

Arterial blood gas (ABG) analysis assesses *oxygenation* (partial pressure of arterial oxygen [PaO_2]), *alveolar ventilation* (partial pressure of arterial carbon dioxide [PaCO_2]), and *acid-base balance*. Blood gas studies provide information for monitoring treatment results, adjusting oxygen therapy, and evaluating the patient's responses (Pruitt, 2010). See Chapter 14 for more details on blood gas analysis.

Sputum specimens can help identify organisms or abnormal cells, such as in cancer or an allergy. Sputum culture and sensitivity analyses identify bacterial infection and determine which specific antibiotics will be most effective. Sputum cytologic examination can identify cancer cells. Noncancerous conditions, such as allergy or autoimmunity, may also be identified by cytologic testing. Eosinophils and Curschmann's spirals (a mucus form) are often found by cytologic study in patients with allergic asthma.

Imaging Assessment

Chest x-rays with digital images are used for patients with pulmonary problems to evaluate the status of the chest and to provide a baseline for comparison with future changes. Standard chest x-rays are performed from **posteroanterior** (PA; back to front) and left lateral (LL) positions.

Chest x-rays are used to assess pathologic changes in the lung, such as with pneumonia, atelectasis, pneumothorax, and tumor. The x-rays also can detect pleural fluid and the position and placement of an endotracheal tube or other invasive catheters. A computer enhances the image to give the greatest amount of detail. The image can be adjusted to emphasize a specific area. These images have limitations, however, and may appear normal, even when severe chronic bronchitis, asthma, or emphysema is present.

Sinus and facial x-rays are used to assess fluid levels in the sinus cavities to assist in the diagnosis of acute or chronic sinusitis.

Computed tomography (CT) is useful when an x-ray reveals a suspicious lesion or when a clot is suspected, because pulmonary soft tissue densities, tumors, and blood clots can be seen. Chest CT is usually performed with consecutive 5- to 10-mm cross-sectional views of the entire chest. Then, using higher resolution, 1-mm scans are taken of suspicious areas. Chest CTs, especially "spiral CT" scans, in which the patient table moves continuously as images are acquired, can now identify pulmonary embolisms.

Usually CT scans require a contrast agent injected IV. The contrast enhances the visibility of structures such as tumors, blood vessels, and chambers of the heart. These scans assist in making a diagnosis. Your role in this diagnostic test is to provide information to the patient and to determine whether the patient has any sensitivity to the contrast material. Ask the patient whether he or she has a known allergy to iodine or shellfish.

Other Noninvasive Diagnostic Assessment

Pulse Oximetry. Pulse oximetry identifies hemoglobin saturation. Usually hemoglobin is almost 100% saturated with oxygen. The pulse oximeter uses a wave of infrared light and a sensor placed on the patient's finger, toe, nose, earlobe, or forehead (Fig. 29-12). Ideal normal pulse oximetry values are 95% to 100%. Normal values are a little lower in older patients and in patients with dark skin. To avoid confusion with the PaO_2 values from arterial blood gases, pulse oximetry readings are recorded as the SpO_2 (peripheral arterial oxygen saturation) or Sao_2 .

Pulse oximetry can detect desaturation before manifestations (e.g., dusky skin, pale mucosa, pale or blue nail beds) occur (DeMeulenaere, 2007). Causes for false low readings include patient movement, hypothermia, decreased peripheral blood flow, ambient light (sunlight, infrared lamps), decreased hemoglobin, edema, and fingernail polish. When patients have any degree of impaired peripheral blood flow, the most accurate place to test oxygen saturation is on the forehead ("Monitoring Your," 2008; Valdez-Lowe et al., 2009). Covering the sensor with a fingertip cut from a glove or changing its position may help accuracy if too much ambient light is present.

Results lower than 91% (and certainly below 86%) are an emergency and require immediate assessment and treatment. When the SpO_2 is below 85%, body tissues have a difficult time becoming oxygenated. An SpO_2 below 70% is usually life threatening, but in some cases, values below 80% may be life threatening. Pulse oximetry is less accurate at lower values (DeMeulenaere, 2007).

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

The client's oxygen saturation by pulse oximetry on the finger is 84%. What is the nurse's best first action?

- A. Recheck the value on the forehead.
- B. Assess the client's cognitive function.
- C. Notify the Rapid Response Team immediately.
- D. Apply supplemental oxygen by mask or nasal cannula.

Capnometry and Capnography. Capnometry and capnography are methods that measure the amount of carbon dioxide present in exhaled air, which is an indirect

CHART 29-3 LABORATORY PROFILE

Respiratory Assessment

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS
Blood Studies		
Complete Blood Count		
Red blood cells	Females: 4.2-5.4 million/mm ³ Males: 4.7-6.1 million/mm ³	<i>Elevated levels</i> (polycythemia) may be due to the excessive production of erythropoietin, which occurs in response to a hypoxic stimulus, as in COPD, and from living at a high altitude. <i>Decreased levels</i> indicate possible anemia, hemorrhage, or hemolysis.
Hemoglobin, total	Females: 12-16 g/dL, or 7.4-9.9 mmol/L Males: 14-18 g/dL, or 8.7-11.2 mmol/L	Same as for red blood cells.
Hematocrit	Females: 37%-47%, or 0.37-0.47 SI units Males: 42%-52%, or 0.42-0.52 SI units	Same as for red blood cells.
White blood cell count (leukocyte count, WBC count)	Total: 5,000-10,000/mm ³	<i>Elevations</i> indicate possible acute infections or inflammations, pneumonia, meningitis, tonsillitis, or emphysema. <i>Decreased levels</i> may indicate an overwhelming infection, an autoimmune disorder, or immunosuppressant therapy.
Differential White Blood Cell (Leukocyte) Count		
Neutrophils	2500-8000/mm ³ , or 55%-70% of total	<i>Elevations</i> indicate possible acute bacterial infection (pneumonia), COPD, or inflammatory conditions (smoking). <i>Decreased levels</i> indicate possible viral disease (influenza).
Eosinophils	50-500/mm ³ , or 1%-4% of total	<i>Elevations</i> indicate possible COPD, asthma, or allergies. <i>Decreased levels</i> indicate pyogenic infections.
Basophils	25-100/mm ³ , or 0.5%-1% of total	<i>Elevations</i> indicate possible inflammation; seen in chronic sinusitis, hypersensitivity reactions. <i>Decreased levels</i> may be seen in an acute infection.
Lymphocytes	1000-4000/mm ³ , or 20%-40% of total	<i>Elevations</i> indicate possible viral infection, pertussis, and infectious mononucleosis. <i>Decreased levels</i> may be seen during corticosteroid therapy.
Monocytes	100-700/mm ³ , or 2%-8% of total	<i>Elevations</i> : see Lymphocytes; also may indicate active tuberculosis. <i>Decreased levels</i> : see Lymphocytes.
Arterial Blood Gases		
PaO ₂	80-100 mm Hg Older adults: values may be lower	<i>Elevations</i> indicate possible excessive oxygen administration. <i>Decreased levels</i> indicate possible COPD, asthma, chronic bronchitis, cancer of the bronchi and lungs, cystic fibrosis, respiratory distress syndrome, anemias, atelectasis, or any other cause of hypoxia.
Paco ₂	35-45 mm Hg	<i>Elevations</i> indicate possible COPD, asthma, pneumonia, anesthesia effects, or use of opioids (respiratory acidosis). <i>Decreased levels</i> indicate hyperventilation/respiratory alkalosis.
pH	Up to 60 yr: 7.35-7.45 60-90 yr: 7.31-7.42 >90 yr: 7.26-7.43	<i>Elevations</i> indicate metabolic or respiratory alkalosis. <i>Decreased levels</i> indicate metabolic or respiratory acidosis.
HCO ₃ ⁻	21-28 mEq/L	<i>Elevations</i> indicate possible respiratory acidosis as compensation for a primary metabolic alkalosis. <i>Decreased levels</i> indicate possible respiratory alkalosis as compensation for a primary metabolic acidosis.
SpO ₂	95%-100% Older adults: values may be slightly lower	<i>Decreased levels</i> indicate possible impaired ability of hemoglobin to release oxygen to tissues.

COPD, Chronic obstructive pulmonary disease; HCO₃⁻, bicarbonate ion; Paco₂, partial pressure of arterial carbon dioxide; PaO₂, partial pressure of arterial oxygen; SpO₂, peripheral oxygen saturation.

measurement of arterial carbon dioxide levels. These noninvasive tests measure end-tidal carbon dioxide levels (ETCO₂) in both intubated patients and those breathing spontaneously. With capnometry, the exhaled air sample is tested with a sensor that changes the CO₂ level into a color or number for analysis. With capnography, the CO₂ level is graphed as a specific waveform along with a number. These methods provide information about CO₂ production, pulmonary perfusion, alveolar ventilation, respiratory patterns, ventilator effectiveness, and possible rebreathing of exhaled air.

The normal pressure of end-tidal carbon dioxide (PETCO₂) ranges between 20 and 40 mm Hg, just slightly lower than the normal range of arterial PCO₂. Changes in PETCO₂ reflect changes in breathing effectiveness and may occur before hypoxia can be detected using pulse oximetry. Thus the use of both pulse oximetry and PETCO₂ for critically ill patients and those with respiratory problems can provide information to direct early intervention.

Factors or conditions that increase PETCO₂ above normal levels are those that reflect *inadequate oxygenation*, such as

TABLE 29-6 CHARACTERISTICS AND PURPOSES OF PULMONARY FUNCTION TESTS

TEST	PURPOSE
<i>FVC (forced vital capacity)</i> records the maximum amount of air that can be exhaled as quickly as possible after maximum inspiration.	<i>FVC</i> gives an indication of respiratory muscle strength and ventilatory reserve. <i>FVC</i> is often reduced in obstructive disease (because of air trapping) and in restrictive disease.
<i>FEV₁ (forced expiratory volume in 1 sec)</i> records the maximum amount of air that can be exhaled in the first second of expiration.	<i>FEV₁</i> is effort dependent and declines normally with age. It is reduced in certain obstructive and restrictive disorders.
<i>FEV₁/FVC</i> is the ratio of expiratory volume in 1 sec to <i>FVC</i> .	This ratio provides a much more sensitive indication of obstruction to airflow. This ratio is the hallmark of obstructive pulmonary disease. It is normal or increased in restrictive disease.
<i>FEF_{25%-75%}</i> records the forced expiratory flow over the 25%-75% volume (middle half) of the <i>FVC</i> .	This measure provides a more sensitive index of obstruction in the smaller airways.
<i>FRC (functional residual capacity)</i> is the amount of air remaining in the lungs after normal expiration. <i>FRC</i> test requires use of the helium dilution, nitrogen washout, or body plethysmography technique.	Increased <i>FRC</i> indicates hyperinflation or air trapping, which may result from obstructive pulmonary disease. <i>FRC</i> is normal or decreased in restrictive pulmonary diseases.
<i>TLC (total lung capacity)</i> is the amount of air in the lungs at the end of maximum inhalation.	Increased <i>TLC</i> indicates air trapping associated with obstructive pulmonary disease. Decreased <i>TLC</i> indicates restrictive disease.
<i>RV (residual volume)</i> is the amount of air remaining in the lungs at the end of a full, forced exhalation.	<i>RV</i> is increased in obstructive pulmonary disease such as emphysema.
<i>DLCO (diffusion capacity of the lung for carbon monoxide)</i> reflects the surface area of the alveolocapillary membrane. The patient inhales a small amount of CO, holds for 10 sec, and then exhales. The amount inhaled is compared with the amount exhaled.	<i>DLCO</i> is reduced whenever the alveolocapillary membrane is diminished, such as occurs in emphysema, pulmonary hypertension, and pulmonary fibrosis. It is increased with exercise and in conditions such as polycythemia and congestive heart disease.

FIG. 29-12 A typical pulse oximeter.

fever, hypoventilation, partial airway obstruction, and rebreathing exhaled air. Factors or conditions that decrease PETCO_2 below normal levels are those that reflect poor ventilation, such as hypothermia, poor cardiac output, hypotension, hypovolemia, pulmonary embolism, apnea, total airway obstruction, and tracheal extubation.

Pulmonary Function Tests. Pulmonary function tests (PFTs) evaluate lung function and breathing problems. These tests include lung volumes and capacities, flow rates, diffusion capacity, gas exchange, airway resistance, and distribution of ventilation (Booker, 2009). The results are interpreted by comparing the patient's data with expected findings for age, gender, race, height, weight, and smoking status.

The PFTs are useful in screening patients for lung disease even before the onset of manifestations. Serial testing (repeated tests over time) provides objective data that may be used as a guide to treatment (e.g., changes in lung function

can support a decision to continue, change, or discontinue a specific therapy). PFTs done before surgery may identify the patient at risk for lung complications after surgery. One of the most common reasons for performing such tests is to determine the cause of dyspnea. When performed while the patient exercises, PFTs help determine whether dyspnea is caused by lung or cardiac dysfunction or by muscle weakness. These tests also help determine the effect of occupation or disability on lung function.

Patient Preparation. Explain the purpose of the tests for planning care. Advise the patient not to smoke for 6 to 8 hours before testing. According to institutional policy and procedure, bronchodilator drugs may be withheld for 4 to 6 hours before the test. The patient with breathing problems often fears further breathlessness and is anxious before these “breathing” tests. Help reduce anxiety by describing what will happen during and after the testing.

Procedure. PFTs can be performed at the bedside or in the respiratory laboratory by a respiratory therapist or respiratory technician. The patient is asked to breathe through the mouth only. A nose clip may be used to prevent air from escaping. The patient performs different breathing maneuvers while measurements are obtained. Table 29-6 describes the most commonly used PFTs and their purpose.

Follow-up Care. Because many breathing maneuvers are performed during PFTs, observe the patient for increased dyspnea or bronchospasm after these studies. Document any drugs given during testing.

Exercise Testing. Exercise increases metabolism and increases gas transport because energy is used. Exercise testing assesses the patient's ability to work and perform ADLs, differentiates reasons for exercise limitation, evaluates disease influence on exercise capacity, and determines whether supplemental oxygen is needed during exercise. These tests are performed on a treadmill or bicycle or by a self-paced 12-minute walking test. The normal patient's exercise is limited by circulatory factors, whereas the pulmonary patient

is limited by breathing capacity, gas exchange compromise, or both. Explain exercise testing, and assure the patient that he or she will be closely monitored by trained professionals throughout the test.

Skin Tests. Skin tests are used with other diagnostic data to identify various infectious diseases (e.g., tuberculosis), viral diseases (e.g., mononucleosis, mumps), and fungal diseases (e.g., coccidioidomycosis, histoplasmosis). Allergies and the status of the immune system also can be checked through skin testing. Exposure to the allergen or organism used in testing produces a specific reaction (delayed hypersensitivity reaction) of the patient's immune system. (See [Chapters 19 and 22](#) for further discussion of these tests.)

Other Invasive Diagnostic Assessment

Endoscopic Examinations. Endoscopic studies to assess breathing problems include bronchoscopy, laryngoscopy, and mediastinoscopy. With *laryngoscopy*, a tube for visualization is inserted into the larynx to assess the function of the vocal cords, remove foreign bodies caught in the larynx, or obtain tissue samples for biopsy or culture. A *mediastinoscopy* is the insertion of a flexible tube through the chest wall just above the sternum into the area of the upper chest between the lungs. This procedure is performed in the operating room (OR) with the patient under general anesthesia to examine local structures for the presence of tumors and to obtain tissue samples for biopsy or culture. Most complications are related to the anesthetic agents and bleeding. The most common procedure is the bronchoscopy, described next.

A **bronchoscopy** is the insertion of a tube in the airways, usually as far as the secondary bronchi, for the purpose of viewing airway structures and obtaining tissue samples for biopsy or culture. It is used to diagnose and manage pulmonary diseases. Flexible bronchoscopy can be performed in the intensive care unit (ICU) with low-dose sedation. Rigid bronchoscopy usually requires general anesthesia and the use of the OR. A flexible bronchoscopy can be used to evaluate the airway, assist with placing or changing an endotracheal tube, collecting specimens, and diagnosing infections. Bronchoscopy is often used for lung cancer staging and removal of secretions that are not cleared with normal suctioning procedures. Stents can be placed during bronchoscopy procedures to open up strictures in the trachea and bronchus.

Patient Preparation. Explain the procedure to the patient, and verify that consent for the procedure was obtained. Expected outcomes, risks, and benefits of the procedure must be discussed with the patient or the legal guardian. Document patient allergies. Laboratory tests that may be required include a complete blood count (CBC), platelet count, prothrombin time, electrolytes, and chest x-ray. The patient should be NPO for 4 to 8 hours before the procedure to reduce the risk for aspiration. Premedication with one of the benzodiazepines may be used to provide both sedation and amnesia. Opioids may also be used.

! NURSING SAFETY PRIORITY

Critical Rescue

Verify the patient's identity with two types of identifiers (name, birth date, medical record number, or social security number) before a bronchoscopy. Ask the patient to tell you his or her name.

Benzocaine spray as a topical anesthetic to numb the oropharynx is used cautiously, if at all. This agent may induce a condition called **methemoglobinemia**, which is the conversion of normal hemoglobin to methemoglobin ("Benzocaine Spray," 2009). Methemoglobin is an altered iron state that does not carry oxygen, resulting in tissue hypoxia. Other topical anesthetic sprays, such as lidocaine, appear less likely to induce this problem.

The normal blood level of methemoglobin is less than 1%. When this level increases, tissue oxygenation is reduced. Cyanosis occurs with methemoglobin levels between 10% and 20%. Anxiety, tachycardia, and lethargy develop at levels between 20% and 50%. Death can occur when levels reach 50% to 70%. Methemoglobinemia should be suspected if a patient becomes cyanotic after receiving a topical anesthetic, if he or she does not respond to supplemental oxygen, and if blood is a characteristic chocolate-brown in color ([Wesley, 2006](#)). It can be reversed with oxygen and IV injection of 1% methylene blue (1 to 2 mg/kg).

! NURSING SAFETY PRIORITY

Critical Rescue

Notify the Rapid Response Team if the patient has any symptoms of methemoglobinemia (cyanosis unresponsive to oxygen therapy, chocolate-brown-colored blood) after the use of benzocaine topical anesthetic.

Procedure. The procedure can be done in a bronchoscopy suite or at the bedside, especially in an ICU. The bronchoscope is inserted either through the naris or the oropharynx. Maintain IV access, and continuously monitor the patient's pulse, blood pressure, respiratory rate, and oxygen saturation. Apply supplemental oxygen.

Follow-up Care. Monitor the patient until the effects of the sedation have resolved and a gag reflex has returned. Continue to monitor the patient's vital signs, including oxygen saturation, and assess breath sounds every 15 minutes for the first 2 hours. Also assess for potential complications. These may include bleeding, infection, or hypoxemia (possibly related to a pneumothorax or methemoglobinemia).

Thoracentesis. **Thoracentesis** is the aspiration of pleural fluid or air from the pleural space. It can be used for diagnosis or treatment. Microscopic examination of the pleural fluid helps in making a diagnosis. Pleural fluid may be drained to relieve blood vessel or lung compression and the respiratory distress caused by cancer, empyema, pleurisy, or tuberculosis. Drugs can also be instilled into the pleural space during thoracentesis.

Patient Preparation. Patient preparation is essential before thoracentesis to ensure cooperation during the procedure and to prevent complications. Tell the patient to expect a stinging sensation from the local anesthetic agent and a feeling of pressure when the needle is pushed through the tissues of the posterior chest. Stress the importance of not moving during the procedure (avoiding coughing, deep breathing, or sudden movement) to avoid puncture of the pleura or lung.

[Fig. 29-13](#) shows the best position for thoracentesis. This position widens the spaces between the ribs and permits easy access to the pleural fluid. Properly position and physically support the patient during the procedure. Use pillows to make the patient comfortable and to provide physical

FIG. 29-13 Position for thoracentesis.

support. When the sitting position is used for the procedure, stand in front of the patient to prevent the table from moving and the patient from falling.

Before the procedure, ask the patient about any allergy to local anesthetic agents. Verify that the patient has signed an informed consent. The entire chest or back is exposed, and the aspiration site is clipped if necessary. The actual site depends on the volume and location of the effusion (determined by x-rays, sonography, and percussion).

Procedure. Thoracentesis is often performed at the bedside by a nurse practitioner or a physician, although computed tomography or ultrasound may be used to guide it. The person performing the procedure and any assistants wear goggles and masks to prevent accidental eye or oral splash exposure to the pleural fluid. After the skin is cleansed with an antiseptic agent, a local anesthetic is injected into the selected site. Keep the patient informed of the procedure while observing for shock, pain, nausea, pallor, diaphoresis, cyanosis, tachypnea, and dyspnea.

The short 18- to 25-gauge thoracentesis needle (with an attached syringe) is advanced into the pleural space. Gentle suction is applied as the fluid in the pleural space is slowly aspirated. A vacuum collection bottle is sometimes needed to remove larger volumes of fluid. To prevent re-expansion pulmonary edema, usually no more than 1000 mL of fluid is removed at one time. If a pleural biopsy is to be performed, a second, larger needle with a cutting edge and collection chamber is used. After the needle is withdrawn, pressure is applied to the puncture site and a small sterile dressing is applied. In some cases, pigtail drain catheters may be left in place to a waterseal, rather than doing a thoracentesis aspiration on a recurring basis.

Follow-up Care. After thoracentesis, a chest x-ray is performed to rule out possible pneumothorax and **mediastinal shift** (shift of central thoracic structures toward one side). Monitor vital signs, and auscultate breath sounds for absent or reduced sounds on the affected side. Check the puncture site and dressing for leakage or bleeding. Also assess for complications, such as reaccumulation of fluid in the pleural space, subcutaneous emphysema, infection, and tension pneumothorax. Urge the patient to breathe deeply to promote expansion of the lung. Document the procedure, including the patient's response; the volume and character of the fluid removed; any specimens sent to the laboratory; the location

of the puncture site; and respiratory assessment findings before, during, and after the procedure (Rushing, 2006).

Teach the patient about the manifestations of a **pneumo-thorax** (partial or complete collapse of the lung), which can occur within the first 24 hours after a thoracentesis. Manifestations include:

- Pain on the affected side that is worse at the end of inhalation and the end of exhalation
- Rapid heart rate
- Rapid, shallow respirations
- A feeling of air hunger
- Prominence of the affected side that does not move in and out with respiratory effort
- Trachea slanted more to the unaffected side instead of being in the center of the neck
- New onset of “nagging” cough
- Cyanosis

Instruct the patient to come to the emergency department immediately if these manifestations occur.

NCLEX EXAMINATION CHALLENGE

Psychosocial Integrity

The client, in a panicky voice, tells the nurse during a thoracentesis that he feels as if he is being pushed off the table. What is the nurse's best response?

- A. Stop the procedure to administer an anxiety-reducing drug.
- B. Remind the client not to talk or breathe during the procedure.
- C. Reassure the client this is a normal sensation as the needle is inserted into the chest cavity.
- D. Relay this information to the health care provider performing the procedure so that the needle can be repositioned.

Lung Biopsy. A lung biopsy is performed to obtain tissue for histologic analysis, culture, or cytologic examination. The tissue samples are used to make a definite diagnosis of cancer, infection, inflammation, or lung disease. There are several types of lung biopsies. The site and extent of the lesion determine which one is used. Transbronchial biopsy (TBB) and transbronchial needle aspiration (TBNA) are performed during bronchoscopy. Transthoracic needle aspiration is performed through the skin (percutaneous) for areas that cannot be reached by bronchoscopy. An open lung biopsy is performed in the operating room.

Patient Preparation. The patient may worry about the outcome of the biopsy and may associate the term *biopsy* with *cancer*. Explain what to expect before and after the procedure, and explore the patient's feelings. An analgesic or sedative may be prescribed before the procedure. Inform the patient undergoing percutaneous biopsy that discomfort is reduced with a local anesthetic agent but that pressure may be felt during needle insertion and tissue aspiration. Open lung biopsy is performed in the operating room with the patient under general anesthesia, and the usual preparations before surgery apply (see Chapter 16).

Procedure. Percutaneous lung biopsy is usually performed in the radiology department after an informed consent has been obtained. Fluoroscopy or CT is often used to visualize the area undergoing biopsy and to guide the procedure. The patient is usually placed in the lying position depending on the location of the lesion. The skin is cleansed with an antiseptic agent, and a local anesthetic is given. Under sterile conditions, a spinal-type 18- to 22-gauge needle is

inserted through the skin into the desired area (e.g., tissue, nodule, lymph node) and tissue needed for microscopic examination is obtained. Apply a dressing after the procedure. A CT or chest x-ray must follow the biopsy to confirm there is no pneumothorax.

An open lung biopsy is performed in the operating room. The patient undergoes a thoracotomy in which lung tissue is exposed. At least two tissue specimens are taken (usually from an upper lobe and a lower lobe site). A chest tube is placed to remove air and fluid so the lung can re-inflate, and then the chest is closed.

Follow-up Care. Monitor the patient's vital signs and breath sounds at least every 4 hours for 24 hours, and assess for signs of respiratory distress (e.g., dyspnea, pallor, diaphoresis, tachypnea). Pneumothorax is a serious complication of needle biopsy and open lung biopsy. Report reduced or absent breath sounds immediately. Monitor for hemoptysis (which may be scant and transient) or, in rare cases, for frank bleeding from vascular or lung trauma.

DECISION-MAKING CHALLENGE

Safety; Teamwork and Collaboration; Quality Improvement

Your patient is a 63-year-old man admitted with pancreatitis and a left lower leg infection. A central venous catheter (CVC) was just placed in the right subclavian vein for fluid administration, prolonged antibiotic use, and possible parenteral nutrition. You are called to the patient's room by his wife, who has noticed her husband has become progressively short of breath. He tells you, "I can't breathe." He is tachypneic and tachycardic.

1. What problems could have caused this change in breathing status? Explain your response.
2. Is this an emergency situation? Why or why not?
3. What should you do first and why?
4. What additional diagnostic assessment tests do you anticipate and why?
5. What should your ongoing management include?
6. How could this problem have been prevented or discovered earlier?

NURSING CONCEPT REVIEW

What should you expect to NOTICE in a patient with adequate oxygenation and tissue perfusion related to respiratory function?

Vital signs

- Respiratory rate and heart rate within normal range
- Oxygen saturation of 95% or higher

Physical assessment

- Able to speak a sentence of 12 words without stopping for breath
- Able to walk and talk without stopping for breath
- Skin color normal (no cyanosis, pallor, or jaundice)
- Oral mucous membrane and nail beds pink with rapid capillary refill
- Fingertips and nails normal-shaped, no clubbing
- Anterior to posterior diameter of chest about two-thirds smaller than lateral diameter
- Space between each rib no larger than the breadth of the patient's finger

- Usually breathes in through the nose and out through the mouth or nose
- Breathing quiet
- Air movement heard (with a stethoscope) in all lobes of both lungs
- Sputum production minimal, clear or white
- Muscle development even with no muscle loss on arms and legs
- Weight proportionate to height; does not appear underweight

Psychological assessment

- Oriented and not confused
- Energy level good, can engage in desired work, recreational, and personal activities

Laboratory assessment

- Red blood cell, hemoglobin, hematocrit, and white blood cell levels within normal limits for age and gender

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Health Promotion and Maintenance

- Encourage all people to use masks and adequate ventilation when exposed to inhalation irritants.

Psychosocial Integrity

- Explain all diagnostic procedures, restrictions, and follow-up care to the patient scheduled for tests.

Physiological Integrity

- Assess the degree to which breathing problems interfere with the patient's ability to perform ADLs.
- Document any known specific allergies that have respiratory manifestations.
- Ask the patient about recent travel.
- Assess the airway and breathing effectiveness for any patient who has shortness of breath or any change in mental status.
- Assess the patient's respiratory status every 15 minutes for at least the first 2 hours after undergoing an endoscopic test for respiratory disorders.

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Act as a patient advocate for patients receiving oxygen or who have tracheostomies.
2. Protect from injury the patient receiving oxygen or who has a tracheostomy.
3. Use medical asepsis when providing tracheostomy care.
4. Verify safe use of appropriate oxygen delivery systems and tracheostomy equipment.

Health Promotion and Maintenance

5. Teach the patient requiring oxygen therapy to not smoke when using oxygen.

Psychosocial Integrity

6. Support the patient and family in coping with changes in breathing status and the need for a tracheostomy.
7. Develop and evaluate an appropriate nonverbal form of communication for a patient with a tracheostomy.

Physiological Integrity

8. Perform a focused respiratory assessment and re-assessment to determine adequacy of oxygenation and tissue perfusion.
9. Administer oxygen therapy by nasal cannula, mask, endotracheal tube, or tracheal tube, and evaluate the patient's response.
10. Apply knowledge of anatomy to prevent aspiration in a patient with a tracheal tube.
11. Teach the patient and family about home management of oxygen therapy or tracheostomy.
12. Assess for complications of oxygen therapy for those patients whose respiratory efforts are controlled by the hypoxic drive.
13. Use laboratory data and clinical manifestations to determine the presence of hypoxemia or hypercarbia.

Oxygen is essential for the life and function of all cells and tissues. Three systems—the respiratory system, the cardiovascular system, and the hematologic system—work together to ensure sufficient tissue perfusion with oxygen for cell survival and proper function (see Fig. 29-1). *Oxygenation and tissue perfusion* needs can be inadequate as a result of many problems with the lungs. When a respiratory problem interferes

with adequate oxygenation, both the cardiac system and the hematologic system adjust (compensate) and work harder to restore balance and maintain oxygenation and tissue perfusion (Fig. 30-1). Oxygen therapy and the use of a tracheostomy are interventions that can help improve *oxygenation and tissue perfusion* and, at the same time, reduce the burden on the cardiovascular and hematologic systems.

OXYGEN THERAPY

Overview

Oxygen (O_2) is a gas used as a drug for relief of **hypoxemia** (low levels of oxygen in the blood) and **hypoxia** (decreased tissue oxygenation). The oxygen content of atmospheric air is about 21%. Oxygen therapy is prescribed when the oxygen needs of the patient cannot be met by atmospheric or “room air” alone. It is used for both acute and chronic breathing problems that cause decreased blood and tissue oxygen levels as indicated by decreased partial pressure of arterial oxygen (Pao_2) levels or by decreased arterial oxygen saturation (Sao_2). Non-respiratory conditions, such as heart failure, sepsis, fever, some poisons, and decreased hemoglobin levels or poor hemoglobin quality, can affect oxygenation. These conditions increase oxygen demand, decrease oxygen-carrying capability of the blood, or decrease cardiac output. Their presence is an indication for oxygen therapy.

The purpose of oxygen therapy is to use the lowest *fraction of inspired oxygen* (Fio_2) to have an acceptable blood oxygen level without causing harmful side effects. *Although oxygen improves the Pao_2 level, it does not cure the problem or stop the disease process.* Most patients with some degree of hypoxia require an oxygen flow of 2 to 4 L/min via nasal cannula or up to 40% via Venturi mask. A patient who is hypoxemic and has chronic **hypercarbia** (increased partial pressure of arterial carbon dioxide [$Paco_2$] levels) needs lower levels of oxygen delivery, usually 1 to 2 L/min via nasal cannula, to prevent decreased respiratory effort. (A low Pao_2 level is this patient’s primary drive for breathing.)

FIG. 30-1 Restoration of adequate oxygenation and tissue perfusion by oxygen delivery adjustments and oxygen therapy when respiratory problems interfere with meeting tissue oxygen needs. *Hgb*, Hemoglobin, *RBCs*, red blood cells.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Arterial blood gas (ABG) analysis is the best measure for determining the need for oxygen therapy and for evaluating its effects. Oxygen need can also be determined by noninvasive monitoring, such as pulse oximetry.

INTERVENTIONS

Before starting oxygen therapy and while caring for a patient receiving oxygen therapy, you must be knowledgeable about oxygen hazards and complications. Know the rationale and the expected outcome related to oxygen therapy for each patient receiving oxygen. **Chart 30-1** lists best practices for patients using oxygen therapy.

Hazards and Complications of Oxygen Therapy

Combustion. Oxygen itself does not burn, but it supports and enhances combustion. Therefore a fire burns better in the presence of oxygen. For example, when the oxygen content of the air around a lighted cigarette is nearly 50%, the entire cigarette flames up and can catch items nearby on fire (Edelman et al., 2008). Open fires, even small ones like candles or cigarettes, should not be in the same room during oxygen therapy. Take special precautions during oxygen delivery, including posting a sign on the door of the patient’s room. Smoking is prohibited in the patient’s room, including at home, when oxygen is in use.

CHART 30-1 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Oxygen Therapy

- Check the physician’s prescription with the type of delivery system and liter flow or percentage of oxygen actually in use.
- Obtain a prescription for humidification if oxygen is being delivered at 4 L/min or more.
- Be sure the oxygen and humidification equipment are functioning properly.
- Check the skin around the patient’s ears, back of the neck, and face every 4 to 8 hours for pressure points and signs of irritation.
- Ensure that mouth care is provided every 8 hours and as needed; assess nasal and oral mucous membranes for cracks or other signs of dryness.
- Pad the elastic band and change its position frequently to prevent skin breakdown.
- Pad tubing in areas that put pressure on the skin.
- Cleanse the cannula or mask by rinsing with clear, warm water every 4 to 8 hours or as needed.
- Cleanse skin under the tubing, straps, and mask every 4 to 8 hours or as needed.
- Lubricate the patient’s nostrils, face, and lips with nonpetroleum cream to relieve the drying effects of oxygen.
- Position the tubing so it does not pull on the patient’s face, nose, or artificial airway.
- Ensure that there is no smoking and that no candles or matches are lit in the immediate area.
- Assess and document the patient’s response to oxygen therapy.
- Ensure that the patient has an adequate oxygen source during any periods of transport.
- Provide the patient with ongoing teaching and reassurance to enhance his or her adherence with oxygen therapy.

All electrical equipment must be grounded to prevent fires from electrical arcing sparks. Grounded plugs may have three prongs or only two prongs with one prong being wider than the other. Grounded outlets in the hospital setting usually have a green or red dot on the plate. Frayed cords must be repaired because they can cause a spark that can ignite a flame. Flammable solutions (containing high concentrations of alcohol or oil) are not used in rooms in which oxygen is in use. (This does not include alcohol-based hand rubs.)

Oxygen-Induced Hypoventilation. Assess for oxygen-induced hypoventilation in the patient whose main respiratory drive is hypoxia (*hypoxic drive*), such as in the patient with chronic lung disease who also has carbon dioxide retention (**hypercarbia**). The arterial carbon dioxide (Paco_2) level for these patients gradually rises over time. The central chemoreceptors in the brain (medulla) are normally sensitive to increased Paco_2 levels. When these receptors are active, they stimulate breathing and increase respiratory rate. When the Paco_2 increases gradually to above 60 to 65 mm Hg, this normal mechanism to trigger breathing no longer functions. The central chemoreceptors lose sensitivity to increased levels of Paco_2 and do not respond by increasing the rate and depth of respiration. This loss of sensitivity to high levels of Paco_2 is called **CO_2 narcosis**. For these patients, the stimulus to breathe is a *decreased arterial oxygen level*. The low oxygen levels are sensed by peripheral chemoreceptors in the carotid sinus areas and aortic arch. When arterial oxygen (Pao_2) levels drop (hypoxemia), these receptors signal the brain to increase the respiratory rate and depth; this is known as the *hypoxic drive* to breathe.

The hypoxic drive occurs only in the presence of severely elevated Paco_2 levels that have occurred slowly, over years (i.e., in the patient who has hypoxemia and hypercarbia). When the patient with low Pao_2 levels and high Paco_2 levels receives oxygen therapy, the Pao_2 level increases, removing the trigger for breathing, and the patient has respiratory depression. (The patient being ventilated mechanically is not at risk for this complication.)

Oxygen therapy is prescribed at the lowest liter flow (e.g., 1, 2, or 3 L/min) needed to manage hypoxemia. A system that delivers more precise oxygen levels (e.g., a Venturi mask) is preferred. However, a patient with chronic obstructive pulmonary disease may not tolerate a facemask.

Closely monitor the respiratory rate and depth while the patient is receiving oxygen. Monitoring is especially important when it is the first time he or she receives oxygen or when the Paco_2 levels are not known. Manifestations of hypoventilation are seen during the first 30 minutes of oxygen therapy. The patient's color improves (from ashen or gray to pink) because of an increase in the Pao_2 level before the apnea or respiratory arrest occurs from slower and shallow respirations. Therefore carefully monitor the level of consciousness, respiratory pattern and rate, and pulse oximetry for those at risk for oxygen-induced hypoventilation, apnea, and respiratory arrest. *Although oxygen-induced hypoventilation is a serious concern, untreated or inadequately treated hypoxemia is a greater threat to life.*

Oxygen Toxicity. Oxygen toxicity is related to the concentration of oxygen delivered, duration of oxygen therapy, and degree of lung disease present. In general, an oxygen level greater than 50% given continuously for more than 24 to 48 hours may damage the lungs.

The causes and manifestations of lung injury from oxygen toxicity are the same as those for acute respiratory distress syndrome (ARDS) (see [Chapter 34](#)). Initial symptoms include dyspnea, nonproductive cough, chest pain beneath the sternum, and GI upset. As exposure to high levels of oxygen continues, the symptoms become more severe with decreased vital capacity, decreased compliance, crackles, and hypoxemia. Prolonged exposure to high oxygen levels damages lung tissues. Atelectasis, pulmonary edema, hemorrhage, and hyaline membrane formation result. Surviving this critical condition depends on correcting the underlying disease process and decreasing the oxygen amount delivered.

The toxic effects of oxygen are difficult to treat, making prevention a priority. The lowest level of oxygen needed to maintain oxygenation and prevent oxygen toxicity is prescribed. Closely monitor arterial blood gases (ABGs) during oxygen therapy, and notify the health care provider of Pao_2 levels greater than 90 mm Hg. Also monitor the prescribed oxygen level and length of therapy to identify patients at higher risk. High oxygen levels are avoided unless absolutely necessary. The use of continuous positive airway pressure (CPAP) with an oxygen mask, bi-level positive airway pressure (BiPAP), or positive end-expiratory pressure (PEEP) on the mechanical ventilator (see [Chapter 34](#)) may reduce the amount of oxygen needed. As soon as the patient's condition allows, the prescribed amount of oxygen is decreased.

Absorption Atelectasis. Nitrogen in the air helps maintain patent airways and alveoli. Making up 79% of room air, nitrogen prevents alveolar collapse because it does not cross the alveolar-capillary membranes and remains in the airways and alveoli. When high oxygen levels are delivered, nitrogen is diluted, oxygen diffuses from the alveoli into the circulation, and the alveoli collapse. Collapsed alveoli cause atelectasis (called *absorption atelectasis*), which is detected by auscultation.

! NURSING SAFETY PRIORITY

Action Alert

Monitor the patient receiving high levels of oxygen closely for indications of absorption atelectasis (new onset of crackles and decreased breath sounds) every 1 to 2 hours when oxygen therapy is started and as often as needed thereafter.

Drying of the Mucous Membranes. When the prescribed oxygen flow rate is higher than 4 L/min, humidify the delivery system ([Fig. 30-2](#)). Ensure that oxygen bubbles through the water in the humidifier.

Oxygen can also be humidified via a large-volume jet nebulizer in mist form (aerosol). A heated nebulizer raises the humidity even more and is used for oxygen delivery through an artificial airway. Usually the upper airway passages warm the air during breathing, but these passages are bypassed with an artificial airway, such as an endotracheal tube.

For the patient to receive properly humidified oxygen, the humidifier or nebulizer must have a sufficient amount of sterile water and the flow rate must be adequate. Condensation often forms in the tubing. Remove this condensation as it collects by disconnecting the tubing and emptying the water. Minimize the time the tubing is disconnected because the patient does not receive oxygen during this period. Some humidifiers and nebulizers have a water trap that hangs from

FIG. 30-2 A bubble humidifier bottle used with oxygen therapy.

the tubing so that the condensation can be drained without disconnecting. Check the water level and change the humidifier as needed.

NURSING SAFETY PRIORITY

Action Alert

To prevent bacterial contamination of the oxygen delivery system, never drain the fluid from the water trap back into the humidifier or nebulizer.

Infection. The humidifier or nebulizer may be a source of bacteria, especially if it is heated. *Pseudomonas aeruginosa* is often the organism involved. Oxygen delivery equipment such as cannulas and masks can also harbor organisms. Change equipment as per policy or protocol, which ranges from every 24 hours for humidification systems to every 7 days or whenever necessary for cannulas and masks.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

Why can oxygen therapy cause hypoventilation in clients who have hypercarbia?

- A. Low arterial oxygen levels are the neurologic trigger for these clients to breathe.
- B. Excessive carbon dioxide levels reduce the ability of hemoglobin molecules to carry oxygen.
- C. High concentrations of oxygen cause sedation, which reduces the strength of respiratory muscle contractions.
- D. Unlike people who do not have hypercarbia, these clients are no longer sensitive to changing levels of arterial oxygen.

Oxygen Delivery Systems

Oxygen can be delivered by many systems. Regardless of the type of delivery system used, it is important to understand its indications, advantages, and disadvantages. Use the equipment properly, and ensure appropriate equipment

maintenance. Consult a respiratory therapist whenever there is a question or concern about an oxygen delivery system.

The type of delivery system used depends on:

- Oxygen concentration required by the patient
- Oxygen concentration achieved by a delivery system
- Importance of accuracy and control of the oxygen concentration
- Patient comfort
- Expense to the patient
- Importance of humidity
- Patient mobility

Oxygen delivery systems are classified by the rate of oxygen delivery. There are two systems: low-flow systems and high-flow systems. Low-flow systems do not provide enough flow of oxygen to meet the total oxygen need and air volume of the patient. So, part of the tidal volume is supplied by breathing room air. The total level of oxygen inspired depends on the respiratory rate and tidal volume. High-flow systems have a flow rate that meets the entire oxygen need and tidal volume regardless of the patient's breathing pattern. High-flow systems are used for critically ill patients and when delivery of precise levels of oxygen is needed.

If the patient needs a mask but is able to eat, request a prescription for a nasal cannula to be used at mealtimes only. Reapply the mask after the meal is completed. To increase mobility, up to 50 feet of connecting tubing can be used with connecting pieces.

Low-Flow Oxygen Delivery Systems. Low-flow delivery systems include the nasal cannula, simple facemask, partial rebreather mask, and non-rebreather mask (Table 30-1). These systems are inexpensive, easy to use, and fairly comfortable. A disadvantage is that the actual amount of oxygen delivered varies and depends on the patient's breathing pattern. The oxygen is diluted with room air (21% oxygen), which lowers the amount of oxygen actually inspired.

Nasal Cannula. The nasal cannula, or nasal prongs (Fig. 30-3), is used at flow rates of 1 to 6 L/min. Oxygen concentrations of 24% (at 1 L/min) to 44% (at 6 L/min) can be achieved. Flow rates greater than 6 L/min do not increase oxygenation because the **anatomic dead space** (places where air flows but the structures are too thick for gas exchange) is full. In addition, high flow rates increase mucosal irritation.

The nasal cannula is often used for chronic lung disease and for any patient needing long-term oxygen therapy. The patient who retains carbon dioxide is rarely prescribed to receive oxygen at a rate higher than 2 to 3 L/min because of the risk for losing the drive to breathe, thereby increasing the risk for apnea or respiratory arrest. Place the nasal prongs in the nostrils, with the openings facing the patient, following the natural anatomic curve of the nares.

Facemasks. Facemasks for oxygen delivery can deliver a wide range of oxygen flow rates and concentrations.

Simple facemasks are used to deliver oxygen concentrations of 40% to 60% for short-term oxygen therapy or in an emergency (Fig. 30-4). A minimum flow rate of 5 L/min is needed to prevent the rebreathing of exhaled air. Ensure the mask fits well to maintain inspired oxygen levels. Care for the skin under the mask and strap to prevent skin breakdown.

Partial rebreather masks provide oxygen concentrations of 60% to 75% with flow rates of 6 to 11 L/min. It is a mask with a reservoir bag but no flaps (Fig. 30-5). With each breath, the patient rebreathes one third of the exhaled tidal volume,

TABLE 30-1 COMPARISON OF LOW-FLOW OXYGEN DELIVERY SYSTEMS

FiO ₂ DELIVERED	NURSING INTERVENTIONS	RATIONALES
Nasal Cannula 24%-40% FiO ₂ at 1-6 L/min ≈24% at 1 L/min ≈28% at 2 L/min ≈32% at 3 L/min ≈36% at 4 L/min ≈40% at 5 L/min ≈44% at 6 L/min	Ensure that prongs are in the nares properly. Apply water-soluble jelly to nares PRN. Assess the patency of the nostrils. Assess the patient for changes in respiratory rate and depth.	A poorly fitting nasal cannula leads to hypoxemia and skin breakdown. This substance prevents mucosal irritation related to the drying effect of oxygen; promotes comfort. Congestion or a deviated septum prevents effective delivery of oxygen through the nares. The respiratory pattern affects the amount of oxygen delivered. A different delivery system may be needed.
Simple Facemask 40%-60% FiO ₂ at 5-8 L/min; flow rate must be set at least at 5 L/min to flush mask of carbon dioxide ≈40% at 5 L/min ≈45%-50% at 6 L/min ≈55%-60% at 8 L/min	Be sure mask fits securely over nose and mouth. Assess skin and provide skin care to the area covered by the mask. Monitor the patient closely for risk for aspiration. Provide emotional support to the patient who feels claustrophobic. Suggest to the health care provider to switch the patient from a mask to the nasal cannula during eating.	A poorly fitting mask reduces the FiO ₂ delivered. Pressure and moisture under the mask may cause skin breakdown. The mask limits the patient's ability to clear the mouth, especially if vomiting occurs. Emotional support decreases anxiety, which contributes to a claustrophobic feeling. Use of the cannula prevents hypoxemia during eating.
Partial Rebreather Mask 60%-75% at 6-11 L/min, a liter flow rate high enough to maintain reservoir bag two-thirds full during inspiration and expiration	Make sure that the reservoir does not twist or kink, which results in a deflated bag. Adjust the flow rate to keep the reservoir bag inflated.	Deflation results in decreased oxygen delivered and rebreathing of exhaled air. The flow rate is adjusted to meet the pattern of the patient.
Non-Rebreather Mask 80%-95% FiO ₂ at a liter flow high enough to maintain reservoir bag two-thirds full	Interventions as for partial rebreather mask; this patient requires close monitoring. Make sure that valves and rubber flaps are patent, functional, and not stuck. Remove mucus or saliva. Closely assess the patient on increased FiO ₂ via non-rebreather mask. Intubation is the only way to provide more precise FiO ₂ .	Rationales as for partial rebreather mask. Monitoring ensures proper functioning and prevents harm. Valves should open during expiration and close during inhalation to prevent dramatic decrease in FiO ₂ . Suffocation can occur if the reservoir bag kinks or if the oxygen source disconnects. The patient may require intubation.

FiO₂, Fraction of inspired oxygen.

which is high in oxygen and provides a higher fraction of inspired oxygen (FiO₂). Be sure that the bag remains slightly inflated at the end of inspiration; otherwise, the desired amount of oxygen is not delivered. If needed, call the respiratory therapist for assistance.

Non-rebreather masks provide the highest oxygen level of the low-flow systems and can deliver an FiO₂ greater than 90%, depending on the patient's breathing pattern. This mask is often used with patients whose respiratory status is unstable and who may require intubation.

The non-rebreather mask has a one-way valve between the mask and the reservoir and two flaps over the exhalation ports (Fig. 30-6). The valve allows the patient to draw all needed oxygen from the reservoir bag, and the flaps prevent room air from entering through the exhalation ports (room air would dilute the oxygen concentration). During exhalation, air leaves through these exhalation ports while the one-way valve prevents exhaled air from re-entering the

reservoir bag. Some models include only one flap on the mask, or one of the exhalation flaps may be removed for safety purposes. The flow rate is kept high (10 to 15 L/min) to keep the bag inflated during inhalation. Assess for this safety feature at least hourly.

! NURSING SAFETY PRIORITY

Critical Rescue

Ensure that the valve and flaps on a non-rebreather mask are intact and functional during each breath. If the oxygen source should fail or be depleted when both flaps are in place, the patient would not be able to inhale room air.

High-Flow Oxygen Delivery Systems. High-flow systems (Table 30-2) include the Venturi mask, aerosol mask, face tent, tracheostomy collar, and T-piece. These devices deliver an accurate oxygen level when properly fitted. A high-flow

FIG. 30-3 A nasal cannula (prongs).

FIG. 30-4 A simple facemask used to deliver oxygen.

system delivers oxygen concentrations from 24% to 100% at 8 to 15 L/min.

Venturi masks (commonly called *Venti masks*) deliver the most accurate oxygen concentration without intubation. It works by pulling in a proportional amount of room air for each liter flow of oxygen. An adaptor is located between the bottom of the mask and the oxygen source (Fig. 30-7). Adaptors with holes of different sizes allow specific amounts of air to mix with the oxygen. More precise delivery of oxygen results. Each adaptor uses a different flow rate. For example, to deliver 24% of oxygen, the flow rate must be 4 L/min. Another type of Venturi mask has one adaptor with a dial that is used to select the amount of oxygen desired. Humidification is not needed with the Venturi mask. This system is best for the patient with chronic lung disease because it delivers a more precise oxygen concentration.

Other high-flow systems include the face tent, aerosol mask, tracheostomy collar, and T-piece. They are often used to provide high humidity with oxygen delivery. A dial on the humidity source regulates the delivered oxygen level. A face tent fits over the chin, with the top extending halfway across the face. The oxygen level delivered varies, but the face tent,

FIG. 30-5 A partial rebreather mask.

FIG. 30-6 A non-rebreather mask.

instead of a tight-fitting mask, is useful for facial trauma or burns. An aerosol mask is used when high humidity is needed after extubation or upper airway surgery or for thick secretions. The tracheostomy collar is used to deliver high humidity and the desired oxygen to the patient with a tracheostomy. A special adaptor, called the *T-piece*, is used to deliver any desired FiO_2 to the patient with a tracheostomy, laryngectomy,

TABLE 30-2 COMPARISON OF HIGH-FLOW OXYGEN DELIVERY SYSTEMS

FiO ₂ DELIVERED	NURSING INTERVENTIONS	RATIONALES
Venturi Mask (Venti Mask) 24%-50% FiO ₂ with flow rates as recommended by the manufacturer, usually 4-10 L/min; provides high humidity	Perform constant surveillance to ensure an accurate flow rate for the specific FiO ₂ . Keep the orifice for the Venturi adaptor open and uncovered. Provide a mask that fits snugly and tubing that is free of kinks. Assess the patient for dry mucous membranes. Change to a nasal cannula during mealtime.	An accurate flow rate ensures FiO ₂ delivery. If the Venturi orifice is covered, the adaptor does not function and oxygen delivery varies. FiO ₂ is altered if kinking occurs or if the mask fits poorly. Comfort measures may be indicated. Oxygen is a drug that needs to be given continuously.
Aerosol Mask, Face Tent, Tracheostomy Collar 24%-100% FiO ₂ with flow rates of at least 10 L/min; provides high humidity	Assess that aerosol mist escapes from the vents of the delivery system during inspiration and expiration. Empty condensation from the tubing. Change the aerosol water container as needed.	Humidification should be delivered to the patient. Emptying prevents the patient from being lavaged with water, promotes an adequate flow rate, and ensures a continued prescribed FiO ₂ . Adequate humidification is ensured only when there is sufficient water in the canister.
T-Piece 24%-100% FiO ₂ with flow rates of at least 10 L/min; provides high humidity	Empty condensation from the tubing. Keep the exhalation port open and uncovered. Position the T-piece so that it does not pull on the tracheostomy or endotracheal tube. Make sure the humidifier creates enough mist. A mist should be seen during inspiration and expiration.	Condensation interferes with flow rate delivery of FiO ₂ and may drain into the tracheostomy if not emptied. If the port is occluded, the patient can suffocate. The weight of the T-piece pulls on the tracheostomy and causes pain or erosion of skin at the insertion site. An adequate flow rate is needed to meet the inspiration effort of the patient. If not, the patient will be "air-hungry."

FiO₂, Fraction of inspired oxygen.

FIG. 30-7 A Venturi mask for precise oxygen delivery.

or endotracheal tube (Fig. 30-8). Adjust the flow rate so that the aerosol appears on the exhalation side of the T-piece.

Noninvasive Positive-Pressure Ventilation. Noninvasive positive-pressure ventilation (NPPV) is a technique using positive pressure to keep alveoli open and improve gas

FIG. 30-8 A T-piece apparatus for attachment to an endotracheal or tracheostomy tube.

exchange without the need for airway intubation. NPPV is now being used to manage dyspnea, hypercarbia and acute exacerbations of chronic obstructive pulmonary disease (COPD), cardiogenic pulmonary edema, and acute asthma attacks. Although NPPV prevents the complications associated with intubation, including ventilator-associated pneumonia (VAP), some risks and complications are associated with this type of therapy. Masks must fit tightly in order to form a proper seal. This can lead to skin breakdown over the bridge of the nose or other areas of the face. Leaks can cause uncomfortable pressure around the eyes, and gastric insufflation can lead to vomiting and the potential for aspiration. Thus NPPV should be used only on patients with an intact mental status and the ability to protect

FIG. 30-9 Nasal continuous positive airway pressure (CPAP).

their airway, although a nasogastric (NG) tube may still be required for safety.

NPPV can deliver oxygen or may use just room air. A nasal mask, nasal pillows, or full-face mask delivery system allows mechanical delivery. The three most common modes of delivery for NPPV are (1) CPAP, which delivers a set positive airway pressure throughout each cycle of inhalation and exhalation; (2) volume-limited or flow-limited, which delivers a set tidal volume with the patient's inspiratory effort; and (3) pressure-limited, which includes pressure support, pressure control, and bi-level positive airway pressure (BiPAP), which cycles different pressures at inspiration and at expiration.

For BiPAP, a cycling machine delivers a set inspiratory positive airway pressure each time the patient begins to inspire. As he or she begins to exhale, the machine delivers a lower set end-expiratory pressure. Together, these two pressures improve tidal volume, can reduce respiratory rate, and may relieve dyspnea.

For CPAP, the effect is to open collapsed alveoli. Patients who may benefit from this form of oxygen or air delivery include those with atelectasis after surgery or cardiac-induced pulmonary edema or those with COPD. It is not beneficial for patients with respiratory failure following extubation. NPPV is also being used in palliative care for alleviating dyspnea, including for those patients with "do-not-intubate" orders. However, this practice is controversial. The Society of Critical Care Medicine (SCCM) recommends that goals of therapy and expected outcomes be discussed with the patient and family before initiating therapy.

NPPV is also used for sleep apnea. The effect of this use is to hold open the upper airways (Fig. 30-9). Patients using CPAP or BiPAP at home to manage sleep apnea often bring their home equipment to the hospital. They are familiar with their own machines and feel more comfortable using their own masks. The reasons for using NPPV at home still exist when the patient enters the hospital, and depending on their

diagnosis, there may be a greater need for them to continue NPPV while hospitalized.

The number of patients using NPPV therapy is increasing, and these patients are frequently cared for outside of the ICU setting. Nurses caring for the patient with NPPV must be knowledgeable about the equipment, the technique, and the potential complications. Adequate respiratory therapy support also is needed to safely manage a patient receiving NPPV.

Transtracheal Oxygen Therapy. Transtracheal oxygen (TTO) is a long-term method of delivering oxygen directly into the lungs. A small, flexible catheter is passed into the trachea through a small incision with the patient under local anesthesia. TTO avoids the irritation that nasal prongs cause. Patients also report it to be more cosmetically acceptable. A TTO team provides patient education, including the purpose of TTO and care of the catheter. TTO flow rates are prescribed for rest and for activity. A flow rate also is prescribed for the nasal cannula, which is used when the TTO catheter is being cleaned. Most patients using this delivery method have a 55% reduction in required oxygen flow at rest and a 30% decrease with activity.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Teamwork and Collaboration

Your patient is a 44-year-old woman with stage IV ovarian cancer. The surgical and oncology teams have confirmed that there are no curative surgical or medical treatment options available to her. She and her family have decided to institute a do-not-resuscitate (DNR) comfort care (DNR-CC) order. Later that evening she becomes increasingly short of breath. The patient does not wish for her morphine infusion to be increased at this point. The physician offers the family a trial of noninvasive positive-pressure ventilation (NPPV). Your colleagues are concerned this is a violation of the patient's and family's wishes.

1. Is this a violation of the DNR-CC order?
2. Explain why the use of NPPV may be acceptable in this situation.
3. What discussions should be held with the family and patient, if possible, before starting NPPV?

Community-Based Care

Home Care Management

The patient must be stable before home oxygen is considered. For Medicare to cover the cost of home oxygen therapy, the patient must have severe hypoxemia defined as a partial pressure of arterial oxygen (P_{aO_2}) level of less than 55 mm Hg or an arterial oxygen saturation (SpO_2) of less than 88% on room air and at rest. The criteria vary when hypoxemia is caused by cardiac rather than pulmonary problems or when oxygen is needed only at night or with exercise.

After the need for home oxygen therapy is verified, begin a teaching plan about oxygen therapy. Work with the discharge planner to help the patient select a durable medical equipment (DME) company to deliver oxygen equipment and select a community health nursing agency for follow-up care in the home. The patient is re-evaluated for the need for oxygen therapy on a periodic basis.

While providing discharge planning and teaching, be sensitive to the patient's emotional adjustment to oxygen therapy. Encourage the patient to share feelings and concerns. He or she may be concerned about social acceptance. Help him or

FIG. 30-10 Small E size oxygen tank (cylinder) for portability.

her realize that adherence to oxygen therapy is important for being able to participate in ADLs and other events that bring enjoyment.

Home Care Preparation

The nurse or respiratory therapist teaches the patient about the equipment needed for home oxygen therapy, including the oxygen source, delivery devices, humidity sources, and safety aspects of using and maintaining the equipment.

Home oxygen therapy is provided in one of three ways: compressed gas in a tank or a cylinder, liquid oxygen in a reservoir, or an oxygen concentrator. Compressed gas in an oxygen tank (green) is the most often used oxygen source. An oxygen tank is economical, and pure oxygen can be delivered at a wide range of flow rates. The large H cylinder may be used as a stationary source, and the small E tank is available for transporting the patient (Fig. 30-10). Teach the patient and family to check the gauge daily to assess the amount of oxygen left in the tank. As a safety precaution, the tanks must always be in a stand or rack. A tank that is accidentally knocked over could suddenly decompress and move around in an uncontrolled manner. Smaller (and lighter) D and C cylinders are available for the patient to carry.

Liquid oxygen for home use is oxygen gas that has been liquefied. A concentrated amount of oxygen is available in a lightweight and easy-to-carry container similar to a Thermos bottle (Fig. 30-11). The patient can fill the portable tank from the large stationary liquid vessel. This type of oxygen lasts longer than gaseous oxygen in a conventional tank of the same size; however, it is expensive and the oxygen evaporates if it is not used continuously.

The **oxygen concentrator** or oxygen extractor is a machine that removes nitrogen, water vapor, and hydrocarbons from room air. Oxygen is concentrated from room air to more than 90%. The concentrator, although noisy and large, is the least expensive system and does not need to be filled. It is often used in the home as a stationary system. A smaller version of

FIG. 30-11 Portable liquid oxygen.

the machine that can plug into DC electrical outlets can be rented for use during car or boat trips. Liquid oxygen and E tanks are used when the patient leaves home for short trips.

With the use of these home oxygen systems, an oxygen-conserving reservoir-type nasal cannula can be used to reduce oxygen flow needs by about 50%. A reservoir for storage of exhaled oxygen is attached to the tubing. The stored oxygen is then delivered back to the patient on the next inhalation.

Regardless of the type of oxygen delivery system used, review safety issues with the patient and all family members.

NURSING SAFETY PRIORITY

Action Alert

Stress to the patient the importance of not smoking when he or she is using oxygen. Teach the patient and all family members that smoking materials, candles, gas burners, and fireplaces (and other open flames) are not to be used in the same room that oxygen is being used.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

Which action is most important for the nurse to teach the family of a client who is receiving oxygen therapy at home by continuous nasal cannula?

- A. Providing mouth care every 8 hours
- B. Lubricating the lips with water-soluble jelly
- C. Draining the condensation in the tubing every 2 hours
- D. Changing the position of the elastic band every 4 hours

TRACHEOSTOMY

Overview

Tracheotomy is the surgical incision into the trachea to create an airway. **Tracheostomy** is the (tracheal) stoma, or opening, that results from the tracheotomy. A tracheotomy can be an emergency procedure or a scheduled surgery. Tracheostomies can be temporary or permanent. Some indications for tracheostomy include acute airway obstruction, the need for airway protection, laryngeal trauma, and airway involvement during head or neck surgery.

FIG. 30-12 A vertical tracheal incision for a tracheostomy.

PATIENT-CENTERED COLLABORATIVE CARE

ANALYSIS

Priority problems for patients requiring tracheostomy include:

1. Reduced oxygenation related to weak chest muscles, obstruction, or other physical problems
2. Inadequate communication related to tracheostomy or intubation
3. Inadequate nutrition related to presence of endotracheal tube
4. Potential for infection related to invasive procedures
5. Damaged oral mucosa related to mechanical factors (endotracheal tube)

INTERVENTIONS

Preoperative Care

The care for the patient having a tracheostomy is similar to that for a laryngectomy (see [Chapter 31](#)). Focus on his or her knowledge deficits through teaching, and discuss tracheostomy care, communication, and speech.

Operative Procedures

Initially, the neck is extended and an endotracheal (ET) tube is placed by the anesthesia provider to maintain the airway. An incision is then made through the anterior skin of the neck, exposing the tracheal rings and moving other tissues out of the surgical path. A second incision is made through the tracheal rings to enter the trachea ([Fig. 30-12](#)). The types of incisions and specific techniques vary, depending on the surgeon's preference and the reason for the surgery.

After the trachea is entered, the ET tube is removed while the tracheostomy tube is inserted. The tracheostomy tube is secured in place with sutures and tracheostomy ties or Velcro tube holders. A chest x-ray determines proper placement of the tube. If intubation is not possible, a tracheotomy can be done with the patient awake under local anesthesia.

Postoperative Care

Immediately after surgery, focus care on ensuring a patent airway. Confirm the presence of bilateral breath sounds. Perform a respiratory assessment at least every 2 hours. Assess the patient for complications from the procedure.

Complications

Major complications can arise after surgery. [Table 30-3](#) lists manifestations, management, and prevention of other serious complications of tracheostomy.

Tube obstruction can occur as a result of secretions or by cuff displacement. Indicators of obstruction include difficulty breathing; noisy respirations; difficulty inserting a suction catheter; thick, dry secretions; and unexplained peak pressures (if a mechanical ventilator is in use). Assess the patient at least hourly for tube patency. Prevent obstruction by helping the patient cough and deep breathe, providing inner cannula care, humidifying the oxygen source, and suctioning. If tube obstruction occurs as a result of cuff prolapse over the end of the tracheostomy tube, the physician or advanced practice nurse repositions or replaces the tube.

Tube dislodgement and accidental decannulation can occur when the tube system is not secure. This problem can be prevented by securing the tube in place. This action reduces movement and traction on the tube from oxygen or ventilator tubing or accidental pulling by the patient. *Tube dislodgment in the first 72 hours after surgery is an emergency because the tracheostomy tract has not matured and replacement is difficult. The tube may end up in the subcutaneous tissue instead of in the trachea.*

! NURSING SAFETY PRIORITY

Critical Rescue

If the tube is dislodged on an immature tracheostomy, ventilate the patient using a manual resuscitation bag and facemask while another nurse calls the Rapid Response Team.

For safety, ensure that a tracheostomy tube of the same type (including an obturator) and size (or one size smaller) is at the bedside at all times, along with a tracheostomy insertion tray. If decannulation occurs after 72 hours, extend the patient's neck and open the tissues of the stoma with a curved Kelly clamp to secure the airway. With the obturator inserted into the tracheostomy tube, quickly and gently replace the tube and remove the obturator. Check for airflow through the tube and for bilateral breath sounds. If you cannot secure the airway, notify a more experienced nurse, respiratory therapist, or physician for assistance. Ventilate with a bag-valve mask. If the patient is in distress, call the Rapid Response Team for help.

Pneumothorax (air in the chest cavity) can develop during the tracheotomy procedure if the chest cavity is entered. When pneumothorax occurs during tracheotomy, it usually does so at the apex of the lung. Chest x-rays after placement are used to assess for pneumothorax.

Subcutaneous emphysema occurs when there is an opening or tear in the trachea and air escapes into fresh tissue planes of the neck. Air can also progress throughout the chest and other tissues into the face. Inspect and palpate for air under the skin around the new tracheostomy.

TABLE 30-3 COMPLICATIONS OF TRACHEOSTOMY

COMPLICATIONS AND DESCRIPTION	MANIFESTATIONS	MANAGEMENT	PREVENTION
Tracheomalacia: constant pressure exerted by the cuff causes tracheal dilation and erosion of cartilage.	An increased amount of air is required in the cuff to maintain the seal. A larger tracheostomy tube is required to prevent an air leak at the stoma. Food particles are seen in tracheal secretions. The patient does not receive the set tidal volume on the ventilator.	No special management is needed unless bleeding occurs.	Use an uncuffed tube as soon as possible. Monitor cuff pressure and air volumes closely, and detect changes.
Tracheal stenosis: narrowed tracheal lumen is due to scar formation from irritation of tracheal mucosa by the cuff.	Stenosis is usually seen after the cuff is deflated or the tracheostomy tube is removed. The patient has increased coughing, inability to expectorate secretions, or difficulty in breathing or talking.	Tracheal dilation or surgical intervention is used.	Prevent pulling of and traction on the tracheostomy tube. Properly secure the tube in the midline position. Maintain proper cuff pressure. Minimize oronasal intubation time.
Tracheoesophageal fistula (TEF): excessive cuff pressure causes erosion of the posterior wall of the trachea. A hole is created between the trachea and the anterior esophagus. The patient at highest risk also has a nasogastric tube present.	Similar to tracheomalacia: Food particles are seen in tracheal secretions. Increased air in cuff is needed to achieve a seal. The patient has increased coughing and choking while eating. The patient does not receive the set tidal volume on the ventilator.	Manually administer oxygen by mask to prevent hypoxemia. Use a small, soft feeding tube instead of a nasogastric tube for tube feedings. A gastrostomy or jejunostomy may be performed by the physician. Monitor the patient with a nasogastric tube closely; assess for TEF and aspiration.	Maintain cuff pressure. Monitor the amount of air needed for inflation, and detect changes. Progress to a deflated cuff or cuffless tube as soon as possible.
Trachea–innominate artery fistula: a malpositioned tube causes its distal tip to push against the lateral wall of the tracheostomy. Continued pressure causes necrosis and erosion of the innominate artery. This is a medical emergency.	The tracheostomy tube pulsates in synchrony with the heartbeat. There is heavy bleeding from the stoma. This is a life-threatening complication.	Remove the tracheostomy tube immediately. Apply direct pressure to the innominate artery at the stoma site. Prepare the patient for immediate repair surgery.	Correct the tube size, length, and midline position. Prevent pulling or tugging on the tracheostomy tube. Immediately notify the physician of the pulsating tube.

! NURSING SAFETY PRIORITY

Critical Rescue

If the skin around a new tracheostomy is puffy and you can feel a crackling sensation when pressing on the skin, notify the physician immediately.

Bleeding in small amounts from the tracheostomy incision can be expected for the first few days, but constant oozing is abnormal. Wrap gauze around the tube and pack gauze gently into the wound to apply pressure to the bleeding sites.

Infection can occur at any time. In the hospital, use sterile technique to prevent infection during suctioning and tracheostomy care. Assess the stoma site at least once per shift for purulent drainage, redness, pain, or swelling. Tracheostomy dressings may be used to keep the stoma clean and dry. These dressings resemble a 4 × 4 gauze pad with an area removed to fit around the tube. If tracheostomy dressings are not available, fold standard sterile 4 × 4s to fit around the tube. *Do not cut the dressing because small bits of gauze could then be aspirated through the tube.* Change these dressings often because moist dressings provide a medium

for bacterial growth. Careful wound care prevents most local infections.

Tracheostomy Tubes

Many types of tracheostomy tubes are available (Fig. 30-13). The one chosen depends on the specific needs of the patient. Tracheostomy tubes are available in many sizes and are made of plastic or metal. The tubes may be reusable; however, most tubes in use today are disposable. A tracheostomy tube may or may not have a cuff. It also may have an inner cannula. For patients receiving mechanical ventilation, a cuffed tube is used in acute care settings. A noncuffed tube is used when mechanical ventilation is not required.

For tubes with a reusable inner cannula, inspect, suction, and clean the inner cannula. During the first 24 hours after surgery, perform cannula care as often as needed, perhaps every 30 to 60 minutes. Thereafter, care is determined by the patient's needs and agency policy. In planning for self-care, teach him or her to remove the inner cannula and check for cleanliness. Also instruct him or her about suctioning and tracheostomy cleaning.

Because breathing and swallowing move the tube, a cuffed tube does not protect against aspiration. Having a cuffed tube

FIG. 30-13 Tracheostomy tubes. **A**, Dual-lumen cuffed tracheostomy tube with disposable inner cannula. **B**, Dual-lumen cuffed fenestrated tracheostomy tube. **C**, Single-lumen cannula cuffed tracheostomy tube.

inflated may give a false sense of security that aspiration cannot occur during feeding or mouth care. In addition, the pilot balloon does not reflect whether the correct amount of air is present in the cuff.

A fenestrated tube can function in many different ways. When the inner cannula is in place, the fenestration is covered over (closed) and this tube works like a double-lumen tube. With the inner cannula removed and the plug or red stopper locked in place, air can pass through the fenestration, around the tube, and up through the natural airway. The patient can then cough and speak. If the patient has trouble with any of these actions, he or she should be evaluated for proper tube placement, patency, size, and fenestration. *Do not cap the tube until the problem is identified and corrected.*

A fenestrated tube may or may not have a cuff. With a cuff, some air flows through the natural airway when the patient is not being mechanically ventilated.

! NURSING SAFETY PRIORITY

Action Alert

Always deflate the cuff before capping the tube with the decannulation cap; otherwise, the patient has no airway.

Patients with metal tracheostomy tubes scheduled for magnetic resonance imaging (MRI) need to change to a plastic tube. Metal tubes could be dislodged or heat up with exposure to the magnetic field during the scan.

Care Issues for the Patient with a Tracheostomy

Preventing Tissue Damage

Tissue damage can occur at the point where the inflated cuff presses against the tracheal mucosa. Mucosal ischemia occurs when the pressure exerted by the cuff on the mucosa exceeds

FIG. 30-14 An aneroid pressure manometer for cuff inflation and measuring cuff pressures.

the capillary perfusion pressure. To reduce the risk for tracheal damage, keep the cuff pressure between 14 and 20 mm Hg or 20 and 30 cm H₂O (ideally, 25 cm H₂O or less) (Sole, et al., 2011).

Most cuffs are designed to use a high volume of air while keeping low pressure on the tracheal mucosa. Inflate the cuff to form a seal between the trachea and the cuff while creating the least amount of pressure. If the cuff cannot be inflated to seal well enough, a larger-diameter tube may be needed. A pressure cuff inflator can be used to inflate the cuff to a specified pressure or to check the cuff pressure (Fig. 30-14).

Check the cuff pressure at least once during each shift, especially with the minimal leak technique, and keep the pressure at 14 to 20 mm Hg or 20 to 30 cm H₂O. In rare situations, the cuff pressure is increased to maintain ventilator volumes when peak pressures are greater than 50 mm Hg (65 cm H₂O) and positive end-expiratory pressure (PEEP) is greater than 10 mm Hg (14 cm H₂O). High PEEP values can deflate the cuff over time, and more air may need to be added to maintain a proper seal. Manufacturers have guidelines for the specific volumes for each cuff size. Most cuffs are adequately inflated with less than 10 mL of air.

Although a high cuff pressure alone causes tracheal damage, other factors may make the damage worse. The patient who is malnourished, dehydrated, hypoxic, older, or receiving corticosteroids has poor tissue healing and is at risk for greater tissue damage. Tube friction and movement are common events that damage the mucosa and lead to tracheal stenosis. Reduce local airway damage by maintaining proper

cuff pressures, stabilizing the tube, suctioning only when needed, and preventing and treating malnutrition, dehydration, and hypoxia.

Ensuring Air Warming and Humidification

The tracheostomy tube bypasses the nose and mouth, which normally humidify, warm, and filter the air before it reaches the lower respiratory tract. If humidification and warming are not adequate, tracheal damage can occur. Thick, dried secretions can occlude the airways.

To prevent these complications, humidify the air as prescribed. On an ongoing basis, assess for a fine mist emerging from the tracheostomy collar or T-piece during inspiration and expiration. To increase the amount of humidity delivered, a warming device can be attached to the water source with a temperature probe placed in the tubing circuit. Monitor the circuit temperature hourly by feeling the tubing and by checking the probe. Ensure adequate hydration, which also helps liquefy secretions. Increasing the flow rate at the flowmeter also increases the amount of delivered humidity.

! NURSING SAFETY PRIORITY

Action Alert

Keep the temperature of the air entering a tracheostomy between 98.6° and 100.4° F (37° and 38° C), and never exceed 104° F (40° C).

Suctioning

Suctioning maintains a patent airway and promotes gas exchange by removing secretions when the patient cannot cough adequately. Chart 30-2 lists best practices for suctioning. Assess the patient's need for suctioning. Suctioning is

CHART 30-2 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Suctioning the Artificial Airway

1. Assess the need for suctioning (routine unnecessary suctioning causes mucosal damage, bleeding, and bronchospasm).
2. Wash hands. Don protective eyewear. Maintain Standard Precautions.
3. Explain to the patient that sensations such as shortness of breath and coughing are to be expected but that any discomfort will be very brief.
4. Check the suction source. Occlude the suction source, and adjust the pressure dial to between 80 and 120 mm Hg to prevent hypoxemia and trauma to the mucosa.
5. Set up a sterile field.
6. Preoxygenate the patient with 100% oxygen for 30 seconds to 3 minutes (at least three hyperinflations) to prevent hypoxemia. Keep hyperinflations synchronized with inhalation.
7. Quickly insert the suction catheter until resistance is met. *Do not apply suction during insertion.*
8. Withdraw the catheter 0.4 to 0.8 inch (1 to 2 cm), and begin to apply suction. Use intermittent suction and a twirling motion of the catheter during withdrawal. *Never suction longer than 10 to 15 seconds.*
9. Hyperoxygenate for 1 to 5 minutes or until the patient's baseline heart rate and oxygen saturation are within normal limits.
10. Repeat as needed for up to three total suction passes.
11. Suction mouth as needed, and provide mouth care.
12. Wash hands.
13. Describe secretions, and document patient's responses.

? NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

Which technique or action does the nurse use to prevent tracheal stenosis in a client after a tracheotomy has been performed?

- A. Assessing breath sounds bilaterally every 2 hours
- B. Securing the tracheostomy tube in a midline position
- C. Holding the tube continually when changing the tracheostomy ties
- D. Suctioning the tracheostomy tube with as small a catheter as possible

needed when secretions are audible or noisy, when crackles or wheezes are heard on auscultation, or when restlessness, increased pulse or respiratory rates, or mucus in the artificial airway is present. Other indications include patient requests for suctioning or an increase in the peak airway pressure on the ventilator.

Suctioning is often performed through an artificial airway but the nose or mouth also can be used. Suctioning of both routes is routine for the patient with retained secretions.

Suctioning through the nose has similar complications as suctioning through an artificial airway and can be painful. Slow, careful placement of the catheter following the nasopharyngeal anatomy makes the procedure less traumatic. Placing a nasopharyngeal airway and suctioning through it can prevent trauma to the nasal mucosa. Advance the catheter through the nasopharynx and into the laryngopharynx while the patient receives oxygen by mask or nasal cannula. Once the catheter enters the larynx, the patient may cough. On inhalation, insert the catheter through the vocal cords and into the trachea. Occasionally, the catheter can be disconnected from suction and attached to an oxygen source, with the patient receiving oxygen via the catheter.

Suctioning can cause hypoxia, tissue (mucosal) trauma, infection, vagal stimulation, bronchospasm, and cardiac dysrhythmias.

Hypoxia can be caused by these factors in the patient with a tracheostomy:

- Ineffective oxygenation before, during, and after suctioning
- Use of a catheter that is too large for the artificial airway
- Prolonged suctioning time
- Excessive suction pressure
- Too frequent suctioning

Prevent hypoxia by hyperoxygenating the patient with 100% oxygen with a manual resuscitation bag attached to an oxygen source. If the patient can take deep breaths, instruct him or her to do so three or four times with the existing oxygen delivery system before suctioning. If possible, monitor the heart rate or use a pulse oximeter while suctioning to assess tolerance of the procedure. Assess for hypoxia (e.g., increased heart rate and blood pressure, oxygen desaturation, cyanosis, restlessness, anxiety, dysrhythmias). Oxygen saturation below 90% by pulse oximetry indicates hypoxemia. If hypoxia occurs, stop the suctioning procedure. Using the 100% oxygen delivery system, reoxygenate the patient until baseline parameters return.

Use a catheter of the correct size to reduce the risk for hypoxia. The size should not exceed half of the size of the tracheal lumen. In adults, the standard catheter size is 12 Fr or 14 Fr. Correct catheter size allows efficient removal of secretions without causing hypoxemia.

Tissue trauma can result from frequent suctioning, prolonged suctioning time, excessive suction pressure, and non-rotation of the catheter. Prevent trauma to this fragile mucosa by suctioning only when needed. Lubricate the catheter with sterile water or saline before insertion. *Apply suction only during the withdrawal of the catheter.* Use a twirling motion during withdrawal to prevent grabbing of the mucosa.

Apply suction intermittently for only 10 to 15 seconds. Estimate this time frame by holding your own breath and counting to 10 or 15 during suctioning. After 15 seconds, end the suctioning procedure. Most patients cannot tolerate more

than 15 seconds of suctioning. Prolonged suctioning can cause alveolar collapse (*suction atelectasis*).

Infection is possible because each catheter pass introduces bacteria into the trachea. In the hospital, use sterile technique for suctioning and for all suctioning equipment, including suction catheters, gloves, and saline or water. Suction the mouth *after* suctioning the artificial airway. *Never use oral suction equipment for suctioning an artificial airway, because this can introduce oral bacteria into the lungs.* Use clean technique with home suctioning procedures because the number of virulent organisms in the home environment is lower than in the hospital.

Vagal stimulation and bronchospasm are possible during suctioning. Vagal stimulation results in severe bradycardia, hypotension, heart block, ventricular tachycardia, asystole, or other dysrhythmias. *If vagal stimulation occurs, stop suctioning immediately and oxygenate the patient manually with 100% oxygen.* Bronchospasm sometimes occurs when the catheter passes into the airway. The patient may need a bronchodilator to relieve bronchospasm and respiratory distress. In addition, hypoxia caused by suctioning can stimulate a variety of cardiac dysrhythmias. If the patient has cardiac monitoring in place, check the monitor during suctioning.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

Which action does the nurse take to prevent hypoxia in a client during nasotracheal suctioning?

- A. Measuring pulse oximetry throughout the procedure
- B. Inserting the suction catheter through the vocal cords only when the client exhales
- C. Administering 100% oxygen by manual resuscitation bag before initiating suctioning
- D. Removing the suction tube from the nasopharynx as soon as the client begins to cough

Providing Tracheostomy Care

Tracheostomy care keeps the tube free of secretions, maintains a patent airway, and provides wound care. This procedure is performed whether or not the patient can clear secretions. Perform tracheostomy care according to agency policy, usually every shift and as needed. [Chart 30-3](#) outlines best practices for tracheostomy care.

Before proceeding with tracheostomy care, assess the patient as described in [Chart 30-4](#). The need for suctioning and tracheostomy care is determined by the amount and consistency of secretions, the specific pulmonary disease, the ability of the patient to cough and deep breathe, the need for mechanical ventilation, and wound care. Using a penlight, inspect the inner lumen of a single-lumen tube to assess for secretions.

Secure tracheostomy tubes in place using either twill tape ties or Velcro tracheostomy tube holders. Both devices require

NURSING SAFETY PRIORITY

Critical Rescue

Prevent accidental decannulation during tracheostomy care by keeping the old ties or holder on the tube while applying new ties or holder or by keeping a hand on the tube until it is securely stable. (This may require the assistance of another person.)

CHART 30-3 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Tracheostomy Care

1. Assemble the necessary equipment.
2. Wash hands. Maintain Standard Precautions.
3. Suction the tracheostomy tube if necessary.
4. Remove old dressings and excess secretions.
5. Set up a sterile field.
6. Remove and clean the inner cannula. Use half-strength hydrogen peroxide to clean the cannula and sterile saline to rinse it. If the inner cannula is disposable, remove the cannula and replace it with a new one.
7. Clean the stoma site and then the tracheostomy plate with half-strength hydrogen peroxide followed by sterile saline. Ensure that none of the solutions enters the tracheostomy.
8. Change tracheostomy ties if they are soiled. Secure new ties in place before removing soiled ones to prevent accidental decannulation. If a knot is needed, tie a square knot that is visible on the side of the neck. One or two fingers should be able to be placed between the tie tape and the neck.
9. Wash hands.
10. Document the type and amount of secretions and the general condition of the stoma and surrounding skin. Document the patient's response to the procedure and any teaching or learning that occurred.

FIG. 30-15 Placement of tracheostomy gauze dressing and Velcro tracheostomy tube holder.

coughing, which in turn may cause decannulation. Keeping the tube secure while changing the ties or holder to prevent accidental decannulation is critical. Include the patient in tracheostomy care as a step toward self-management. **Fig. 30-15** shows correct placement of a tracheostomy dressing.

CHART 30-4 FOCUSED ASSESSMENT

The Patient with a Tracheostomy

- Note the quality, pattern, and rate of breathing:
 - Within patient's baseline?
 - Tachypnea can indicate hypoxia.
 - Dyspnea can indicate secretions in the airway.
- Assess for any cyanosis, especially around the lips, which could indicate hypoxia.
- Check the patient's pulse oximetry reading.
- If oxygen is prescribed, is the patient receiving the correct amount, with the correct equipment and humidification?
- Assess the tracheostomy site:
 - Note the color, consistency, and amount of secretions in the tube or externally.
 - If the tracheostomy is sutured in place, is there any redness, swelling, or drainage from suture sites?
 - If the tracheostomy is secured with ties, what is the condition of the ties? Are they moist with secretions or perspiration? Are the secretions dried on the ties? Is the tie secure?
 - Assess the condition of the skin around the tracheostomy and neck. Be sure to check underneath the neck for secretions that may have drained to the back. Check for any skin breakdown related to pressure from the ties or related to excess secretions.
 - Assess behind the faceplate for the size of the space between the outer cannula and the patient's tissue. Are any secretions collected in this area?
- If the tube is cuffed, check cuff pressure.
- Auscultate the lungs.
- Are a second (emergency) tracheostomy tube and obturator available?

changing when soiled or at least once a day to keep them clean, to prevent infection, and to assess for skin irritation under the ties. A properly secured tie or holder allows space for only one or two fingers to be placed between the tie or holder and the neck. Tube movement causes irritation and

Providing Bronchial and Oral Hygiene

Bronchial hygiene promotes a patent airway and prevents infection. Turn and reposition the patient every 1 to 2 hours, support out-of-bed activities, and encourage ambulation. These actions promote lung expansion and gas exchange and help remove secretions. Coughing and deep breathing, combined with the chest percussion, vibration, and postural drainage, promote pulmonary hygiene (see **Chapter 32**).

Oral hygiene is important to keep the airway patent, to prevent bacterial overgrowth and dental caries, and to promote comfort. Maintain Standard Precautions during the procedure. Avoid using glycerin swabs or mouthwash that contains alcohol to clean the mouth because these products dry the mouth, change its pH, and promote bacterial growth. Instead, use a sponge tooth cleaner or soft-bristled toothbrush moistened in water for mouth care. Hydrogen peroxide solutions can help remove crusted matter but may break down healing tissue. Use these agents only with a physician's prescription. Help the patient rinse his or her mouth with normal saline every 4 hours while awake or as often as he or she desires.

Examine the mouth for open areas or dental problems. Ulcers, bacterial or fungal (*Candida*) growth, and other infections are treated medically. Apply lip balm or water-soluble jelly to prevent cracked lips and promote patient comfort. Mouth care helps promote oral health, comfort, and aesthetic appearance. Offering an opportunity for the patient or family member to perform mouth care allows participation in care and increases self-esteem.

Oral secretions can move down the trachea and collect above the inflated cuff of the endotracheal tube. When the cuff is deflated, the secretions can move into the lungs. The Hi-Lo Evac endotracheal tube has an additional lumen open to the area above the cuff and can help prevent aspiration of oral secretions. The extra lumen allows suctioning of the airway above the cuff before deflating, thus preventing movement of oral secretions deeper into the airway.

CHART 30-5 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Preventing Aspiration During Swallowing

- Avoid serving meals when the patient is fatigued.
- Provide smaller and more frequent meals.
- Provide adequate time; do not “hurry” the patient.
- Provide close supervision if the patient is self-feeding.
- Keep emergency suctioning equipment close at hand and turned on.
- Avoid water and other “thin” liquids.
- Thicken all liquids, including water.
- Avoid foods that generate thin liquids during the chewing process, such as fruit.
- Position the patient in the most upright position possible.
- When possible, completely (or at least partially) deflate the tube cuff during meals.
- Suction after initial cuff deflation to clear the airway and allow maximum comfort during the meal.
- Feed each bite or encourage the patient to take each bite slowly.
- Encourage the patient to “dry swallow” after each bite to clear residue from the throat.
- Avoid consecutive swallows of liquids.
- Provide controlled small volumes of liquids, using a spoon.
- Encourage the patient to “tuck” his or her chin down and move the forehead forward while swallowing.
- Allow the patient to indicate when he or she is ready for the next bite.
- If the patient coughs, stop the feeding until he or she indicates that the airway has been cleared.
- Continuously monitor tolerance to oral food intake by assessing respiratory rate, ease, pulse oximetry, and heart rate.

Ensuring Nutrition

Swallowing can be a major problem for the patient with a tracheostomy tube in place. In a normal swallow, the larynx lifts and moves forward to protect itself from the passing stream of food and saliva. Laryngeal lift also opens the upper esophageal sphincter. The tracheostomy tube sometimes tethers the larynx in place, making it unable to move effectively. The result is difficulty in swallowing. Also, when the tracheostomy tube cuff is inflated, it can balloon backwards and interfere with the passage of food through the esophagus. The wall between the back of the trachea and the front of the esophagus is very thin, allowing this pushing problem.

Instruct the patient to keep the head of the bed elevated for at least 30 minutes after eating. [Chart 30-5](#) outlines best practices to prevent aspiration during swallowing.

Maintaining Communication

The patient can speak when there is a cuffless tube, when a fenestrated tracheostomy tube is in place, and when the fenestrated tube is capped or covered. Until natural speech is feasible, teach him or her and the family about other communication means. A writing tablet, Magic Slate, communication board with pictures and letters, communication “flash cards” on a ring, hand signals, or a computer, as well as a call light within reach, are used to promote communication and decrease frustration from not being able to speak or be understood. Phrase questions for “yes” or “no” answers to help the patient respond easily. Move the patient closer to the nurses’ station, and mark the central call light system to indicate that he or she cannot speak.

The inability to talk is a major stressor for the patient. Helping communication is an important nursing function and is required by The Joint Commission’s National Patient Safety Goals (NPSGs). When the patient can tolerate cuff deflation, he or she places a finger over the tracheostomy tube on exhalation. This forces air up through the larynx, vocal cords, and mouth and allows speech. During the process of decannulation, when the fenestrated tube is “capped,” the patient has the benefit of speech without the need to cover the tube.

A device to facilitate speech for the patient with a tracheostomy is a special one-way valve that fits over the tube and replaces the need for finger occlusion. The valve allows him or her to breathe in through the tracheostomy tube. On exhalation, the valve closes so that air is forced through the vocal cords, allowing speech. For this valve to assist in speech, the patient must not be connected to a ventilator, must have the cuff deflated, and must be able to breathe around the tube. Some valves have an extra port for supplemental oxygen without impairing the ability to speak.

Supporting Psychosocial Needs and Self-Image

Addressing psychological concerns is an important aspect of nursing care of patients recovering from a tracheostomy. While providing physical care, keep in mind the emotional impact of an artificial airway. Acknowledge the patient’s frustration with communication, and allow time for communication. When speaking to him or her, use a normal tone of voice. The tracheostomy tube does not alter hearing or comprehension.

The patient may have a change in self-image because of deformity, the presence of a stoma or artificial airway, speech changes, a change in the method of eating, or difficulty with speech. Help the patient set realistic goals, starting with involvement in self-care.

Work with the family to ease the patient into a more normal social environment. Provide encouragement and positive reinforcement while demonstrating acceptance and caring behaviors. Assess the family for the need for counseling.

After surgery, the patient may feel shy and socially isolated. He or she can wear loose-fitting shirts, decorative collars, or scarves to cover the tracheostomy tube.

Weaning

Weaning the patient from a tracheostomy tube entails a gradual decrease in the tube size and ultimate removal of the tube. Carefully monitor this process, especially after each change. The physician or respiratory advanced practice nurse performs the steps in the process.

First, the cuff is deflated as soon as the patient can manage secretions and does not need mechanical ventilation. This change allows him or her to breathe through the tube and through the upper airway. Next, the tube is changed to an uncuffed tube. If this is tolerated, the size of the tube is gradually decreased. When a small fenestrated tube is placed (No. 4 or 6, depending on the size of the airway), the tube is capped so that all air passes through the upper airway and the fenestra, with none passing through the tube. Assess the patient to ensure adequate airflow around the tube when it is capped. The tube may be removed after he or she tolerates more than 24 hours of capping. Place a dry dressing over the stoma (which gradually heals on its own).

Another device used for the transition from tracheostomy to natural breathing is a *tracheostomy button*. The button maintains stoma patency and assists spontaneous breathing. The Kistner tracheostomy tube and Olympic tracheostomy button are examples of this type of device. To function, the button must fit properly. A disadvantage is the possibility of decannulation—the tube can dislodge from the trachea but remain in the neck tissues.

DECISION-MAKING CHALLENGE

Safety; Patient-Centered Care

Your patient is a 66-year-old man with end-stage COPD. He was unable to be successfully extubated after several attempts and subsequently required a tracheostomy. He was weaned from the ventilator 7 days ago and transferred from the ICU to your floor yesterday. A fenestrated tracheostomy was placed by the surgical team before transfer. He has been successfully capped intermittently so that he can communicate with his family. Shortly after trach care is performed and his trach is capped by another member of the health care team, the patient's wife calls for help, stating that her husband is unable to breathe.

1. What is your first action?
2. What are some possible causes for the patient's inability to breathe? Explain how these causes affect breathing.
3. What else could you do to troubleshoot this problem?
4. What follow-up should occur?

Community-Based Care

By the time of discharge from the hospital, the patient should be able to provide self-care, which may include tracheostomy care, nutritional care, suctioning, and communication. Although education begins before surgery, most self-care is taught in the hospital. Teach the patient and family how to care for the tracheostomy tube. Review airway care, including cleaning and signs of infection. Teach clean suction technique, and review the plan of care.

Instruct the patient to use a shower shield over the tracheostomy tube when bathing to prevent water from entering the airway. Teach him or her to cover the airway loosely with a small cotton cloth to protect it during the day. Covering the permanent opening filters the air entering the stoma, keeps humidity in the airway, and enhances appearance. Attractive coverings are available as cotton scarves, decorative collars, crocheted bibs, and jewelry. Using colored seam binding for tracheostomy ties after the stoma has matured may enhance overall body image. Shirt or dress color can be matched or coordinated with seam bindings.

Teach the patient to increase humidity in the home. If it is prescribed, instruct him or her to instill normal saline into the artificial airway 10 to 15 times a day. Tell him or her to continue using the method of communication that began in the hospital and to wear a medical alert bracelet that identifies the inability to speak.

The health care team assesses specific discharge needs and makes referrals to home care agencies and durable medical equipment companies (for suction equipment and tracheostomy supplies). Follow-up visits occur early after discharge, but the home care nurse also is an important resource for the patient and family. This nurse initiates and coordinates the services of dietitians, nurses, speech pathologists, and social workers, as prescribed, and informs the patient and family of community resources that can offer support and friendship.

CONSIDERATIONS FOR OLDER ADULTS

Self-managing tracheostomy care and oxygen therapy can be difficult for the older patient who has vision problems or difficulty with upper arm movement. Teach him or her to use magnifying lenses or glasses to ensure the proper setting on the oxygen gauge. Assess his or her ability to reach and manipulate the tracheostomy. If possible, work with a family member who can provide assistance during tracheostomy care.

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing inadequate oxygenation and tissue perfusion as a result of respiratory problems?

- Respirations rapid and shallow
- Respirations noisy
- Cannot speak more than 4 or 5 words without pausing for breath
- Change in cognition, acute confusion
- Decreased oxygen saturation by pulse oximetry
- Skin cyanosis or pallor (in lighter-skinned patients)
- Cyanosis or pallor of the lips and oral mucous membranes (in patients of any skin color)
- Tachycardia
- Patient appears to strain to catch breath
- Fatigue

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate oxygenation and tissue perfusion as a result of a respiratory problem?

Perform and interpret physical assessment, including:

- Taking vital signs
- Auscultating all lung fields
- Monitoring oxygen saturation by pulse oximetry
- Checking the accuracy of pulse oximetry readings
- Checking most recent laboratory values for hematocrit, hemoglobin, and ABG levels
- Assessing cognition (Mini-Mental State Examination [MMSE])
- Assessing for the use of accessory muscles
- Assessing for the presence of thick or excessive secretions
- Assessing the patient's ability to cough and clear the airway

Respond by:

- Applying oxygen and assessing the patient's responses to this intervention
- Keeping the patient's head elevated to about 30 degrees
- Suctioning (oral, pharyngeal, endotracheal, tracheostomy), if needed

NURSING CONCEPT REVIEW—cont'd

- Notifying the physician or Rapid Response Team
- Prioritizing and pacing activities to prevent fatigue

On what should you REFLECT?

- Observe the patient for evidence of restored oxygenation (see [Chapter 29](#)).
- Think about what may have precipitated this episode and what steps could be taken to either prevent a similar episode or identify it earlier.
- Think about what additional resources could improve the nursing response to this situation.

GET READY FOR THE NCLEX® EXAMINATION!**KEY POINTS**

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use sterile technique when performing endotracheal or tracheal suctioning.
- Inspect the oral mucous membranes each shift for anyone who has an endotracheal tube.
- Keep a tracheostomy tube (and obturator) and tracheostomy insertion tray at the bedside for the first 72 hours after a tracheostomy has been performed.
- Never use oral suctioning equipment to suction an artificial airway.
- Use aspiration precautions for any patient with an altered level of consciousness or who has an endotracheal tube (see [Chart 30-5](#)).

Health Promotion and Maintenance

- Monitor the rate and depth of respiration at least every hour for any patient with hypercarbia and CO₂ narcosis who is receiving oxygen by mask or nasal cannula.
- Teach the patient and family how to perform tracheostomy care (see [Chart 30-3](#)).

Psychosocial Integrity

- Provide opportunity for the patient and family to express concerns about a change in breathing status or the possibility of intubation and mechanical ventilation.

- Teach family members ways to communicate with a patient who is intubated or being mechanically ventilated.
- Reassure patients who are intubated that the loss of speech is temporary.
- Encourage patients with permanent tracheostomies to become involved in self-care.

Physiological Integrity

- Apply oxygen to anyone who is hypoxemic.
- Ensure that oxygen therapy delivered to the patient is humidified appropriately.
- Monitor arterial blood gases (ABGs) and oxygen saturation of all patients receiving oxygen therapy.
- Assess the skin under the mask and under the plastic tubing every shift for patients receiving oxygen by mask.
- Assess the skin of the nares and under the elastic band every shift for patients receiving oxygen by nasal cannula.
- Observe any patient receiving oxygen at greater than a 50% concentration for early symptoms of oxygen toxicity (i.e., dyspnea, nonproductive cough, chest pain, GI upset).
- Use a manual resuscitation bag to ventilate the patient if the tracheostomy tube has dislodged or become decannulated.
- Assess the new tracheostomy stoma site at least once per shift for purulent drainage, redness, pain, and swelling as indicators of infection.
- Keep the tracheal cuff pressure between 14 and 20 mm Hg to prevent tissue injury.

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Supervise care delegated to licensed practical nurses/ licensed vocational nurses (LPNs/LVNs) or nursing assistants to patients who have risk factors for airway obstruction.
2. Act as a patient advocate for patients receiving oxygen or who have tracheostomies.

Health Promotion and Maintenance

3. Assess the patient for risk factors for head and neck cancer.
4. Teach people how to avoid common risk factors for head and neck cancer.

Psychosocial Integrity

5. Support the patient and family in coping with changes in breathing status and the need for a laryngectomy.
6. Use an appropriate nonverbal form of communication for a patient with a laryngectomy.

Physiological Integrity

7. Perform a focused upper respiratory assessment and re-assessment to determine adequacy of oxygenation and tissue perfusion.

8. Prioritize nursing care needs of a patient after a nasoseptoplasty.
9. Recognize manifestations and care needs of a patient with an anterior nosebleed and of a patient with a posterior nosebleed.
10. Prioritize nursing care needs of a patient with facial trauma.
11. Describe the pathophysiology and the potential complications of sleep apnea.
12. Apply knowledge of anatomy to prevent aspiration in a patient with a tracheostomy.
13. Explain the techniques for wound care and laryngectomy care.
14. Use correct technique to suction via a tracheostomy or laryngectomy tube.
15. Teach the patient and family about home management of a laryngectomy stoma or tracheostomy.

The nose, sinuses, oropharynx, larynx, and trachea are the upper airway structures. They are important for *oxygenation* and *tissue perfusion* by providing the entrance site for air. Problems of the upper airways, especially the larynx and trachea, can interfere with oxygen delivery. The upper airway structures may have specific health problems

and also may be affected by other common acute and chronic disorders. Patients with upper respiratory problems are found in the community and many health care settings. *The major nursing priority with disorders of the upper respiratory tract is to promote oxygenation by ensuring a patent airway.*

DISORDERS OF THE NOSE AND SINUSES

FRACTURE OF THE NOSE

Pathophysiology

Nasal fractures often result from injuries received during falls, sports activities, car crashes, or physical assaults. If the bone or cartilage is not displaced, serious complications usually do not result from the fracture and treatment may not be needed. Displacement of either the bone or cartilage, however, can cause airway obstruction or cosmetic deformity and is a potential source of infection.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Document any nasal problem, including deviation, malaligned nasal bridge, a change in nasal breathing, crackling of the skin (*crepitus*) on palpation, bruising, and pain. Blood or clear fluid (cerebrospinal fluid [CSF]) rarely drains from one or both nares as a result of a simple nasal fracture and, if present, indicates a more serious injury (e.g., skull fracture). CSF can be differentiated from normal nasal secretions because CSF contains glucose that will test positive with a dipstick. When CSF dries on a piece of filter paper, a yellow “halo” appears as a ring at the dried edge of the fluid. X-rays are not always useful in the diagnosis of simple nasal fractures.

INTERVENTIONS

The health care provider performs a simple **closed reduction** (manipulation of the bones by palpation to position them in proper alignment) of the nasal fracture using local or general anesthesia within the first 24 hours after injury. After 24 hours, the fracture is more difficult to reduce because of edema and scar formation. Then reduction may be delayed for several days until edema is gone. Simple closed fractures may not need surgical intervention. Management focuses on pain relief and cold compresses to decrease swelling.

Rhinoplasty

Reduction and surgery may be needed for severe fractures or for those that do not heal properly. **Rhinoplasty** is a surgical reconstruction of the nose. It can be performed to repair a fractured nose and also is a common plastic surgery procedure to change the shape of the nose. The patient returns from surgery with packing in both nostrils; this packing prevents bleeding and provides support for the reconstructed nose. The gauze packing is treated with an antibiotic to reduce the risk for infection. A “moustache” dressing (or drip pad), often a folded 2 × 2 gauze pad, is usually placed under the nose (Fig. 31-1). A splint or cast may cover the nose for better alignment and protection. The nurse or patient changes the drip pad as necessary.

After surgery, observe for edema and bleeding. Check vital signs every 4 hours until the patient is discharged. The patient with uncomplicated rhinoplasty is discharged the day of surgery. Instruct him or her and the family about the routine care described below.

Instruct the patient to stay in a semi-Fowler’s position and to move slowly. Teach him or her to rest and use cool

FIG. 31-1 Immediate postoperative appearance of a patient who has undergone rhinoplasty. Note the splint and gauze drip pad (moustache dressing).

! NURSING SAFETY PRIORITY

Action Alert

Assessing how often the patient swallows after nasal surgery is a priority because repeated swallowing may indicate posterior nasal bleeding. Use a penlight to examine the throat for bleeding, and notify the surgeon if bleeding is present.

compresses on the nose, eyes, and face to help reduce swelling and bruising. If a general anesthetic was used, the patient may eat soft foods once he or she is alert and the gag reflex has returned. Urge the patient to drink at least 2500 mL/day.

To prevent bleeding, teach the patient to limit Valsalva maneuvers (e.g., forceful coughing or straining during a bowel movement), not to sniff upward or blow the nose, and not to sneeze with the mouth closed for the first few days after the packing is removed. Laxatives or stool softeners may be prescribed to ease bowel movement. Instruct the patient to avoid aspirin and other NSAIDs to prevent bleeding. Antibiotics may be prescribed to prevent infection. Recommend the use of a humidifier to prevent drying of the mucosa. Explain that edema and bruising last for weeks and that the final surgical result will be evident in 6 to 12 months.

Nasoseptoplasty

Nasoseptoplasty, or **submucous resection (SMR)**, may be needed to straighten a deviated septum when chronic symptoms (e.g., “stuffy” nose, snoring, sinusitis) or discomfort occurs. Most adults have a slight nasal septum deviation with no symptoms. Major deviations, however, may obstruct the nasal passages or interfere with airflow and sinus drainage. The deviated section of the cartilage and bone is removed as an ambulatory surgical procedure. The amount resected depends on the deformity. Newer surgical procedures for a severely deviated septum include actual removal of part of the septal cartilage. The cartilage is then straightened separate from the body (extracorporeal) and then replaced into the nose along with sutures and struts for maintaining shape and position (Jang & Kwon, 2010). Nursing care is similar to that for a rhinoplasty.

EPISTAXIS

Pathophysiology

Epistaxis (nosebleed) is a common problem because of the many capillaries within the nose. Nosebleeds occur as a result of trauma, hypertension, blood dyscrasia (e.g., leukemia), inflammation, tumor, decreased humidity, nose blowing, nose picking, chronic cocaine use, and procedures such as nasogastric suctioning. Men usually are affected more often than women. Older adults tend to bleed most often from the posterior portion of the nose.

PATIENT-CENTERED COLLABORATIVE CARE

The patient often reports that the bleeding started after sneezing or blowing the nose. Document the amount and color of the blood, and take the vital signs. Ask the patient about the number, duration, and causes of previous bleeding episodes. Record this information in the patient's medical record.

Chart 31-1 lists the best practices for emergency care of the patient with a nosebleed. An additional intervention for

CHART 31-1 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Emergency Care of a Patient with an Anterior Nosebleed

- Maintain Standard Precautions or Body Substance Precautions.
- Position the patient upright and leaning forward to prevent blood from entering the stomach and possible aspiration.
- Reassure the patient and attempt to keep him or her quiet to reduce anxiety and blood pressure.
- Apply direct lateral pressure to the nose for 10 minutes, and apply ice or cool compresses to the nose and face if possible.
- If nasal packing is necessary, loosely pack both nares with gauze or nasal tampons.
- To prevent rebleeding from dislodging clots, instruct the patient to not blow the nose for 24 hours after the bleeding stops.
- Seek medical assistance if these measures are ineffective or if the bleeding occurs frequently.

use at home or in the emergency department is a special nasal plug that contains an agent to promote blood clotting (sold by HemCon). The plug expands on contact with blood and compresses mucosal blood vessels. This device can be removed in an hour.

Medical attention is needed if the nosebleed does not respond to these interventions. In such cases, the affected capillaries may be cauterized with silver nitrate or electrocautery and the nose packed. Anterior packing controls bleeding from the anterior nasal cavity.

Posterior nasal bleeding is an emergency because it cannot be easily reached and the patient may lose a lot of blood quickly. Posterior packing, epistaxis catheters (nasal pressure tubes), or a gel tampon are used to stop bleeding that originates in the posterior nasal region. With packing, the health care provider positions a large gauze pack in the posterior nasal cavity above the throat, threads the attached string through the nose, and tapes it to the patient's cheek to prevent pack movement. Epistaxis catheters look like very short (about 6 inches) urinary catheters (Fig. 31-2, A). These tubes have an exterior balloon along the tube length in addition to an anchoring balloon on the end. The tubes are inserted into both nares. The anchoring balloon is inflated first to keep the tubes in place. Then the pressure balloons are inflated carefully for both tubes at the same time to compress bleeding vessels (Fig. 31-2, B). Placement of posterior packing or pressure tubes is uncomfortable, and the airway may be obstructed if the pack slips. Most patients who have posterior nasal bleeding are hospitalized (Rushing, 2009).

Observe the patient for respiratory distress and for tolerance of the packing or tubes. Humidity, oxygen, bedrest, and antibiotics may be prescribed. Opioid drugs may be prescribed for pain. Assess patients receiving opioids at least hourly for gag and cough reflexes. Oral care and hydration are important because of mouth breathing. Use pulse oximetry to monitor for hypoxemia. The tubes or packing is usually removed after 1 to 3 days.

After the tubes or packing is removed, teach the patient and family the following interventions to use at home for comfort and safety. Petroleum jelly can be applied to the nares for lubrication and comfort. Nasal saline sprays and humidification add moisture and prevent rebleeding. Instruct the

FIG. 31-2 A, The Ultra-Stat epistaxis catheter. B, Patient with epistaxis catheters in place to control a posterior nasal bleed.

patient to avoid vigorous nose blowing, the use of aspirin or other NSAIDs, and strenuous activities such as heavy lifting for at least 1 month (Rushing, 2009).

NASAL POLYPS

Nasal polyps are benign, grapelike clusters of mucous membrane and connective tissue. They often occur bilaterally and are caused by irritation to the nasal mucosa or sinuses, allergies, or infection (chronic sinusitis). Large polyps may obstruct the airway. Manifestations include obstructed nasal breathing, increased nasal discharge, and a change in voice quality.

Benign nasal polyps are managed with nasally inhaled steroids followed by surgical removal (**polypectomy**), with standard or laser surgery, performed under local or general anesthesia. Observe the patient for bleeding after surgery. The nostrils are usually packed with gauze for 24 hours after surgery. Polyps often recur after treatment.

CANCER OF THE NOSE AND SINUSES

Tumors of the nasal cavities and sinuses are rare and may be either benign or malignant. Malignant tumors can occur at all ages, but the peak incidence is 40 to 45 years of age in men and 60 to 65 years of age in women. Asian Americans have a higher incidence of nasopharyngeal cancer. This type of cancer is more common among people with chronic exposure to wood dusts, dusts from textiles, leather dusts, flour, nickel and chromium dust, mustard gas, and radium. Cigarette smoking along with these exposures increases the risk (American Cancer Society [ACS], 2011).

The onset of sinus cancer is slow, and manifestations resemble sinusitis. Thus the patient may have advanced disease at diagnosis. Manifestations of nasal or sinus cancer include persistent nasal obstruction, drainage, bloody discharge, and pain that persists after treatment of sinusitis. Lymph node enlargement often occurs on the side with tumor mass. Tumor location is identified with x-ray, computed tomography (CT), or magnetic resonance imaging (MRI). A biopsy is performed to confirm the diagnosis.

Surgical removal of all or part of the tumor is the main treatment for nasopharyngeal cancers. It is usually combined with radiation therapy, especially intensity modulated radiation therapy (IMRT). This type of radiation breaks up the single beam into thousands of smaller beams that allow better focus on the tumor (see Chapter 24). The specific surgery depends on tumor size, location, and degree of invasion. Problems after surgery include a change in body image or speech and altered nutrition. These problems are most common when the maxilla and floor of the nose are involved in the surgery. Patients often also have changes in taste and smell.

Provide general postoperative care (see Chapter 18), including maintaining a patent airway, monitoring for hemorrhage, providing wound care, assessing nutritional status, and performing tracheostomy care (if needed). (See Chapter 30 for tracheostomy care.) Perform careful mouth and sinus cavity care with saline irrigations using an electronic irrigation system (e.g., Waterpik, Sonicare) or a syringe. Assess the patient for pain and infection. Good nutrition is essential after surgery to promote healing. Collaborate with the

dietitian to help the patient make food selections that promote healing.

Chemotherapy may be used in conjunction with surgery and radiation for some tumors. The most commonly used agents for cancer of the nose and sinuses include carboplatin, cisplatin, 5-fluorouracil, docetaxel, and paclitaxel, although other drugs may be used depending on the features of the tumor. Chapter 24 discusses care of the patient undergoing chemotherapy.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

A client who works in a furniture factory reports that he is worried about his health because two co-workers have been diagnosed with sinus cancer in the past year. Which suggestion does the nurse make to reduce this client's risk for sinus cancer?

- A. Avoid the use of over-the-counter nasal sprays.
- B. Wear a fine particulate mask when working with wood.
- C. Spend as much time as possible outdoors, away from cities.
- D. Wear gloves when working with paint thinners and liquid glue.

FACIAL TRAUMA

Pathophysiology

Facial trauma is described by the specific bones (e.g., mandibular, maxillary, orbital, nasal fractures) and the side of the face involved. Mandibular (lower jaw) fractures can occur at any point on the jaw and are common facial fractures. *Le Fort I* is a nasoethmoid complex fracture. *Le Fort II* is a maxillary and nasoethmoid complex fracture. *Le Fort III* combines I and II plus an orbital-zygoma fracture, called “craniofacial disjunction” because the midface has no connection to the skull. The rich facial blood supply allows extensive bleeding and bruising.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The priority action to take for a patient with facial trauma is *airway assessment*. Manifestations of airway obstruction include stridor, shortness of breath, dyspnea, anxiety, restlessness, hypoxia, **hypercarbia** (elevated blood levels of carbon dioxide), decreased oxygen saturation, cyanosis, and loss of consciousness. After establishing the airway, assess the site of trauma for bleeding and possible fractures. Check for soft-tissue edema, facial asymmetry, pain, or leakage of spinal fluid through the ears or nose, indicating a temporal bone or basilar skull fracture. Assess vision and eye movement because orbital and maxillary fractures can entrap the eye. Check behind the ears (mastoid area) for extensive bruising, known as the “battle sign.” Because facial trauma can occur with spinal trauma and skull fractures, cranial computed tomography, facial series, and cervical spine x-rays are obtained.

INTERVENTIONS

The priority action is to establish and maintain a patent airway. Anticipate the need for emergency intubation, **tracheotomy** (surgical incision into the trachea to create an airway), or **cricothyroidotomy** (creation of a temporary airway by

making a small opening in the throat between the thyroid cartilage and the cricoid cartilage). Upon patient arrival, care focuses on establishing an airway, controlling hemorrhage, and assessing for the extent of injury. If shock is present, fluid resuscitation and identification of bleeding sites are started immediately.

Time is critical in stabilizing the patient who has head and neck trauma. Early response and treatment by special services (e.g., trauma team, maxillofacial surgeon, general surgeon, otolaryngologist, plastic surgeon, dentist) optimize the patient's recovery.

Stabilizing the fractured segment of a jaw fracture allows the teeth to heal in proper alignment. This process involves **fixed occlusion** (wiring the jaws together in the mouth closed position). The patient remains in fixed occlusion for 6 to 10 weeks. Antibiotic therapy may be prescribed because of oral wound contamination. Treatment delay, tooth infection, or poor oral care may cause mandibular bone infection, which may require surgical **débridement** (removal of dead tissue), IV antibiotic therapy, and a longer period with the jaws in a fixed position.

More extensive jaw fractures may require open reduction with internal fixation (ORIF) procedures. Compression plates and reconstruction plates with screws may be applied. Plates may be made of stainless steel, titanium, or Vitallium. If the mandibular fracture is repaired with titanium plates, teach the patient about oral care, soft-diet restrictions, and follow-up care with a dentist. These plates are permanent and do not interfere with MRI studies.

Facial fractures may be repaired with microplating surgical systems that involve bone substitutes (e.g., BoneSource). These shaping plates hold the bone fragments in place until new bone growth occurs. Bone cells grow into the bone substitute and re-matrix into a stable bone support. The plates may remain in place permanently or may be removed after healing.

Fixation methods may use resorbable devices (plates and screws) to hold tissues in place. These devices are made from a plastic-like material that retains its integrity for about 8 weeks and then slowly biodegrades. Resorbable devices are not used when the area has previously been irradiated or for patients who smoke or who have drug or alcohol dependence, uncontrolled diabetes mellitus, immunosuppression, or impaired cardiac function, all of which impair healing.

Inner maxillary fixation (IMF) is another method of securing a mandibular fracture. The bones are realigned and then wired in place with the bite closed. Nondisplaced aligned fractures can be repaired in a clinic or office using local dental anesthesia. General anesthesia is used to repair displaced or complex fractures or fractures that occur with other facial bone fractures.

After surgery, teach the patient about oral care with an irrigating device, such as a Waterpik or Sonicare. If the patient has inner maxillary fixation, teach self-management with wires in place, including a dental liquid diet. If the patient vomits, watch for aspiration because of the patient's inability to open the jaws to allow ejection of the emesis. Teach him or her how to cut the wires if emesis occurs. *Instruct the patient to keep wire cutters with him or her at all times in case this emergency arises.* If the wires are cut, instruct him or her to return to the surgeon for rewiring as soon as possible to reinstitute fixation.

Nutrition is important and difficult for a patient with fractures because of oral fixation, pain, and surgery. Collaborate with the dietitian for patient teaching and support.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

Which nursing action has the highest priority when caring for a client with facial trauma?

- A. Managing pain
- B. Providing nutrition
- C. Assessing self-image
- D. Maintaining a patent airway

OBSTRUCTIVE SLEEP APNEA

Pathophysiology

Sleep apnea is a breathing disruption during sleep that lasts at least 10 seconds and occurs a minimum of 5 times in an hour. Although sleep apnea can have a neurologic origin, the most common form occurs as a result of upper airway obstruction by the soft palate or tongue. Factors that contribute to sleep apnea include obesity, a large uvula, a short neck, smoking, enlarged tonsils or adenoids, and oropharyngeal edema (Berry, 2008). Men are affected more often than women, and the risk increases with age (Townsend-Roccichelli et al., 2010).

During sleep, the muscles relax and the tongue and neck structures are displaced. As a result, the upper airway is obstructed but chest movement is unimpaired. The apnea increases blood carbon dioxide levels and decreases the pH. These blood gas changes stimulate neural centers. The sleeper awakens after 10 seconds or longer of apnea and corrects the obstruction, and respiration resumes. After he or she goes back to sleep, the cycle begins again, sometimes as often as every 5 minutes (Berry, 2008).

This cyclic pattern of disrupted sleep prevents the deep sleep needed for best rest. Thus the person may have excessive daytime sleepiness, an inability to concentrate, and irritability.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Patients are often unaware that they have sleep apnea. The disorder should be suspected for any person who has persistent daytime sleepiness or reports "waking up tired," particularly if he or she also snores heavily. Other manifestations include irritability and personality changes. Sleep apnea may be verified by family members who observe the problem when the person sleeps on his or her back. A complete health assessment should be performed when excessive daytime sleepiness is a problem.

The most accurate test for sleep apnea is polysomnography (PSG) performed during an overnight sleep study. The patient is directly observed while wearing a variety of monitoring equipment, including an electroencephalograph (EEG), an electrocardiograph (ECG), a pulse oximeter, and an electromyograph (EMG). This test determines the depth

of sleep, type of sleep, respiratory effort, oxygen saturation, and muscle movement.

INTERVENTIONS

A change in sleeping position or weight loss may reduce or correct mild sleep apnea. Position-fixing devices may prevent subluxation of the tongue and neck structures and reduce obstruction. Severe sleep apnea requires nonsurgical or surgical methods to prevent obstruction.

A common method to prevent airway collapse is the use of noninvasive, positive-pressure ventilation (NPPV) to hold open the upper airways. A nasal mask or full-face mask delivery system allows mechanical delivery of either bi-level positive airway pressure (BiPAP), autotitrating positive airway pressure (APAP), or nasal continuous positive airway pressure (CPAP). With BiPAP, a machine delivers a set inspiratory positive airway pressure at the beginning of each breath. As the patient begins to exhale, the machine delivers a lower end expiratory pressure. These two pressures hold open the upper airways. With APAP, the machine adjusts continuously, resetting the pressure throughout the breathing cycle to meet the patient's needs. Nasal CPAP delivers a set positive airway pressure continuously during each cycle of inhalation and exhalation. For any positive-pressure ventilation through a facemask during sleep, a small electric compressor is required. Proper fit of the mask over the nose and mouth or just over the nose is key to successful treatment (see Fig. 30-9 in Chapter 30). Although noisy, these methods are accepted by most patients after an adjustment period.

One drug has been approved to help manage the daytime sleepiness associated with sleep apnea. Modafinil (Attenace, Provigil) is helpful for patients who have *narcolepsy* (uncontrolled daytime sleep) from sleep apnea by promoting daytime wakefulness. This action does *not* treat the cause of sleep apnea.

Surgical intervention may involve a simple adenoidectomy, uvulectomy, or remodeling of the entire posterior oropharynx (uvulopalatopharyngoplasty [UPP]). Both conventional and laser surgeries are used for this purpose (Robinson et al., 2009). A tracheostomy may be needed for very severe sleep apnea that is not relieved by more moderate interventions.

DISORDERS OF THE LARYNX

VOCAL CORD PARALYSIS

Vocal fold (cord) paralysis may result from injury, trauma, or diseases that affect the larynx, laryngeal nerves, or vagus nerve. Prolonged intubation with an endotracheal (ET) tube may cause temporary or permanent paralysis. Paralysis may occur in patients with neurologic disorders. Damage to the vagus nerve (by chest injury), brain, or brainstem may lead to nerve dysfunction. The laryngeal nerves may be damaged from trauma or disorders that involve the chest, esophagus, or thyroid. Paralysis of both vocal cords may result from direct injury, stroke involving the brainstem, or total thyroidectomy.

Vocal fold paralysis may affect both cords or only one. When only one vocal cord is involved (most common), the airway remains patent but the voice is affected.

Manifestations of open bilateral vocal cord paralysis include hoarseness; a breathy, weak voice; and aspiration of food. *Bilateral closed vocal cord paralysis causes airway obstruction and is an emergency if the symptoms are severe and the patient cannot compensate. Stridor is the major manifestation.*

Securing an airway is the main intervention. Place the patient in a high-Fowler's position to aid in breathing and proper alignment of airway structures. Assess for airway obstruction.

! NURSING SAFETY PRIORITY

Critical Rescue

Immediately notify the Rapid Response Team if dyspnea with stridor occurs. Emergency endotracheal intubation or tracheostomy may be needed.

Various surgical procedures can improve the voice. One simple procedure for open vocal cord paresis involves injecting polytetrafluoroethylene (Teflon) into the affected cord so it enlarges toward the unaffected cord. This technique improves closure during speaking and eating.

The patient with open cord paralysis is at risk for aspiration because the airway is open during swallowing. Teach him or her to hold the breath during swallowing to allow the larynx to rise, close, and push food back into the esophagus. Teach the patient to tuck the chin down and tilt the forehead forward during swallowing. Indications of aspiration include immediate coughing on swallowing of liquids or solids, a “wet”-sounding voice, and “tearing up” or watery eyes on swallowing. Chest x-rays are used to diagnose aspiration pneumonia.

VOCAL CORD NODULES AND POLYPS

Nodules are enlarged, fibrous tissues caused by infectious processes or overuse of the voice. They often occur where the vocal cords touch during speech. People most affected are those who often speak loudly, such as teachers, coaches, sports fans, and singers.

Polyps are edematous masses that occur most often in smokers and people with allergies. Vocal cysts also may occur. Nodules and polyps are painless. The main manifestation is painless hoarseness because of the loss of coordinated vocal cord closure (Fig. 31-3).

Management of cord nodules or polyps focuses on patient education. Instruct the patient about smoking cessation and the importance of voice rest. Treatment includes not speaking, especially not whispering, and avoiding heavy lifting. Stool softeners are used to avoid bearing down during elimination, which closes the glottis. Humidifying the air soothes the cords and prevents overdrying. Speech and language therapy is used to help the patient learn to reduce speech intensity and may make surgery unnecessary.

If hoarseness is not relieved by voice rest or speech and language therapy, the surgeon may remove the nodules or polyps using laryngoscopy. Laser and surgical resection are used to remove the membrane of the affected cord. If both cords are involved, one cord is usually allowed to heal before the other cord is resected. Before these ambulatory surgical procedures, teach the patient about the care techniques needed for after surgery.

FIG. 31-3 **A**, Close-up view of normal vocal cords in phonation. **B**, Vocal cord nodules and polyps prevent approximation of the vocal cords. Hoarseness results.

After surgery, the patient must maintain complete voice rest for about 14 days to promote healing. [Chart 31-2](#) lists methods for nonverbal communication. Teach about alternative methods of communication such as a slate, picture board, pen and paper, alphabet board, or programmable speech-generating device ([Rodriguez & Rowe, 2010](#)). Place a sign on the patient's door, over the bed, and on the intercom system to help implement voice rest.

LARYNGEAL TRAUMA

Laryngeal trauma occurs with a crushing or direct blow injury, fracture, or injury induced by prolonged endotracheal intubation. Manifestations include difficulty breathing (**dyspnea**), inability to produce sound (**aphonia**), hoarseness, and **subcutaneous emphysema** (air present in the subcutaneous tissue). Bleeding from the airway (**hemoptysis**) may occur, depending on the location of the trauma. The health care provider performs a direct visual examination of the larynx by laryngoscopy or fiberoptic laryngoscopy to determine the extent of the injury.

Management of patients with laryngeal injuries consists of assessing the airway and monitoring vital signs (including respiratory status and pulse oximetry) every 15 to 30 minutes. *Maintaining a patent airway is a priority.* Apply oxygen and humidification as prescribed to maintain adequate oxygen saturation. Manifestations of respiratory difficulty include tachypnea, nasal flaring, anxiety, sternal retraction, shortness of breath, restlessness, decreased oxygen saturation, decreased level of consciousness, and stridor.

! NURSING SAFETY PRIORITY

Critical Rescue

If the patient has respiratory difficulty, stay with him or her and instruct other trauma team members or the Rapid Response Team to prepare for an emergency intubation or tracheotomy.

Surgical intervention is needed for lacerations of the mucous membranes, cartilage exposure, and cord paralysis. Laryngeal repair is performed as soon as possible to prevent laryngeal stenosis and to cover any exposed cartilage. An artificial airway may be needed.

OTHER UPPER AIRWAY DISORDERS

UPPER AIRWAY OBSTRUCTION

Pathophysiology

Upper airway obstruction is a life-threatening emergency in which airflow is interrupted through the nose, mouth, pharynx, or larynx. Early recognition is essential to prevent complications, including respiratory arrest. Causes of upper airway obstruction include:

- Tongue edema (surgery, trauma, angioedema as an allergic response to a drug)
- Tongue occlusion (e.g., loss of gag reflex, loss of muscle tone, unconsciousness, coma)
- Laryngeal edema
- Peritonsillar and pharyngeal abscess
- Head and neck cancer
- Thick secretions
- Stroke and cerebral edema
- Smoke inhalation edema
- Facial, tracheal, or laryngeal trauma
- Foreign-body aspiration
- Burns of the head or neck area
- Anaphylaxis

One preventable cause of airway obstruction leading to asphyxiation is inspissated oral and nasopharyngeal secretions ([Prahlow et al., 2009](#)). In this condition, poor oral hygiene leads to thickening and hardening of secretions that can completely block the airway and lead to death. Proper assessment and nursing care can eliminate this cause of airway obstruction. Patients at highest risk are nursing home residents who have an altered mental status and level of consciousness, are dehydrated, are unable to communicate, are unable to cough effectively, or have any other risk factors for aspiration.

! NURSING SAFETY PRIORITY

Action Alert

Assess the oral care needs of the patient with risk factors for inspissated secretions daily. Ensure that whoever provides oral care understands the importance and the correct techniques for preventing secretion buildup and airway obstruction.

CHART 31-2 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Communicating with a Patient Who Is Unable to Speak

- Assess the patient's reading skills and cognition.
- Determine in what language (languages) the patient is most fluent.
- Collaborate with a speech and language pathologist.
- If the patient requires vision-enhancing devices or hearing-enhancing devices, be sure these are available and in use.
- Provide the patient with a variety of techniques to practice before verbal skills are lost to determine with which one(s) the patient feels most comfortable. These may include:
 - Alphabet board
 - Picture board
 - Paper and pencil
 - Magic Slate
 - Hand signals/gestures
 - Computer with e-triloquist program
 - Programmable speech-generating devices (text-to-speech communication aid)
- Reinforce to the patient the technique for esophageal speech presented by the speech and language pathologist, and provide the time for practice.
- Use a normal tone of voice to talk with the patient (unless hearing is a pre-existing problem, a change in the ability to speak does not interfere with the patient's ability to hear).
- Ensure that the call-light board at the nurses' station indicates a non-speaking patient.
- Teach the patient to make noise to indicate immediate attention is needed at the bedside when he or she signals by call light. Such noises can include tapping the siderail with a spoon, making clicking noises with the tongue, using a bell, or working a noisemaker. Be sure that whatever method is selected is listed on the call-light board.
- When face-to-face with the patient:
 - Phrase questions in a "yes" or "no" format.
 - Watch the patient's face for indications of understanding or the lack of it.
 - Listen attentively to any sound the patient makes.
- If writing is selected as the method to communicate, assess whether the patient is right-handed or left-handed and ensure appropriate writing materials are within reach. Use the other arm for IV placement.
- Ensure the preferred method of communication is documented in the patient record and is communicated to all care providers.
- Encourage the family to work with the patient in the use of the selected method.
- Provide praise and encouragement.
- Do not avoid talking with the patient.
- Allow the patient to set the pace for communication.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Airway obstruction is frightening, and prompt care is essential to prevent a partial obstruction from progressing to a complete obstruction. Partial obstruction produces subtle or general manifestations such as diaphoresis, tachycardia, and elevated blood pressure. Persistent or unexplained symptoms must be evaluated even though the symptoms are vague. Diagnostic procedures include chest or neck x-rays, laryngoscopic examination, and computed tomography.

Observe for hypoxia and hypercarbia, restlessness, increasing anxiety, sternal retractions, a "seesawing" chest,

abdominal movements, or a feeling of impending doom related to actual air hunger. Use pulse oximetry for ongoing monitoring of oxygen saturation. Continually assess for stridor, cyanosis, and changes in level of consciousness.

INTERVENTIONS

Assess for the cause of the obstruction. When the obstruction is due to the tongue falling back or excessive secretions, slightly extend the patient's head and neck and insert a nasal or an oral airway. Suction to remove obstructing secretions. If the obstruction is caused by a foreign body, perform abdominal thrusts (Fig. 31-4).

Upper airway obstruction may require emergency procedures such as cricothyroidotomy, endotracheal intubation, or tracheotomy. Direct laryngoscopy may be performed before or with these procedures to determine the cause of obstruction or to remove foreign bodies.

Cricothyroidotomy is an emergency procedure often performed outside the hospital by emergency medical personnel. A **cricothyroidotomy** is a stab wound at the cricothyroid membrane between the thyroid cartilage and the cricoid cartilage (see Fig. 29-4). Any hollow tube—but preferably a tracheostomy tube—can be placed through the opening to hold this airway open until a tracheotomy can be performed. This procedure is used when it is the *only* way to secure an airway. Another emergency procedure to bypass an obstruction is the insertion of a 14-gauge needle directly into the cricoid space to allow air flow into and out of the lungs.

Endotracheal intubation is performed by inserting a tube into the trachea via the nose (**nasotracheal**) or mouth (**orotracheal**) by a physician, anesthesia provider, or other specially trained personnel.

Tracheotomy is a surgical procedure and takes about 5 to 10 minutes to perform. It is best performed in the operating room (OR) with the patient under local or general anesthesia but can be performed at the bedside. Local anesthesia is used if there is concern that the airway will be lost during the induction of anesthesia. A tracheotomy is reserved for the patient who cannot be easily intubated with an endotracheal tube. An emergency tracheotomy can establish an airway in less than 2 minutes. See Chapter 30 for a discussion of care of the patient with a tracheotomy.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Quality Improvement; Safety; Teamwork and Collaboration

The patient is a 42-year-old woman with a traumatic brain injury from a car crash who has been at a skilled nursing/rehabilitation center for 3 weeks. During that time, she has been unresponsive. Her family reports that the patient has very bad breath and seems to have food in her mouth (she is fed by gastrostomy tube). When you assess the patient's mouth, you find that she has many layers of thickened material on all aspects of her palate, teeth, and tongue. When you check with the nursing assistant who is assigned to her, the nursing assistant admits that she and other assistants have not been performing oral care for this patient, stating "Her mouth is so gross I would rather change her soiled diapers than brush her teeth."

1. What should you do first?
2. What should you say to the nursing assistants?
3. What potential problems could occur related to this situation?
4. What steps could be taken to either prevent a similar episode or identify it earlier?

With the conscious victim standing or sitting, place your fist between the victim's lower rib cage and navel. Wrap the palm of your hand around your fist. A quick inward, upward thrust expels the air remaining in the victim's lungs, and with it the foreign body. If the first thrust is unsuccessful, repeat several thrusts in rapid succession until the foreign body is expelled or until the victim loses consciousness.

With the unconscious victim lying supine, straddle the victim's thighs. Place one hand on top of the other as shown, with the heel of the bottom hand just above the victim's navel. Quickly thrust inward and upward, toward the victim's head.

FIG. 31-4 The abdominal thrust maneuver (formerly known as the *Heimlich maneuver*) for relief of upper airway obstruction caused by a foreign body.

Patients receiving mechanical ventilation for upper airway obstruction or respiratory failure may require a tracheostomy after 7 or more days of continuous intubation. In such cases, a tracheotomy is performed to prevent laryngeal injury by the endotracheal tube.

NECK TRAUMA

Neck injuries may be caused by a knife, gunshot, or traumatic accident. The patient with neck trauma may have more than one injury, including cardiovascular, respiratory, intestinal, and neurologic damage. The final outcome of this type of injury depends on initial assessment and care. Consult a critical care textbook and see [Chapter 47](#) for more detailed information.

The priority nursing care for a patient with neck trauma is assessing for and maintaining a patent airway. After airway patency is ensured, assess for bleeding or impending shock.

Perform a neurologic assessment for mental status, sensory level, and motor function. Injury to the carotid artery may result in death, stroke, or paralysis from disruption of blood flow to the brain (see [Chapter 43](#)). A carotid angiogram may be needed to rule out vascular injuries.

Esophagus injury may occur with neck trauma. Assess for chest pain and tenderness, oral bleeding, and **crepitus** (crackling sounds when palpating the skin). A barium or meglumine diatrizoate (Gastrografin) swallow may be needed to rule out an esophageal perforation injury.

Cervical spine injuries often occur at the same time as a neck injury (see [Chapter 45](#)). Obstruction can occur as a

result of the initial injury or from swelling after surgery to repair the injury ([Tocco, 2008](#)). Health care personnel must take great care not to make these injuries worse by causing neck movement while establishing the airway using the jaw-thrust maneuver. Prepare to assist in emergency intubation, cricothyrotomy, or tracheotomy to establish a patent airway. Interventions for patients in shock are detailed in [Chapter 39](#).

HEAD AND NECK CANCER

Pathophysiology

Head and neck cancer can disrupt breathing, eating, facial appearance, self-image, speech, and communication. This form of cancer can be devastating, even when treated successfully. The care needs for patients with these problems are complex, requiring a coordinated and comprehensive team approach. The patient can receive appropriate care only after the location and size of the tumor are accurately identified.

Head and neck cancers are usually squamous cell carcinomas and are slow growing. They are curable when treated early. The prognosis for those who have more advanced disease at diagnosis depends on the extent and location of the tumor. Untreated cancer of the head and neck is a fatal disease within 2 years of diagnosis ([ACS, 2011](#)).

The cancer begins when the mucosa is chronically irritated and becomes tougher and thicker (*squamous metaplasia*), often with a keratin layer (*keratosis*). At the same time, genes controlling cell growth are damaged, allowing excessive growth of these abnormal cells, which eventually

become malignant. These lesions may then be seen as white, patchy lesions (**leukoplakia**) or red, velvety patches (**erythroplakia**).

Head and neck cancer first spreads (**metastasizes**) into nearby structures, such as lymph nodes, muscle, and bone. Later spread is systemic to distant sites, usually to the lungs or liver.

The cancer type and stage are determined by cellular analysis. Earlier stage cancers are described as *carcinoma in situ* and *well differentiated*. Without treatment, cancers progress to be *moderately differentiated* and, finally, *poorly differentiated*. Most head and neck cancers arise from mucous membrane and skin, but they also can start from salivary glands, the thyroid, or other structures. Treatment is based on tumor cell type and degree of spread at diagnosis.

Etiology

The two most important risk factors for head and neck cancer are tobacco and alcohol use, especially in combination. Other risk factors include voice abuse, chronic laryngitis, exposure to chemicals, dusts, and poor oral hygiene. Other possible risk factors are long-term or severe gastroesophageal reflux disease (GERD) and infection with the human papilloma virus (Calloway, 2011).

Incidence/Prevalence

The frequency of head and neck carcinoma is increasing in North America. About 53,810 new cases of oral, pharyngeal, and laryngeal cancers are diagnosed each year and account for more than 13,000 deaths per year (ACS, 2011; Canadian Cancer Society, 2010). They affect men more often than women and are most common in people older than 60 years.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

The patient may have difficulty speaking because of hoarseness, shortness of breath, tumor bulk, and pain. Be sensitive to these difficulties during the interview, and pace the interview to avoid tiring the patient.

Ask about tobacco and alcohol use, history of acute or chronic laryngitis or pharyngitis, oral sores, and lumps in the neck. Calculate the patient's pack-years of smoking history (see Chapter 29). Ask about alcohol intake (how many drinks per day and for how many years). Showing concern and using a "matter-of-fact" approach during the interview may help make the patient more comfortable with these questions. Also ask about exposure to pollutants.

Assess problems related to risk factors. For example, nutrition may be poor because of alcohol intake and impaired liver function. Assess dietary habits and any weight loss. Ask about any chronic lung disease, which may have an impact on the patient's breathing pattern.

Physical Assessment/Clinical Manifestations

Table 31-1 lists the warning signs of head and neck cancer. With laryngeal cancer, painless hoarseness may occur because of tumor size and an inability for the vocal cords

TABLE 31-1 WARNING SIGNS OF HEAD AND NECK CANCER

- Pain
- Lump in the mouth, throat, or neck
- Difficulty swallowing
- Color changes in the mouth or tongue to red, white, gray, dark brown, or black
- Oral lesion or sore that does not heal in 2 weeks
- Persistent or unexplained oral bleeding
- Numbness of the mouth, lips, or face
- Change in the fit of dentures
- Burning sensation when drinking citrus juices or hot liquids
- Persistent, unilateral ear pain
- Hoarseness or change in voice quality
- Persistent or recurrent sore throat
- Shortness of breath
- Anorexia and weight loss

to come together for normal speech (**phonation**). Vocal cord lesions are the earliest form of laryngeal cancer. Any person who has a history of hoarseness, mouth sores, or a lump in the neck for 3 to 4 weeks should be evaluated for laryngeal cancer.

Inspection and palpation of the head and neck are important parts of the physical examination. An advanced practice nurse or physician may perform a laryngeal examination using a laryngeal mirror or fiberoptic laryngoscope. Lesions may be seen on inspection. The neck is palpated to assess for enlarged lymph nodes.

Psychosocial Assessment

Often the patient with head and neck cancer has a long-standing history of cigarette or alcohol use or both. Assess the adequacy of support systems and coping mechanisms. Document social and family support because the patient often needs extensive assistance at home after treatment. Collaborate with a social worker as needed. Assess the level of education or literacy of the patient and family to plan teaching before and after surgery.

Document any family history of cancer, as well as the patient's age, gender, occupation, and ability to perform ADLs. Ask the patient whether his or her occupation requires continual oral communication. Job retraining may be needed if treatment affects speech.

Laboratory Assessment

Diagnostic tests include a complete blood cell count, bleeding times, urinalysis, and blood chemistries. The patient with chronic alcoholism may have low protein and albumin levels from poor nutrition. Liver and kidney function tests are performed to rule out cancer spread and to evaluate the patient's ability to metabolize drugs and chemotherapy agents.

Imaging Assessment

Many types of imaging studies, including x-rays of the skull, sinuses, neck, and chest, are useful in diagnosing cancer spread, other tumors, and the extent of tumor invasion. Computed tomography (CT), with or without contrast media, helps evaluate the tumor's exact location. Magnetic resonance imaging (MRI) can help differentiate normal from diseased tissue.

The brain, bone, and liver are evaluated with nuclear imaging, bone scans, single-photon emission computerized tomography (SPECT) scans, and positron emission tomography (PET) scans. These tests help locate additional tumor sites.

Other Diagnostic Assessment

Other helpful tests include direct and indirect laryngoscopy, tumor mapping, and biopsy. *Panendoscopy* (laryngoscopy, nasopharyngoscopy, esophagoscopy, and bronchoscopy) is performed with general anesthesia to define the extent of the tumor. Tumor-mapping biopsies are performed to identify tumor location. Biopsy tissues taken at the time of the panendoscopy confirm the diagnosis and determine the tumor type, cell features, and location. Tumor staging by the TNM (tumor, nodes, metastasis) method (see Chapter 23) is also performed.

ANALYSIS

The priority problems for the patient with head and neck cancer are:

1. Potential for respiratory obstruction
2. Risk for Aspiration related to edema, anatomic changes, or altered protective reflexes
3. Anxiety related to threat of death, change in role status, or change in economic status
4. Reduced self-concept related to tumor and treatment modalities

PLANNING AND IMPLEMENTATION

Preventing Respiratory Obstruction

Without treatment, head and neck cancers grow to the point of airway obstruction. In addition, airway obstruction can occur as a complication of treatment modalities.

Planning: Expected Outcomes. The patient with head and neck cancer is expected to attain and maintain adequate tissue oxygenation. Indicators include:

- Arterial blood gas values within the normal range
- Rate and depth of respiration within the normal range
- Pulse oximetry within the normal range

Interventions. The focus of treatment is to remove or eradicate the cancer while preserving as much normal function as possible. The physician presents the available treatment options. Surgery, radiation, chemotherapy, or biotherapy may be used alone or in combination. In planning treatment options, the patient's physical condition, nutritional status, and age; the effects of the tumor on body function; and the patient's personal choice are all considered. Treatment for laryngeal cancer may range from radiation therapy (for a small specific area or tumor) to total laryngopharyngectomy with bilateral neck dissections followed by radiation therapy. The specific treatment depends on the extent and location of the lesion. Voice-conservation procedures are used only if they do not risk incomplete removal of the tumor. Nursing care focuses on the patient's total needs, including preoperative preparation, competent in-hospital care, discharge planning and teaching, and extensive outpatient rehabilitation.

Nonsurgical Management. Monitor the respiratory system by assessing respiratory rate, breath sounds, pulse oximetry, arterial blood gas values, and the results of pulmonary function tests. Airway obstruction can occur from tumor growth, edema, or both. Teach the patient to use the

Fowler's and semi-Fowler's positions for best air exchange. Sitting upright in a reclining chair may promote more comfortable breathing. Chapters 5 and 9 provide additional information on palliation and pain control for patients who elect not to have therapy and for those whose therapy has not been effective.

Radiation therapy for treatment of small cancers in specific locations has a cure rate of at least 80%. Standard therapy uses 5000 to 7500 rad (radiation absorbed dose), usually over 6 weeks and in daily or twice-daily doses. Radiation may be used alone or in combination with surgery and chemotherapy (see Chapter 24). Because radiation therapy slows tissue healing, it might not be performed before surgery. Most patients have hoarseness, dysphagia, skin problems, and dry mouth for a few weeks after radiation therapy.

Hoarseness may become worse during therapy. Reassure the patient that voice improves within 4 to 6 weeks after completion of radiation therapy. Urge the patient to use voice rest and alternative means of communication until the effects of radiation therapy have passed.

Most patients have a sore throat and difficulty swallowing during radiation therapy to the neck. Gargling with saline or sucking ice may decrease discomfort. Mouthwashes and throat sprays containing a local anesthetic agent such as lidocaine or diphenhydramine can provide temporary relief. Analgesic drugs may be prescribed.

The skin at the site of irradiation becomes red and tender and may peel during therapy. Instruct the patient to avoid exposing this area to sun, heat, cold, and abrasive treatments such as shaving. Teach the patient to wear protective clothing made of soft cotton and to wash this area gently with a mild soap, such as Dove. At one time, patients were told to avoid using lotions or other skin care products within 4 hours of the radiation therapy; however, this practice is not evidence-based and is now controversial (Bieck, Phillips, & Steele-Moses, 2010). Teach patients to follow the radiation-oncology department's policy regarding the use and timing of skin care products.

If the salivary glands are in the irradiation path, the mouth becomes dry (**xerostomia**). This side effect is long-term and may be permanent. Some of the problems from reduced saliva include increased risk for dental caries, increased risk for oral infections, halitosis (bad breath), and taste changes. Fluoride gel trays and nightly fluoride treatments can reduce the incidence of tooth deterioration. The trays can be worn during radiation therapy to prevent radiation scatter from the beam deflecting off existing metal inside the mouth (Lambert et al., 2010). Although there is no cure for xerostomia, interventions can help reduce the discomfort. Heavy fluid intake, particularly water, and humidification can help ease the discomfort. Some patients benefit from the use of artificial saliva, such as Salivart; moisturizing sprays or gels, such as Mouth Kote; or saliva stimulants, such as Salagen and cevimeline (cholinergic drugs).

Chemotherapy can be used alone or in addition to surgery or radiation for head and neck cancer. Often, chemotherapy and radiation therapy, *chemoradiation*, are used at the same time. Although the exact drugs used may vary, depending on cell origin, most chemotherapy regimens for head and neck cancers include cisplatin (National Comprehensive Cancer Network, 2010). The oral cavity effects of radiation are intensified with concurrent chemotherapy. These can be

uncomfortable, and patients often request breaks in the treatment regimen. However, these breaks in treatment do affect the outcome of treatment and should be avoided (a process called *NO STOPS*). Intense patient education before treatment and support during treatment can improve patient adherence to the treatment plan (Lambertz et al., 2010). Chapter 24 discusses the general care needs of patients receiving chemotherapy.

Biotherapy in the form of epidermal growth factor receptor (EGFR) blockers may be effective for patients whose cancers overexpress the receptor. Currently, the drug approved for this purpose is cetuximab (Erbix). Although it is a targeted therapy, this drug blocks EGFRs in normal tissues as well as those in the tumor. As a result, severe skin reactions are common.

NCLEX EXAMINATION CHALLENGE

Psychosocial Integrity

A client with leukoplakia just above the glottis has just received the results of a biopsy and is confirmed to have squamous cell carcinoma in situ. She begins to cry and says that she would not be able to stand a surgery that would take away her ability to speak. What is the nurse's best response?

- "Your loss of speech would only be temporary until you learned to use esophageal speech."
- "Cancers at this stage are usually treated with chemotherapy alone, which does not permanently affect your ability to speak."
- "Cancers at this stage are usually treated with radiation therapy, which does not permanently affect your ability to speak."
- "A speech and language pathologist will work with you to select the method of communication that fits your lifestyle best."

Surgical Management. Tumor size and location (TNM classification) determines the type of surgery needed for the specific head and neck cancer. Very small, early-stage tumors may be removed by laser therapy or photodynamic therapy; however, few head and neck tumors are found at this stage and most require extensive traditional surgery. Reconstruction is also determined by the tumor size and amount of tissue to be resected and reconstructed. Surgical procedures for head and neck cancers include laryngectomy (total and partial), tracheostomy, and oropharyngeal cancer resections. The major types of surgery for laryngeal cancer include cord stripping, removal of a vocal cord (**cordectomy**), partial laryngectomy, and total laryngectomy. If cancer is in the lymph nodes in the neck or if the tumor has a high rate of nodal spread, the surgeon performs a nodal neck dissection along with removal of the primary tumor ("radical neck"). A pathologist evaluates the resected lymph nodes for possible tumor invasion.

Preoperative Care. Teach the patient and family about the tumor. The surgeon explains the surgical procedure and obtains informed consent. Discuss and interpret the implications of such consent with the patient and family.

Explain about self-management of the airway, suctioning, pain control methods, the critical care environment (including ventilators and critical care routines), nutritional support, feeding tubes, and plans for discharge. The patient will need to learn new methods of speech. Help him or her prepare for this change before surgery and to practice the use of the selected form of communication (see Chart 31-2 and earlier discussion under **Vocal Cord Nodules and Polyps**, pp.

585-586). Determine the communication method most preferred by the patient.

A team approach for planning care and rehabilitation is critical for the best outcome. The team includes nurses, physicians, speech and language pathologists, social workers, dietitians, respiratory therapists, and occupational and physical therapists. These professionals help evaluate and prepare the patient who has head and neck cancer. Chapter 16 describes general preoperative assessment and education.

Operative Procedures. Table 31-2 lists specific information about the various surgical procedures for laryngeal cancer. Hemilaryngectomy (vertical or horizontal) and supraglottic laryngectomy are types of partial voice-conservation laryngectomies.

To protect the airway, a tracheostomy is needed. With a partial laryngectomy, the tracheostomy is usually temporary. With a total laryngectomy, the upper airway is separated from the throat and esophagus, and the trachea is brought out through the skin in the neck and sutured in place, creating a stoma. This airway opening (a laryngectomy stoma) is permanent.

Neck dissection includes the removal of lymph nodes, the sternocleidomastoid muscle, the jugular vein, the 11th cranial nerve, and surrounding soft tissue. Because the 11th cranial nerve (spinal accessory nerve) is cut during this procedure, shoulder drop occurs after surgery. Physical therapy can help the patient ease the shoulder drop by using other muscle groups.

Postoperative Care. Head and neck surgery often lasts 8 hours or longer. Usually the patient spends the immediate

TABLE 31-2 SURGICAL PROCEDURES FOR LARYNGEAL CANCER AND THEIR EFFECT ON VOICE QUALITY

PROCEDURE	DESCRIPTION	RESULTING VOICE QUALITY
Laser surgery	Tumor reduced or destroyed by laser beam through laryngoscope	Normal/hoarse
Transoral cordectomy	Tumor (early lesion) resected through laryngoscope	Normal/hoarse (high cure rate)
Laryngofissure	No cord removed (early lesion)	Normal (high cure rate)
Supraglottic partial laryngectomy	Hyoid bone, false cords, and epiglottis removed Neck dissection on affected side performed if nodes involved	Normal/hoarse
Hemilaryngectomy or vertical laryngectomy	One true cord, one false cord, and one half of thyroid cartilage removed	Hoarse
Total laryngectomy	Entire larynx, hyoid bone, strap muscles, one or two tracheal rings removed Nodal neck dissection if nodes involved	No natural voice

period after surgery in the surgical intensive care unit. Monitor airway patency, vital signs, hemodynamic status, and comfort level. Monitor for hemorrhage and other general complications of anesthesia and surgery (see [Chapter 18](#)). Take vital signs hourly for the first 24 hours and then every 2 hours or according to agency policy until the patient is stable. After the patient is transferred from the critical care unit, monitor vital signs every 4 hours or according to agency policy.

Complications after surgery include airway obstruction, hemorrhage, wound breakdown, and tumor recurrence. *The first priorities after head and neck surgery are airway maintenance and ventilation.* Other priorities are wound, flap, and reconstructive tissue care; pain management; nutrition; and psychological adjustment, including speech and language therapy.

Airway Maintenance and Ventilation. Immediately after surgery, the patient may need ventilatory assistance. Most patients wean easily from the ventilator after this type of surgery because the thoracic and abdominal cavities are not entered. During weaning, the patient usually uses a tracheostomy collar (over the artificial airway or open stoma) with oxygen and humidity to help move mucus secretions. Secretions may remain blood-tinged for 1 to 2 days. Use Standard Precautions, and report any increase in bleeding to the surgeon. Humidity helps remove crusts and prevents obstruction of the tube with secretions. Some surgeons prescribe instillations of 5 to 10 mL of sterile saline or sodium bicarbonate into the airway every 2 hours; however, this practice is controversial and not evidence-based.

A laryngectomy tube is used for patients who have undergone a *total laryngectomy* and need an appliance to prevent scar tissue shrinkage of the skin-tracheal border. This tube is similar to a tracheostomy tube but is shorter and wider with a larger lumen ([Fig. 31-5](#)). Laryngectomy tube care is similar to tracheostomy tube care (see [Chapter 30](#)) except that the patient can change the laryngectomy tube daily or as needed. A laryngectomy button is similar to a laryngectomy tube but

is softer, has a single lumen, and is very short. A button is comfortable for the patient, is easily removed for cleaning, and is available in various sizes and lengths for a custom fit. As described earlier, provide alternative communication techniques because the patient cannot speak.

Coughing, deep breathing, and saline instillation (when this intervention is prescribed) are usually effective in clearing secretions. Instruct the patient how to cough and deep breathe to clear secretions.

Oral secretions can be suctioned by the alert patient using a Yankauer or tonsillar suction or a soft red latex catheter. Teach the patient to suction *away* from the side of the surgery to prevent wound opening. Using a table mirror helps the patient see the area more clearly. Provide a clean environment for the catheter.

Stoma care after a total laryngectomy is a combination of wound care and airway care. Inspect the stoma with a flashlight. Clean the suture line with sterile saline (or whatever solution has been prescribed) to prevent secretions from forming crusts and obstructing the airway. Perform suture line care every 1 to 2 hours during the first few days after surgery and then every 4 hours thereafter. The mucosa of the stoma and trachea should be bright and shiny and without crusts, similar to the appearance of the oral mucosa.

Wound, Flap, and Reconstructive Tissue Care. Tissue “flaps” may be used to close the wound and improve appearance. Flaps are skin, subcutaneous tissue, and sometimes muscle, taken from other body areas that may be used for reconstruction after head and neck resection. After neck dissection, the surgeon places a split-thickness skin graft (STSG) over the exposed carotid artery before covering it with skin flaps or reconstructive flaps.

The first 24 hours after surgery are critical. Evaluate all grafts and flaps hourly for the first 72 hours. Monitor capillary refill, color, drainage, and Doppler activity of the major feeding vessel. Report changes to the surgeon immediately because surgical intervention may be needed. Position the patient so that the side of the head and neck with the flaps is not dependent.

Hemorrhage. Hemorrhage is a possible complication after any surgery, but it is uncommon with laryngectomy. The surgeon often places a closed surgical drain in the neck area to collect blood and drainage for about 72 hours after surgery. The drain also helps maintain the position of the reconstructed skin flaps. Any drain obstruction or equipment malfunction may cause a buildup of blood or serum under the flaps. This buildup can impair blood flow to and from the flaps, resulting in flap failure and tissue loss. A sudden stoppage of drainage may indicate a clot obstructing the drain. Monitor drainage, and record its amount and character. Check the patency and functioning of the drainage system. Report any drain malfunction or change in flap appearance to the surgeon. Depending on the surgeon’s preference and the agency’s policy, you may need to empty the drainage container or “milk” the drain.

Wound Breakdown. Wound breakdown is a common complication caused by poor nutrition, a long smoking history, alcohol use, wound contamination, and previous radiation therapy. Manage wound breakdown with packing and local care as prescribed to keep the wound clean and to stimulate the growth of healthy granulation tissue. Wounds may be extensive, and the carotid artery may be exposed. Split-thickness skin grafts often are placed over the carotid artery

FIG. 31-5 A laryngectomy tube. Note that the outer cannula is shorter and has a wider diameter than that of a tracheostomy tube.

for protection in the event of wound dehiscence. As the wound heals, granulation tissue covers the artery and prevents rupture. If granulation is slow and the carotid artery is at risk, another surgical flap may be made to cover the artery and close the wound.

When the carotid artery ruptures, large amounts of bright red blood spurt quickly. It is also possible for the carotid artery to have a small leak, with continuous oozing of bright red blood. Usually, a small leak leads to a complete rupture within a short time.

! NURSING SAFETY PRIORITY

Critical Rescue

If a carotid artery leak is suspected, call the Rapid Response Team and do not touch the area because additional pressure could cause an immediate rupture. If the carotid artery ruptures because of drying or infection, immediately place constant pressure over the site and secure the airway. Maintain direct manual, continuous pressure on the carotid artery, and immediately transport the patient to the operating room for carotid resection. Do not leave the patient. Carotid artery rupture has a high risk for stroke and death.

Pain Management. Pain is caused by the surgical cutting or manipulation of tissue and by nerve compression. Pain should be controlled, and the patient should still be able to participate in his or her care. Morphine (Statex ) often is given IV by a patient-controlled analgesia (PCA) pump for the first 1 to 2 days after surgery. As the patient progresses, liquid opioid analgesics can be given by feeding tube. Oral drugs for pain and discomfort are started only after the patient can tolerate oral intake. After discharge, the patient still requires pain management, especially if he or she is receiving radiation therapy. An adjunct to the pain regimen may be liquid NSAIDs. These drugs provide excellent pain relief and can be used along with opioid analgesics. Amitriptyline (Elavil) or other tricyclic antidepressants may also be used for the lancinating pain of nerve-root involvement.

Nutrition. Many patients with head and neck cancer have some degree of malnutrition before cancer treatment begins. All patients are at risk for malnutrition during treatment for head and neck cancer (Lambertz et al., 2010). A nasogastric, gastrostomy, or jejunostomy tube is placed during surgery for nutritional support while the head and neck heal. Initially, the patient receives IV fluids or parenteral nutrition until the intestinal tract has recovered from the effects of anesthesia. After that, nutrients can be given via the feeding tube. The nutritional support team or dietitian assesses the patient before surgery and is available for consultation after surgery. A common nutrition plan is to provide 35 to 40 kcal/kg of body weight daily. Replacement of protein and water loss is calculated carefully.

The feeding tube usually remains in place for 7 to 10 days after surgery. Before removing the tube, assess the patient's ability to swallow if nutrition is to be given by mouth. Aspiration *cannot* occur after a total laryngectomy because the airway and esophagus have been completely separated. Reassure the patient that aspiration will not occur, and stay with him or her during the first few swallowing attempts. Swallowing may be uncomfortable at first, and analgesics may be needed.

Speech and Language Rehabilitation. The patient's voice quality and speech are altered after surgery. Although this

problem has enormous effects on the patient's ability to maintain social interactions, continue employment, and maintain a desired quality of life, it is often poorly addressed while he or she is hospitalized. Working with him or her and the family toward developing an acceptable communication method during the inpatient period is essential for a satisfactory outcome (Happ, et al., 2011).

Together with the speech and language pathologist (SLP), discuss the principles of speech therapy with the patient and family early in the course of the treatment plan (see [Chart 31-2](#)). Voice and speech differences depend on the type of surgical resection (see [Table 31-2](#)). Speech production varies with patient practice, amount of tissue removed, and radiation effects, but the speech can be very understandable.

The speech rehabilitation plan for patients who have a total laryngectomy at first consists of writing, using a picture board, or using a computer. The patient then uses an artificial larynx and, ideally, eventually learns esophageal speech. For success, the patient needs encouragement and support from the SLP, hospital team, and family while relearning to speak. This process can be time consuming and requires concentration each time the patient speaks. Having a [laryngectomee](#) (a person who has had a laryngectomy) from one of the local self-help organizations visit the patient and family is often beneficial. The International Association of Laryngectomees is very supportive, as is the American Cancer Society (ACS) Visitor Program.

Common means of speech communication after laryngectomy include esophageal speech, the use of mechanical devices, and the use of a tracheoesophageal puncture (TEP).

Esophageal speech is attempted by most patients who have a total laryngectomy. Sound can be produced this way by “burping” the air swallowed or injected into the esophageal pharynx and shaping the words in the mouth. The voice produced is a monotone; it cannot be raised or lowered and carries no pitch. In the English language, the vocal cords are required for 15 consonants; the remaining 10 consonants can be formed by shaping the mouth. If patients do not have adequate hearing, esophageal speech will be difficult because they need to use their mouth to shape the words as they hear them. Hearing-impaired patients may need hearing aids.

Some patients have intestinal bloating from swallowing air for esophageal speech. Antacids may help reduce bloating sensations. Esophageal speech also helps strengthen the respiratory and abdominal muscles, which aids in clearing secretions and in breathing.

Mechanical devices, called *electrolarynges*, may be used by the patient who cannot attain esophageal speech. Most are battery-powered devices placed against the side of the neck or cheek ([Fig. 31-6](#)). The air inside the mouth and throat is vibrated, and the patient moves his or her lips and tongue as usual. Another external device (Cooper-Rand), also battery powered, consists of a plastic tube that is placed in the patient's mouth and vibrates during speech. The quality of speech generated with these devices is robot-like and does not sound natural.

Tracheoesophageal puncture (TEP) (formerly called a *tracheoesophageal fistula*) may be used if esophageal speech is ineffective and if the patient meets strict criteria. A small surgical puncture is created between the trachea and the esophagus using a special catheter. The puncture can be created either at the time of the laryngectomy or later. After the puncture heals, a silicone prosthesis (e.g., the Blom-Singer

prosthesis or the Panje Voice Button) is inserted in place of the catheter (Fig. 31-7). The patient covers the stoma and the opening of the prosthesis with a finger or opens and closes the opening with a special valve to divert air from the lungs, through the trachea, into the esophagus, and out of the mouth. Lip and tongue movement, not the prosthesis itself, produces speech.

Surgical Procedures for Other Head and Neck Cancers. The major types of surgeries for other head and neck cancers are called *composite resections*. These resections are a combination of surgical procedures, including partial or total glossectomies, partial mandibulectomies, and, if needed, nodal neck dissections. Tracheostomy may be planned to provide an adequate airway. (See Chapter 56 for more information about oral cancer.)

FIG. 31-6 An Electro-Larynx to generate speech after a laryngectomy.

Tracheostomy. A **tracheostomy** is a surgical incision into the trachea for the purpose of establishing an airway (tracheostomy). It can be performed as an emergency procedure or as a scheduled surgical procedure. A tracheostomy can be temporary or permanent. Chapter 30 discusses the nursing care of a patient with a tracheostomy.

Preventing Aspiration

Planning: Expected Outcomes. The patient with head and neck cancer is expected to not aspirate food, gastric contents, or oral secretions into the lungs. Indicators include that the patient often or consistently demonstrates these behaviors:

- Positions self upright for eating or drinking
- Selects foods according to swallowing ability
- Chooses liquids and foods of proper consistency

Interventions. The surgical changes in the upper respiratory tract and altered swallowing mechanisms increase the patient's risk for aspiration. Aspiration can result in pneumonia, weight loss, and prolonged hospitalization. Chart 31-3 lists actions for aspiration prevention.

The presence of a nasogastric (NG) feeding tube may further increase the potential for aspiration because it keeps the lower esophageal sphincter partially open. The one exception is the patient who has undergone a total laryngectomy. In these cases, the airway is separated from the esophagus, making aspiration impossible; such a patient is *not* at risk.

A dynamic swallow study, such as a barium swallow under fluoroscopy, evaluates a patient's ability to protect the airway from aspiration and helps determine the appropriate method of swallow rehabilitation. In many cases, enteral feedings are used either because of the patient's inability to swallow or because of continued aspiration risk.

When an NG tube is in place, help prevent aspiration with the use of routine reflux precautions, including elevating the head of the bed and strictly adhering to tube feeding

FIG. 31-7 Examples of tracheoesophageal prostheses.

regimens (especially no bolus feedings at night). Check residual volume before each bolus feeding (or every 4 to 6 hours with continuous feeding), and evaluate the patient's tolerance of the tube feeding. If the residual volume is high (above 100 mL for bolus feeding or 2 hour's worth of continuous tube feeding, or as otherwise prescribed by the physician), withhold the feeding and notify the physician. Check the pH of pulmonary secretions. Because residual volume cannot be checked with narrow feeding tubes, use other techniques to assess tube placement. (See [Chapter 63](#) for interventions related to NG tubes and tube feedings.)

Swallowing can be a major problem for the patient who has a tracheostomy tube. Swallowing can be normal if the cranial nerves and anatomic structures are intact. In a normal swallow, the larynx rises and moves forward to protect itself from the passing stream of food and saliva. Laryngeal rising also helps open the upper esophageal sphincter. The tracheostomy tube sometimes fixes the larynx in place, resulting in difficulty swallowing.

An inflated tracheostomy tube cuff can balloon backward into the esophagus and interfere with the passage of food. The wall between the posterior trachea and the esophagus is very thin, which allows this pushing action. The patient who is cognitively intact may adapt to eating normal food when the tracheostomy tube is small and the cuff is not inflated.

The patient who has had a partial vertical or supraglottic laryngectomy *must* be observed for aspiration. It is critical to teach the patient to use alternate methods of swallowing without aspirating. The "supraglottic" method of swallowing is especially effective after a partial laryngectomy or base-of-tongue resection ([Chart 31-4](#)). To reinforce teaching and learning, place a chart in the patient's room detailing the

steps. A dynamic swallow study is performed to guide rehabilitation for swallowing and to evaluate the patient's ability to protect the airway.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

The spouse of a client who has had a partial vertical laryngectomy is working with the client to use the supraglottic method of swallowing. Which direction given by the spouse to the client indicates to the nurse that more instruction is needed?

- A. Sit up as straight as you can when eating.
- B. Clear your throat before taking a bite of food.
- C. Only take just a teaspoonful of food at one time.
- D. Swallow once, then take a breath, and swallow again.

Minimizing Anxiety

Planning: Expected Outcomes. The patient with head and neck cancer is expected to have decreased anxiety. Indicators include that the patient often or consistently demonstrates:

- Verbalization of reduced anxiety
- Absence of distress, irritability, and facial tension
- Effective use of coping strategies

Interventions. Conferences with the physician, clinical nurse specialist, dietitian, speech and language pathologist, physical therapist, psychologist, social worker, and general nursing staff may be beneficial. Explore the reason for anxiety (e.g., fear of the unknown, lack of teaching, fear of pain, fear of airway compromise, fear of hospitalization, loss of control). The patient and family often benefit from further information. Before the patient is scheduled for surgery (and while still at home), home care nurses or community-sponsored programs, such as the ACS, may be able to decrease fears about the disease process and surgical interventions.

Give prescribed antianxiety drugs, such as diazepam (Valium, Meval ) , with caution because of the possibility of respiratory depression and because some of these drugs are eliminated slowly. Shorter-duration drugs, such as lorazepam (Ativan), may have fewer respiratory side effects. The location of the tumor and the presence of any other lung disease may

CHART 31-3 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Prevention of Aspiration During Swallowing

- Avoid serving meals when the patient is fatigued.
- Provide smaller and more frequent meals.
- Provide adequate time; do not "hurry" the patient.
- Provide close supervision if the patient is self-feeding.
- Keep emergency suctioning equipment close at hand.
- Avoid water and other "thin" liquids.
- Thicken liquids.
- Avoid foods that generate thin liquids during the chewing process, such as fruit.
- Position the patient in the most upright position possible.
- When possible, completely (or at least partially) deflate the tube cuff during meals.
- Suction after initial cuff deflation to clear the airway and allow maximum comfort during the meal.
- Feed each bite or encourage the patient to take each bite slowly.
- Encourage the patient to "dry swallow" after each bite to clear residue from the throat.
- Avoid consecutive swallows by cup or straw.
- Provide controlled small volumes of liquids, using a spoon.
- Encourage the patient to "tuck" his or her chin down and move the forehead forward while swallowing.
- Allow the patient to indicate when he or she is ready for the next bite.
- If the patient coughs, stop the feeding until the patient indicates the airway has been cleared.
- Continuously monitor tolerance to oral food intake by assessing respiratory rate, ease, pulse oximetry, and heart rate.

CHART 31-4 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

The Supraglottic Method of Swallowing

1. Place yourself in an upright, preferably out-of-bed, position.
2. Clear your throat.
3. Take a deep breath.
4. Place $\frac{1}{2}$ to 1 teaspoon of food into your mouth.
5. Hold your breath, or "bear down" (Valsalva maneuver).
6. Swallow twice.
7. Release your breath, and clear your throat.
8. Swallow twice again.
9. Breathe normally.

This method exaggerates the normal protective mechanisms of cessation of respiration during the swallow. The double swallow attempts to clear food that may be pooling in the pharynx, vallecula, and piriform sinuses. This method is used only after a dynamic radiographic swallow study has demonstrated that it is appropriate and safe for the patient.

cause some degree of airway obstruction. For anxiety in these patients, the physician prescribes drug therapy judiciously and may choose lorazepam (Ativan, Novo-Lorazem ) rather than a sedating agent.

Supporting Self-Concept

Planning: Expected Outcomes. The patient with head and neck cancer is expected to accept body image changes. Indicators include that the patient often or consistently demonstrates:

- Willingness to touch and care for the affected body part
- Willingness to use strategies to enhance appearance
- Interaction with visitors, staff, and family members

Interventions. The patient with head and neck cancer usually has a change in self-concept and image resulting from functional and psychological issues (Noonan & Hegarty, 2010). Common functional issues include the presence of a stoma or artificial airway, speech changes, and a change in the method of eating. Psychological issues often include guilt, regret, and worry about the future. He or she may not be able to speak at all or may have permanent hoarseness or speech deficits. Help him or her set realistic goals, starting with involvement in self-care. Teach the patient alternative communication methods so he or she can functionally communicate in the hospital and after discharge.

Teach the family to ease the patient into a normal social environment. Use positive reinforcement and encouragement while demonstrating acceptance and caring behaviors. The family also may benefit from counseling sessions while the patient is still in the hospital.

After surgery, the patient may feel socially isolated because of the change in voice and facial appearance. Loose-fitting, high-collar shirts or sweaters, scarves, and jewelry can be worn to cover the laryngectomy stoma, tracheostomy tube, and other changes related to surgery. Cosmetics may aid in covering disfigurement. Most surgeons try to place the incisions in the natural skinfold lines if doing so does not pose a risk for cancer recurrence.

Community-Based Care

If no complications occur, the patient is usually discharged home or to an extended care facility within 2 weeks. At the time of discharge, he or she or a family member should be able to perform tracheostomy or stoma care and participate in nutrition, wound care, and communication methods.

The patient and family may feel more secure about discharge if they receive a referral to support groups or a community health agency familiar with the care of patients recovering from head and neck cancer. The nurse coordinates the efforts of the health care team in assessing the specific discharge needs and making the appropriate referrals to home care agencies. Professionals such as dietitians, nurses, physical therapists, speech and language pathologists, and social workers may be needed. Coordinate the scheduling for chemotherapy or radiation therapy with the patient and family.

Home Care Management

Extensive home care preparation is needed after a laryngectomy for cancer. The convalescent period is long, and airway management is complicated. The patient or family must be able to take an active role in care.

General cleanliness of the home is assessed by the home care nurse or case manager. For the patient with severe

CHART 31-5 HOME CARE ASSESSMENT

Patients After Laryngectomy

- Assess respiratory status:
 - Observe rate and depth of respiration.
 - Auscultate lungs.
 - Check patency of airway.
 - Examine the tracheostomy drainage for amount, color, and character.
 - Examine nail beds and mucous membranes for evidence of cyanosis.
 - Obtain a pulse oximetry reading.
- Assess condition of wound:
 - Remove dressings (noting condition of dressings).
 - Cleanse the wound.
 - Compare with previous notations of wound condition:
 - Presence, amount, and nature of exudate
 - Presence/absence of cellulitis
 - Presence/absence of odor
- Assess patient's psychosocial status:
 - Ask the patient about passing the time, visitors, and trips outside the house.
 - Observe whether the patient communicates responses directly or whether a family member speaks for the patient.
 - Observe patient and family member interactions.
 - Determine what method of communication the patient has selected, and observe the patient's skill with it.
 - Observe whether the patient is wearing pajamas or is dressed in street clothes.
- Take the patient's temperature at each home care visit.
- Assess the patient's understanding of illness and adherence to treatment:
 - Manifestations to report to the health care provider
 - Medication plan (correct timing and dose)
 - Ambulation or positioning schedule
 - Dressing changes/skin care
 - Diet modifications (24-hour diet recall)
 - Skill in tracheostomy or dressing care
- Assess patient's nutritional status:
 - Change in muscle mass
 - Lackluster nails/sparse hair
 - Recent weight loss greater than 10% of usual weight
 - Impaired oral intake
 - Difficulty swallowing
 - Generalized edema

respiratory problems, home changes to allow for one-floor living may be needed. Increased humidity is needed. A humidifier add-on to a forced-air furnace can be obtained, or a room humidifier or vaporizer may be used. Be sure to stress that meticulous cleaning of these items is needed to prevent spread of mold or other sources of infection.

A home care nurse often is involved with care after discharge and is an important resource for the patient and family. This nurse assesses the patient and home situation for problems in self-care, complications, adjustment, and adherence to the medical regimen. [Chart 31-5](#) lists assessment areas for the patient in the home after a laryngectomy. This nurse reinforces health care teaching, self-care teaching, and smoking-cessation regimens.

Teaching for Self-Management

Education begins before surgery, and most self-care is taught in the hospital. Teach the patient and family how to care for the stoma or tracheostomy or laryngectomy tube, depending on the type of surgery performed. Review incision and airway care, including cleaning and inspecting for signs of infection.

CHART 31-6 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Home Laryngectomy Care

- Avoid swimming, and use care when showering or shaving.
- Lean slightly forward and cover the stoma when coughing or sneezing.
- Wear a stoma guard or loose clothing to cover the stoma.
- Clean the stoma with mild soap and water. Lubricate the stoma with a non-oil-based ointment as needed.
- Increase humidity by using saline in the stoma as instructed, a bedside humidifier, pans of water, and houseplants.
- Obtain and wear a MedicAlert bracelet and emergency care card for life-threatening situations.

Chart 31-6 lists self-care actions for the patient after laryngeal cancer surgery. Many of these actions also apply to any surgery for head and neck cancer.

Stoma care teaching is focused on protection. Instruct the patient to use a shower shield over the tube or stoma when bathing to prevent water from entering the airway. Teach men who use electric shavers to cover the stoma while shaving to keep hair from falling into it. Suggest that the patient wear a protective cover or stoma guard to protect the stoma during the day. For those with permanent stomas after laryngectomy or for those with permanent tracheostomies, covering the opening has a double benefit: (1) filtering the air entering the stoma while keeping humidity in the airway, and (2) enhancing aesthetic appearance. Attractive coverings are available in the form of cotton scarves, crocheted collars, and jewelry.

Instruct the patient how to increase humidity in the home. If prescribed, teach the patient to instill normal saline into the artificial airway 10 to 15 times a day. Stress the importance of keeping well hydrated to prevent secretions from thickening.

Communication involves having the patient continue the selected method of alternative communication that began in the hospital. Instruct him or her to wear a medical alert (MedicAlert) bracelet and carry a special identification card (Fig. 31-8). For patients with a laryngectomy, this card is available from the local chapters of the International Association of Laryngectomees. The card instructs the reader about providing an emergency airway or resuscitating someone who has a stoma.

Smoking cessation is a difficult but important issue after head and neck cancer surgery. Stress that smoking cessation can reduce the risk for developing other cancers and can increase the rate of healing from surgery.

Smoking cessation is not easy, and most patients need continuing support to sustain this action (Duffy et al., 2010). One study found that patients who perceived that quitting smoking is difficult were more likely to enroll in and complete a smoking-cessation program (see the Evidence-Based Practice box on p. 598). Chemical and psychological assistance are available for smoking cessation. See Chapter 38 for a detailed discussion of smoking-cessation methods.

Psychosocial Preparation

The many changes resulting from a laryngectomy influence physical, social, and emotional functioning. Patients may perceive changes in their quality of life. Begin preparing the

TOTAL NECK BREATHER
 (Front of Card)

EMERGENCY!

I am a Total Neck Breather
(Laryngectomy—No Vocal Cords)

I breathe **ONLY** through an opening in my neck, **NOT** through my nose or mouth.

If I have stopped breathing:

1. Expose my entire neck.
2. Give me **mouth to neck breathing only**.
3. Keep my head straight—chin up.
4. Keep neck opening clear with clean **CLOTH** (not tissue).
5. Use oxygen supply to neck opening. **ONLY**, when I start to breathe again.

**BE PROMPT—SECONDS COUNT
I NEED AIR NOW!**

patient and family by scheduling a visit from a person who has adjusted to these changes.

The patient who is discharged to home with a permanent stoma, tracheostomy tube, nasogastric (NG) tube, and wounds has an altered body image. Stress the importance of returning to as normal a lifestyle as possible. Most patients can resume many of their usual activities within 4 to 6 weeks after surgery. A longer time is needed after a combination of radiation therapy and surgery and for those patients who also have other chronic diseases such as diabetes mellitus, heart failure, or chronic obstructive pulmonary disease. The patient may be frustrated at times while trying to adjust to changes in appearance, smell, taste, and communication.

The patient with a total laryngectomy cannot produce sounds during laughing and crying. Mucus secretions may appear unexpectedly when these emotions arise or when coughing or sneezing occurs. The mucus can be embarrassing, and the patient needs to be prepared to cover the stoma with a handkerchief or gauze. The patient who has undergone composite resections has difficulty with speech and swallowing. He or she may need to deal with tracheostomy and feeding tubes in public places.

Health Care Resources

Inform the patient and family of community organizations (e.g., ACS) and local laryngectomy clubs, which can offer support, information, and friendships. When the patient has problems paying for health care services, equipment, and prescriptions, a visiting nurse agency may be helpful in locating available resources.

In many areas, the local unit of the ACS or Canadian Cancer Society can help provide dressing materials and nutritional supplements to patients in need. These organizations

EVIDENCE-BASED PRACTICE

Excessive Confidence May Be a Detriment

Duffy, S.A., Scheumann, A.L., Fowler, K.E., Darling-Fisher, C., & Terrell, J.E. (2010). Perceived difficulty quitting predicts enrollment in a smoking-cessation program for patients with head and neck cancer. *Oncology Nursing Forum*, 37(3), 349-356.

Cigarette smoking is a major risk factor for the initial development of head and neck cancers and in their recurrence. It also delays healing after surgery for these cancers, and the associated respiratory and cardiac problems reduce the quality of life in those patients who continue to smoke. Therefore smoking cessation in patients with head and neck cancer is strongly encouraged; however, smoking cessation in these patients after diagnosis is less than 50%.

The purpose of this study was to examine factors that predicted participation in a smoking-cessation program. The study was a substudy of a larger randomized trial involving patients with head and neck cancer to determine whether depressive symptoms, perception of smoking-cessation difficulty, or level of alcohol consumption influenced participation in a smoking-cessation intervention.

Data regarding depressive symptoms, perception of smoking-cessation difficulty, and level of alcohol consumption were collected for all 286 study-eligible patients. The instruments used to assess these factors were well established with good internal consistency and appropriate levels of reliability. Of the eligible patients, only 136 (48%) agreed to participate in the smoking-cessation intervention. Analysis of the data between the two groups indicated that the strongest predictor ($p < 0.05$) for participation in a smoking-cessation intervention was the perception on the part of the patient that quitting smoking was difficult to accomplish and that help was needed for success. Overall, eligible patients who chose to not participate in a smoking-cessation intervention held the belief that smoking cessation was less difficult. In addition, more of the patients who chose to not participate had scores that indicated a problem with excessive alcohol consumption, although this factor did not reach statistical significance.

Level of Evidence: 4.

The study used a nonexperimental descriptive approach, which was appropriate for the purpose of the study. The large number of participants and the fact that data were collected as part of a multi-center randomized clinical trial increase the generalizability of the findings.

Commentary: Implications for Practice and Research.

The results of this study regarding the issue of perceived less difficulty or high confidence in one's ability to quit smoking conflict with some previous studies and are congruent with others. Older studies found a positive correlation between high confidence in not smoking and the ability to quit. Other studies had different outcomes and, along with the current investigators, suggest high confidence of smokers in not smoking could interfere with obtaining assistance or support for smoking cessation. The current investigators also concluded that increased alcohol consumption promoted smoking behaviors and reduced resolve.

Patients diagnosed with head and neck cancer often are both cigarette smokers and consumers of alcohol. Although all of these patients are encouraged to stop smoking, the initial approach and type of program needed may vary depending on the patient's perception of smoking-cessation difficulty. Those who perceive that smoking cessation is difficult may be more ready to join a smoking-cessation program and more amenable to working with the strategies proposed. The question of why a person has this perception rather than one of high confidence remains. It is possible that those who believe that they could easily quit smoking may have never tried to do so or believe that requiring assistance is "weak." Such individuals may need a completely different approach. Nurses may be able to identify how difficult a patient perceives smoking cessation to be by asking these questions:

- Have you ever tried to quit smoking?
- How many times?
- What were the results?
- What method did you use (did you have assistance or support)?

may also provide transportation to and from follow-up visits or radiation therapy.

**DECISION-MAKING CHALLENGE****Patient-Centered Care; Evidence-Based Practice; Teamwork and Collaboration**

A patient who had a hemilaryngectomy for laryngeal cancer comes back to the clinic 3 weeks after discharge. He says things are going well at home and that he is glad to be alive. You notice a strong odor of cigarette smoke coming off his clothes. When you ask him how the smoking-cessation program is going, he looks away from you and says "fine."

1. Should you press this question further? Why or why not?
2. Why is smoking cessation an important action for this patient?
3. What other health care professional or resource could be consulted for this issue?

EVALUATION: OUTCOMES

Evaluate the care of the patient with head and neck cancer based on the identified priority patient problems. The expected outcomes are that the patient:

- Maintains a patent airway
- Performs self-care of the artificial airway and wound
- Performs ADLs independently or with minimal assistance
- Attains or maintains adequate nutrition
- Does not aspirate gastric contents or food
- Engages in desired social interactions

Specific indicators for these outcomes are listed for priority patient problems in the [Planning and Implementation](#) section (see earlier).

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing inadequate oxygenation and tissue perfusion as a result of upper airway problems?

- Voice changes (nasal quality if the problem is above the palate, "breathy" or "whispery" if the problem is in the larynx or trachea)
- Snoring or mouth breathing

- Change in cognition or level of consciousness or acute confusion
- Decreased oxygen saturation by pulse oximetry
- Skin cyanosis or pallor (lighter-skinned patients)
- Cyanosis or pallor of the lips and oral mucous membranes (patients of any skin color)
- Tachycardia and dysrhythmia

NURSING CONCEPT REVIEW—cont'd

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate oxygenation and tissue perfusion as a result of a respiratory problem?

Perform and interpret physical assessment, including:

- Taking vital signs
- Monitoring oxygen saturation by pulse oximetry
- Assessing for the presence of thick or excessive secretions
- Assessing the patient's ability to cough and clear the airway
- Assessing nasal drainage and sputum for color and blood
- Checking most recent laboratory values for white blood cell and ABG levels
- Assessing cognition (Mini-Mental State Examination [MMSE])
- Assessing hydration status

Respond by:

- Suctioning (oral, pharyngeal, endotracheal, tracheostomy), if needed
- Applying oxygen, and assessing the patient's responses to this intervention
- Keeping the patient's head elevated to about 30 degrees
- Notifying physician or Rapid Response Team
- Ensuring venous access

On what should you REFLECT?

- Observe patient for evidence of restored oxygenation (see [Chapter 29](#)).
- Think about what may have precipitated this episode and what steps could be taken to either prevent a similar episode or identify it earlier.
- Think about what additional resources could improve the nursing response to this situation.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category

Safe and Effective Care Environment

- Use sterile technique when performing endotracheal or tracheal suctioning.
- Use Standard Precautions when caring for a patient with epistaxis.

Health Promotion and Maintenance

- Encourage people who smoke to quit smoking or using tobacco in any way.
- Encourage people who use alcohol to reduce their intake of alcoholic beverages.
- Use aspiration precautions for any patient with an altered level of consciousness or who has an endotracheal tube (see [Chart 31-3](#)).
- Teach the patient and family how to perform tracheostomy care (see [Chart 30-3](#) in [Chapter 30](#)).
- Teach patients who have had radiation therapy to the oral cavity to have dental examinations at least every 6 months.

Psychosocial Integrity

- Allow the patient and family members the opportunity to express fear or anxiety regarding a cancer diagnosis or a change in breathing status.
- Teach family members ways to communicate with a patient who cannot speak after surgery for head and neck cancer.

- Encourage patients with permanent tracheostomies or laryngectomies to become involved in self-care and to look at the wound and touch the affected area.
- Allow the patient and family to grieve the loss of function and change in body image.
- Allow time to communicate with the patient who has voice loss.
- Refer patients and families to the ACS or the Canadian Cancer Society after surgery for head and neck cancer.

Physiological Integrity

- Assess the airway patency of any patient who experiences facial or nasal trauma.
- Notify the Rapid Response Team when a patient experiences a posterior nasal bleed.
- Check the airway and packing at least every hour for a patient who has posterior nasal packing placed after nasal surgery or posterior epistaxis.
- Instruct patients who have had mandibular immobilization or fixation after a mandibular fracture to keep wire cutters with them at all times.
- Apply oxygen to any patient who develops stridor.
- Use a manual resuscitation bag to ventilate the patient if the tracheostomy tube has dislodged or been decannulated.
- Assess the new tracheostomy stoma site at least once per shift for purulent drainage, redness, pain, and swelling, as indicators of infection.
- Keep the tracheal cuff pressure between 14 and 20 mm Hg to prevent tissue injury.

Concept Map: Respiratory Acidosis (COPD-Related)

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Ensure safe oxygen delivery.
2. Ensure the proper oxygen flow rate for patients with hypercarbia.
3. Use appropriate infection control methods to protect the patient with cystic fibrosis from respiratory infections.
4. Ensure appropriate functioning of the chest tube drainage system after a thoracotomy.

Health Promotion and Maintenance

5. Use assessment information to identify people at increased genetic risk for a respiratory disease.
6. Encourage everyone to not smoke or to quit smoking.
7. Encourage all people who are exposed to inhalation irritants in the workplace or at home to use appropriate protection.
8. Teach patients with asthma or chronic obstructive pulmonary disease (COPD) how to use a peak flowmeter.
9. Teach patients using any type of inhaler for drug delivery the correct way to use these devices.
10. Teach patients who are using controller (preventive) drug therapy for asthma the importance of taking the prescribed drugs daily, even when asthma symptoms are not present.

11. Teach patients with asthma to have their reliever (rescue) inhalers with them at all times.

Psychosocial Integrity

12. Encourage the patient and family to express feelings and concerns about a change in breathing status.
13. Teach the patient with activity limitations from respiratory problems how to modify techniques and conserve energy to perform ADLs and desired activities independently.

Physiological Integrity

14. Compare the pathophysiology and clinical manifestations of asthma, bronchitis, and emphysema.
15. Identify risk factors for COPD and lung cancer.
16. Use laboratory data and clinical manifestations to determine the effectiveness of therapy for impaired oxygenation in a patient with breathing problems.
17. Interpret peak expiratory flow (PEF) readings for the need for intervention.
18. Coordinate care for the patient immediately following lung volume reduction surgery.
19. Compare the side effects of radiation treatment for lung cancer with those of chemotherapy for lung cancer.
20. Coordinate nursing interventions for the patient with chest tubes.

CHART 32-1 NURSING FOCUS ON THE OLDER ADULT

Chronic Respiratory Disorder

- Provide rest periods between such activities as bathing, meals, and ambulation.
- Place the patient in an upright position for meals to prevent aspiration.
- Encourage nutritional fluid intake after the meal to promote increased calorie intake.
- Schedule drugs around routine activities to increase adherence to drug therapy.
- Arrange chairs in strategic locations to allow the patient with dyspnea to stop and rest while walking.
- Urge the patient to notify the health care provider promptly for any manifestation of infection.
- Encourage the patient to receive the pneumococcal vaccine and to have an annual influenza vaccination.

Direct gas exchange occurs in the alveoli and the smallest airways. Any problem of these tissues reduces gas exchange and interferes with oxygenation. Many lower airway problems are chronic and progressive, requiring changes in a person's lifestyle. The older patient with a lower airway problem may need special help before the disorder becomes severe because of age-related changes in breathing effectiveness. [Chart 32-1](#) lists nursing issues for the older patient with a respiratory problem.

CHRONIC AIRFLOW LIMITATION

Chronic airflow limitation (CAL) is a group of chronic lung diseases that includes asthma, chronic bronchitis, and pulmonary emphysema. Emphysema and chronic bronchitis, termed **chronic obstructive pulmonary disease (COPD)**, are characterized by bronchospasm and dyspnea ([Fig. 32-1](#)). The tissue damage is not reversible and increases in severity over time, eventually leading to respiratory failure. Asthma, unlike COPD, is a chronic disease with intermittent *reversible* airflow obstruction and wheezing.

More than 40 million Americans suffer from some form of CAL, and 1 million people between the ages of 40 and 65 years have moderate to severe disability from CAL ([Centers for Disease Control and Prevention \[CDC\], 2010](#)). Although some of the problems are not reversible, good management strategies can help maintain adequate *oxygenation* and improve overall health.

ASTHMA

Pathophysiology

Asthma is usually a chronic condition in which reversible airflow obstruction in the airways occurs intermittently (see [Fig. 32-1](#)). Airway obstruction can occur in two ways: (1) inflammation and (2) airway hyperresponsiveness that leads to bronchoconstriction. Inflammation obstructs the **lumen** (i.e., the inside) of airways ([Fig. 32-2](#)). Airway hyperresponsiveness and constriction of bronchial smooth muscle cause a narrowing of the airway from the outside. Airway inflammation can trigger bronchiolar hyperresponsiveness, and many people with asthma have both problems at the same time. Severe airway obstruction can be fatal. More than

3400 deaths from acute asthma occur in the United States each year ([CDC, 2010](#)).

Etiology and Genetic Risk

Asthma is classified into different types based on how the attacks are triggered; however, the effect on oxygenation is similar for all types of asthma. Inflammation of the mucous membranes lining the airways is a key event in triggering an asthma attack. Inflammation occurs in response to the presence of specific allergens; general irritants such as cold air, dry air, or fine airborne particles; microorganisms; and aspirin and other NSAIDs. Hyperresponsiveness can occur with exercise, with an upper respiratory illness, and for unknown reasons.

GENETIC/GENOMIC CONSIDERATIONS

Results of genome-wide association studies (GWAS) indicate more than 50 gene variations are associated with asthma from inflammation or hyperresponsive airways, although asthma is a multifactorial disorder with both genetic and environmental input required for expression ([Kumar et al., 2010](#); [Online Mendelian Inheritance in Man \[OMIM\], 2010](#); [Weiss et al., 2009](#)). Some of these variations have greater influence than others, especially within certain racial or ethnic groups. In addition, genetic variation in the gene that controls the synthesis and activity of beta-adrenergic receptors has an impact on drug therapy for asthma. Patients who have a mutation in this gene do not respond as expected to short-acting or long-acting beta agonists and need to have an altered therapy plan. Teaching these patients about why their drug therapies are different from standard recommendations is a nursing responsibility that can assist with therapy adherence.

When asthma is well controlled, the airway changes are temporary and reversible. With poor control, chronic inflammation can lead to damage and hyperplasia of the bronchial epithelial cells and of the bronchial smooth muscle ([Global Initiative for Asthma \[GINA\], 2010](#)). When asthma attacks are frequent, even exposure to low levels of the triggering agent or event may stimulate an attack.

Inflammation triggers asthma for some people when allergens bind to specific antibody molecules (especially immunoglobulin E [IgE]). These molecules are attached to tissue cells called *mast cells* and white blood cells (WBCs) called *basophils*. These cells are filled with granules containing chemical mediators that can start local inflammatory responses (see [Chapters 19 and 22](#)). Some mediators, such as histamine, start an immediate inflammatory response, which can be blocked by drugs like diphenhydramine (Benadryl). Others, such as leukotriene and eotaxin, are slower and cause later, prolonged inflammatory responses, which can be blocked by drugs like montelukast (Singulair), zafirlukast (Accolate), and zileuton (Zyflo). Mediators also attract more WBCs (eosinophils, macrophages, basophils) to the area, which then release even more inflammation-inducing mediators. Inflammation of airway mucous membranes causes blood vessel dilation and capillary leak, leading to tissue swelling with increased secretions and mucus production ([McCance et al., 2010](#)). Inflammation can also occur through general irritation rather than allergic responses.

Bronchospasm is a narrowing of the bronchial tubes through constriction of the smooth muscle around and within the bronchial walls. It can occur as a result of hyperresponsive airways when small amounts of pollutants or respiratory viruses stimulate nerve fibers, causing

In **asthma**, the airways overreact to common stimuli with bronchospasm, edematous swelling of the mucous membranes, and copious production of thick, tenacious mucus by abundant hypertrophied mucous glands. Airway obstruction is usually intermittent.

Centriacinar or centrilobular emphysema affects the respiratory bronchioles most severely. It is usually more severe in the upper lung.

In **chronic bronchitis**, infection or bronchial irritants cause increased secretions, edema, bronchospasm, and impaired mucociliary clearance. Inflammation of the bronchial walls causes them to thicken. This thickening, together with excessive mucus, blocks the airways and hinders gas exchange.

In **emphysema**, lung proteases collapse the walls of bronchioles and alveolar air sacs. As these walls collapse, the bronchioles and alveoli transform from a number of small elastic structures with great air-exchanging surface area into fewer, larger, inelastic structures with little surface area. Air is trapped in these distal structures, especially during forced expiration such as coughing, and the lungs hyperinflate. The trapped air stagnates and can no longer supply needed oxygen to the nearby capillaries.

Panacinar or panlobular emphysema affects the entire acinar unit. It is usually more severe in the lower lung.

FIG. 32-1 The pathophysiology of chronic airflow limitation (CAL).

constriction of bronchial smooth muscle. If an inflammatory response is stimulated at the same time, the mediators released during inflammation also trigger constriction. Severe bronchospasm alone, especially in smaller bronchioles, can profoundly limit airflow to the alveoli.

Aspirin and other NSAIDs can trigger asthma in some people, although this response is not a true allergy. It results

from increased production of leukotriene when aspirin or NSAIDs suppress other inflammatory pathways.

Gastroesophageal reflux disease (GERD) is now thought to be a major trigger for asthma in some people, especially in those who have more asthma manifestations at night (GINA, 2010). It does not cause the airway hyperresponsiveness, but the highly acidic stomach contents appear to

FIG. 32-2 Causes of narrowed airways. **A**, Cross section of a small airway showing the tissue layers. **B**, Mucosal swelling. **C**, Constriction of smooth muscle. **D**, Mucosal swelling and constriction of smooth muscle. **E**, Mucus plug.

CHART 32-2 KEY FEATURES

Levels of Asthma Control

CHARACTERISTIC	CONTROLLED (ALL OF THESE CHARACTERISTICS MUST BE PRESENT)	PARTLY CONTROLLED (THE PRESENCE OF ANY ONE OF THESE CHARACTERISTICS IS CONSIDERED PARTLY CONTROLLED)	UNCONTROLLED (THE PRESENCE OF THREE OR MORE CHARACTERISTICS FROM THE PARTLY CONTROLLED LIST IS CONSIDERED UNCONTROLLED ASTHMA)
Daytime symptoms	Symptoms or episodes occur not more than twice per week	Symptoms or episodes occur more than twice per week	
Activity limitations	None	Any	
Nighttime awakening with symptoms	None	Any	
Need for relief treatment	Relief inhaler not used more than twice per week	Relief inhaler used more than twice per week	
PEF or FEV ₁	Normal	Less than 80% of predicted for age, size, and gender or less than 80% of established personal best	
Treatment action	Find and maintain lowest step level that controls symptoms	Increase step until symptoms are controlled on a regular basis, then reduce step to the lowest step level that consistently controls symptoms	Increase step (step up) until control is reached and maintained

PEF, Peak expiratory flow; FEV₁, forced expiratory volume in the first second.

make the hyperresponsiveness worse when these materials enter the airway.

Incidence/Prevalence

Asthma can occur at any age. About half of adults with asthma also had the disease in childhood. Asthma affects nearly 19 million adults in the United States and Canada (CDC, 2010). It is more common in urban settings than in rural settings.

CONSIDERATIONS FOR OLDER ADULTS

Asthma occurs as a new disorder in about 3% of people older than 55 years. Another 3% of people older than 60 years have asthma as a continuing chronic disorder (CDC, 2010). Lung and airway changes as a part of aging make any breathing problem more serious in the older adult. One problem related to aging is a decrease in the sensitivity of beta-adrenergic receptors. When stimulated, these receptors relax smooth muscle and cause bronchodilation. As these receptors become less sensitive, they no longer respond as quickly or as strongly to agonists (epinephrine, dopamine) and beta-adrenergic drugs, which are often used as reliever (rescue) therapy during an acute asthma attack. Thus teaching older patients how to avoid asthma attacks and to correctly use controller (preventive) drug therapy is a nursing priority.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Asthma is classified on the basis of how well controlled the manifestations are, as well as on the patient's response to asthma drugs. These classes are the basis for current asthma therapy (Charts 32-2 and 32-3).

History

The patient with asthma usually has a pattern of intermittent episodes of **dyspnea** (shortness of breath), chest tightness, coughing, wheezing, and increased mucus production. Ask whether the manifestations occur continuously, seasonally, in association with specific activities or exposures, or more frequently at night. Some patients have these manifestations for 4 to 8 weeks after a chest cold or other upper respiratory tract infection. The patient with atopic (allergic) asthma often has other allergic problems such as rhinitis, skin rash, or pruritus. Ask whether any family members have asthma or respiratory problems. Ask about current or previous smoking habits. If the patient smokes, use this opportunity to teach him or her about smoking cessation (Chart 32-4). Wheezing in non-smokers is an important symptom in the diagnosis of asthma.

CHART 32-3 KEY FEATURES

The Step System for Medication Use in Asthma Control

*ICS = Inhaled corticosteroid.

†Leukotriene modifier = Leukotriene receptor antagonist or leukotriene synthesis inhibitor.

‡IgE = Immunoglobulin E.

FIG. 32-3 **A**, Normal adult. The thorax has an oval shape with an anteroposterior-to-transverse diameter of 1 : 1.5 or 5 : 7. **B**, Barrel chest. Note equal anteroposterior-to-transverse diameter and that ribs are horizontal instead of the normal downward slope. This is associated with chronic obstructive pulmonary disease and severe asthma as a result of hyperinflation of the lungs.

Physical Assessment/Clinical Manifestations

The patient with mild to moderate asthma may have no manifestations between asthma attacks. During an acute episode, the most common manifestations are an audible wheeze and increased respiratory rate. At first, the wheeze is louder on exhalation. When inflammation occurs with asthma, coughing may increase.

The patient may use accessory muscles to help breathe during an attack. Observe for muscle retraction at the sternum and the suprasternal notch and between the ribs. The patient with long-standing, severe asthma may have a “barrel chest,” caused by air trapping (Fig. 32-3). The anteroposterior (AP) diameter (diameter between the front and the back of the

chest) increases with air trapping, giving the chest a rounded rather than an oval shape. The normal chest is about 1.5 times as wide as it is thick. In the patient with severe, chronic asthma, the AP diameter may equal or exceed the lateral diameter. Compare the AP diameter of the chest with the lateral diameter. Chronic air trapping also flattens the diaphragm and increases the space between the ribs.

Along with an audible wheeze, the breathing cycle is longer with prolonged exhalation and requires more effort. The patient may be unable to speak more than a few words between breaths. Hypoxia occurs with severe attacks. Pulse oximetry shows **hypoxemia** (poor blood oxygen levels). Examine the oral mucosa and nail beds for cyanosis. Other

CHART 32-4 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Smoking Cessation

- Make a list of the reasons you want to stop smoking (e.g., your health and the health of those around you, saving money, social reasons).
- Set a date to stop smoking, and keep it. Decide whether you are going to begin to cut down on the amount you smoke or are going to stop “cold turkey.” Whatever way you decide to do it, keep this important date!
- Ask for help from those around you. Find someone who wants to quit smoking and “buddy up” for support. Look for assistance in your community, such as formal smoking-cessation programs, counselors, and certified acupuncture specialists or hypnotists.
- Consult your health care provider about nicotine replacement therapy (e.g., patch, gum) or other pharmacologic therapy to assist in smoking cessation.
- Remove ashtrays and lighters from your view.
- Talk to yourself! Remind yourself of all the reasons you want to quit.
- Think of a way to reward yourself with the money you save from not smoking for a year.
- Avoid places that might tempt you to smoke. If you are used to having a cigarette after meals, get up from the table as soon as you are finished eating. Think of new things to do at times when you used to smoke (e.g., taking a walk, exercising, calling a friend).
- Find activities that keep your hands busy: needlework, painting, gardening, even holding a pencil.
- Take five deep breaths of clean, fresh air through your nose and out your mouth if you feel the urge to smoke.
- Keep plenty of healthy, low-calorie snacks, such as fruit and vegetables, on hand to nibble on. Try sugarless gum or mints as a substitute for tobacco.
- Drink at least eight glasses of water each day.
- Begin an exercise program with the approval of your health care provider. Be aware of the positive, healthy changes in your body since you stopped smoking.
- List the many reasons why you are glad that you quit. Keep the list handy as a reminder of the positive things you are doing for yourself.
- If you have a cigarette, think about what the conditions were that caused you to light it. Try and think of a strategy to avoid that (or those) conditions.
- Don’t beat yourself up for backsliding; just face the next day as a new day.
- Think of each day without tobacco as a major accomplishment. It is!!

indicators of hypoxemia include changes in the level of cognition or consciousness and tachycardia.

Laboratory Assessment

Laboratory tests can help determine the type of asthma and the degree of breathing impairment. Arterial blood gas (ABG) levels show how well the patient is obtaining oxygen (see [Chapter 14](#) for discussion of ABGs). The arterial oxygen level (P_{aO_2}) may decrease during an asthma attack. Early in the attack, the arterial carbon dioxide level (P_{aCO_2}) may be decreased as the patient increases respiratory effort. Later in an asthma episode, P_{aCO_2} rises, indicating carbon dioxide retention. Allergic asthma often occurs with an elevated serum eosinophil count and immunoglobulin E levels. The sputum may contain eosinophils and mucus plugs with shed epithelial cells (Curschmann’s spirals).

Pulmonary Function Tests

The most accurate tests for asthma are the pulmonary function tests (PFTs) measured using spirometry. Baseline PFTs are obtained for all patients diagnosed with asthma. The most important PFTs for a patient with asthma are:

- **Forced vital capacity (FVC)** (volume of air exhaled from full inhalation to full exhalation)
- **Forced expiratory volume in the first second (FEV_1)** (volume of air blown out as hard and fast as possible during the first second of the most forceful exhalation after the greatest full inhalation)
- **Peak expiratory flow (PEF)** (fastest airflow rate reached at any time during exhalation)

A decrease in either the FEV_1 or the PEF of 15% to 20% below the expected value for age, gender, and size is common for the patient with asthma. An increase of 12% in these values after treatment with bronchodilators is diagnostic for asthma. Airway responsiveness is tested by measuring the PEF and FEV_1 before and after the patient inhales the drug *methacholine*, which induces bronchospasm in susceptible people.

INTERVENTIONS

The purposes of asthma therapy are to control and prevent episodes, improve airflow, and relieve symptoms. Adult asthma is best managed when the patient is an active partner in the management plan. Priority nursing actions focus on patient education about proper implementation of a personal asthma action plan, which includes drug therapy and lifestyle management strategies to assist the patient in understanding his or her disease and its treatment ([GINA, 2010](#)).

Teaching for Self-Management

Asthma often has intermittent overt symptoms. With guided self-care, patients can co-manage this disease, increasing symptom-free periods and decreasing the number and severity of attacks ([Ellis, 2008](#); [Pruitt, 2011](#)). Good management decreases the number of hospital admissions and increases participation in patient-chosen work and leisure activities. Self-care requires extensive education for the patient to be able to self-assess respiratory status, self-treat (including adjusting the frequency and dosage of prescribed drugs), and know when to consult the health care provider.

Ideally, a personal asthma action plan is developed by the health care provider and the patient. This plan is tailored to meet the patient’s personal triggers, asthma manifestation pattern, and drug responses. This plan includes the prescribed daily controller drug(s) schedule and prescribed reliever drug directions, patient-specific daily asthma control assessment questions, directions for adjusting the daily controller drug schedule, when to contact the health care provider (in addition to regularly scheduled visits), and what emergency actions to take when asthma manifestations are not responding to controller and reliever drugs.

Teach the patient to assess symptom severity at least twice daily with a peak flowmeter ([Fig. 32-4](#)) and to adjust drugs according to his or her personal asthma action plan to manage inflammation and bronchospasms to prevent or relieve symptoms. [Chart 32-5](#) describes the correct method to use the meter. Teach the patient to first establish a baseline or “personal best” peak expiratory flow (PEF) by measuring his or her PEF twice daily for 2 to 3 weeks when asthma is well controlled and recording the results. This way, the patient will

FIG. 32-4 A typical peak flowmeter. This model will show faster exhalation rates in green, reduced exhalation rates in yellow, and seriously reduced exhalation rates in red.

CHART 32-5 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Using a Peak Flowmeter

- Set the peak flowmeter at zero.
- Use a standing position, without leaning or supporting yourself on anything, if possible.
- Take as deep a breath as you can.
- Place the mouthpiece of the meter in your mouth, taking care to wrap your lips tightly around it.
- Blow your breath out through the mouthpiece as hard and as fast as you are able. (If you cough, sneeze, or have any type of interruption while you exhale, reset the meter and perform the test again.)
- Reset and perform the test two additional times.
- Use the highest reading of the three to determine your current peak flow rate.
- Keep a record or graph of your peak flow rates and examine these for trends.

know when his or her peak flow is reduced to the point that more drugs are needed or that emergency assistance is needed. When the patient has established a “personal best,” all other readings are compared with this value in terms of percent of personal best. Some meters are color-coded to help the patient interpret the results. Green zone readings are at least 80% or above the “personal best.” This is the ideal range for asthma control and indicates that no increases in drug therapy are needed. Yellow is a range between 50% and 80% of personal best. When a patient has a reading in this range, he or she needs to use the prescribed “reliever drug” (formerly called a rescue drug). Within a few minutes after using the reliever drug, another PEF reading should be made to determine whether the reliever drug is working. *Frequent readings in the yellow zone or increasing use of reliever drugs is a warning that indicates the need to reassess the asthma plan for a temporary or permanent change in controller (preventive) drugs.* Red is a range below 50% of the patient’s personal best and indicates serious respiratory obstruction.

CHART 32-6 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Asthma Management

- Avoid potential environmental asthma triggers, such as smoke, fireplaces, dust, mold, and weather changes (especially warm to cold or sudden barometric changes).
- Avoid medications that are triggers for your asthma (e.g., aspirin, NSAIDs, beta blockers).
- Avoid food that has been prepared with monosodium glutamate (MSG) or metabisulfite.
- If you experience symptoms of exercise-induced asthma, use your bronchodilator inhaler 30 minutes before exercise to prevent or reduce bronchospasm.
- Be sure you know the proper technique and correct sequence when you use metered dose inhalers.
- Get adequate rest and sleep.
- Reduce stress and anxiety; learn relaxation techniques; adopt coping mechanisms that have worked for you in the past.
- Wash all bedding with hot water to destroy dust mites.
- Monitor your peak expiratory flow rates with a flowmeter at least twice daily.
- Seek immediate emergency care if you experience any of these:
 - Gray or blue fingertips or lips
 - Difficulty breathing, walking, or talking
 - Retractions of the neck, chest, or ribs
 - Nasal flaring
 - Failure of drugs to control worsening symptoms
 - Peak expiratory rate flow declining steadily after treatment, or a flow rate 50% below your usual flow rate

! NURSING SAFETY PRIORITY

Action Alert

Teach the patient that if a red zone reading occurs when using the peak flowmeter, to immediately use the reliever drugs and seek emergency help.

Teach the patient to keep a symptom and intervention diary to learn specific triggers of asthma symptoms, early cues for impending attacks, and personal response to drugs. Stress the importance of proper use of his or her personal asthma action plan for any severity of asthma (Corbridge & Corbridge, 2010). Chart 32-6 lists areas to emphasize when teaching the patient with asthma.

Drug Therapy

Pharmacologic management of adult patients with asthma is based on the step category for severity and treatment (see Charts 32-2 and 32-3) (GINA, 2010). **Control therapy drugs** (formerly called preventive drugs) are drugs used to reduce airway responsiveness to prevent asthma attacks from occurring. *They are used every day, regardless of symptoms.* **Reliever drugs** are those used to actually stop an attack once it has started. Some patients may need drug therapy only during an asthma episode. For others, daily drugs are needed to keep asthma episodic rather than a more frequent problem. This therapy involves the use of bronchodilators and various drug types to reduce inflammation. Some drugs reduce the asthma response, and other drugs actually prevent the response. Combination drugs are two agents from different classes combined together for better response. Chart 32-7 lists the most common preferred drugs in each class for control

CHART 32-7 COMMON EXAMPLES OF DRUG THERAPY

Asthma Prevention and Treatment

DRUG/USUAL DOSAGE	PURPOSE/ACTION	NURSING INTERVENTIONS	RATIONALE
Bronchodilators			
Short-Acting Beta₂ Agonist (SABA)			
Albuterol (Proventil, Ventolin) 1-2 inhalations every 4-6 hr (90 mcg/inhaled dose)	Causes bronchodilation by relaxing bronchiolar smooth muscle through binding to and activating pulmonary beta ₂ receptors. Primary use is a fast-acting reliever (rescue) drug to be used either during an asthma attack or just before engaging in activity that usually triggers an attack.	Teach patient to carry with him or her at all times. Teach patient to monitor heart rate. When taking this drug with other inhaled drugs, teach patient to use this drug at least 5 minutes before the other inhaled drugs. Teach patient the correct technique for using the MDI or DPI, and obtain a return demonstration.	The drug can stop or reduce life-threatening bronchoconstriction, which can occur anytime. Excessive use causes systemic symptoms, especially tachycardia. The bronchodilation effect of the drug allows better penetration of the other inhaled drugs. Correct technique is essential to getting the drug to the site of action. Poor technique allows the drug to escape through the nose and mouth.
Long-Acting Beta₂ Agonist (LABA)			
Salmeterol (Serevent) 2 inhalations every 12 hr (25 mcg/inhalation with MDI) (50 mcg/inhalation with DPI)	Causes bronchodilation by relaxing bronchiolar smooth muscle through binding to and activating pulmonary beta ₂ receptors. Onset of action is slow with a long duration. Primary use is prevention of an asthma attack.	Teach patient to shake inhaler (MDI) well before using. Teach patient to not use this drug with the onset of asthma symptoms or worsening of wheezing. Teach patient the correct technique for using the MDI or DPI, and obtain a return demonstration.	Drug separates easily. Drug has slow onset of action and does not relieve or reverse symptoms. Correct technique is essential to getting the drug to the site of action. Poor technique allows the drug to escape through the nose and mouth.
Cholinergic Antagonist			
Ipratropium (Atrovent), 2-4 inhalations 4-6 times daily (18 mcg/inhalation)	Causes bronchodilation by inhibiting the parasympathetic nervous system, allowing the sympathetic system to dominate, releasing norepinephrine that activates beta ₂ receptors. Purpose is to both relieve and prevent asthma. Drug does not work as well as SABAs but can be used in place of SABAs by patients who cannot tolerate side effects of beta ₂ agonists.	If patient is to use this as a reliever drug, teach him or her to carry it at all times. Teach patient to shake MDI well before using. Teach patient to drink at least 4 L of fluid daily unless another health problem requires fluid restriction. Teach patient to observe for and report blurred vision, eye pain, headache, nausea, palpitations, tremors, inability to sleep. Teach patient the correct technique for using the MDI or DPI, and obtain a return demonstration.	The drug can stop or reduce life-threatening bronchoconstriction, which can occur anytime. Drug separates easily. Drug causes mouth dryness. These are systemic symptoms of overdose and require intervention. Correct technique is essential to getting the drug to the site of action. Poor technique allows the drug to escape through the nose and mouth.
Anti-Inflammatories			
All of these drugs help improve bronchiolar airflow by decreasing the inflammatory response of the mucous membranes in the airways. <i>They do not cause bronchodilation.</i>			

Continued

CHART 32-7 COMMON EXAMPLES OF DRUG THERAPY

Asthma Prevention and Treatment—cont'd

DRUG/USUAL DOSAGE	PURPOSE/ACTION	NURSING INTERVENTIONS	RATIONALE
Corticosteroids			
Fluticasone (Flovent) 50 mcg by MDI twice daily; 100-250 mcg by DPI daily	Disrupts all known production pathways of inflammatory mediators. The main purpose is to prevent an asthma attack caused by inflammation or allergies (controller drug).	Teach patient to use the drug daily, even when no symptoms are present. Teach patient to perform good mouth care and to check the mouth daily for lesions or drainage. Teach patient to not use this drug with the onset of asthma symptoms or worsening of wheezing. Teach patient the correct technique for using the MDI or DPI, and obtain a return demonstration.	Maximum effectiveness requires continued use for 48-72 hr and depends on regular use. Drug reduces local immunity and increases the risk for local infections, especially <i>Candida albicans</i> (yeast). Drug has slow onset of action and does not relieve or reverse symptoms. Correct technique is essential to getting the drug to the site of action. Poor technique allows the drug to escape through the nose and mouth. Knowing the side effects to expect reduces anxiety.
Prednisone (Deltasone, Predone) 1-40 mg orally daily	Not recommended unless asthma symptoms cannot be controlled with any other therapy.	Teach patient about the numerous expected side effects (GI ulceration, fat redistribution, weight gain, hyperglycemia). Teach patient to avoid anyone who has an upper respiratory infection. Teach patient to avoid activities that lead to injury. Teach patient to take drug with food. Teach patient not to suddenly stop taking the drug for any reason. If patient cannot take the oral drug because of vomiting, he or she should receive the drug parenterally.	Drug reduces all protective inflammatory responses, increasing the risk for infection. Blood vessels become more fragile, leading to bruising and petechiae. The drug increases the risk for GI ulceration; food helps reduce the risk. The drug suppresses adrenal production of corticosteroids, which are essential for life.
Cromone			
Nedocromil (Tilade) 4 mg by MDI every 6 hr	Stabilizes the membranes of mast cells and prevents the release of inflammatory mediators. Purpose is to prevent asthma attack triggered by inflammation or allergens.	Teach patient to use the drug daily, even when no symptoms are present. Teach patient to not use this drug with the onset of asthma symptoms or worsening of wheezing. Teach patient the correct technique for using the MDI, and obtain a return demonstration.	Drug has slow onset of action for asthma prevention and is most effective when taken consistently. Drug does not relieve or reverse symptoms. Correct technique is essential to getting the drug to the site of action. Poor technique allows the drug to escape through the nose and mouth.
Leukotriene Modifier			
Montelukast (Singulair) 10 mg orally daily	Blocks the leukotriene receptor, preventing the inflammatory mediator from stimulating inflammation. Purpose is to prevent asthma attack triggered by inflammation or allergens.	Teach patient to use the drug daily, even when no symptoms are present. Teach patient not to decrease the dose of or stop taking any other asthma drugs unless otherwise instructed by the health care professional.	Drug has slow onset of action for asthma prevention and is most effective when taken consistently. This drug is for long-term asthma control and does not replace other drugs, especially corticosteroids and reliever (rescue) drugs.

From National Institutes of Health. (2007). *Guidelines for the diagnosis and management of asthma*. Expert panel report 3. Bethesda, MD: U.S. Department of Health and Human Services.
DPI, Dry powder inhaler; MDI, metered dose inhaler.

(prevention) and relief (rescue) therapy of asthma. The actions, interventions, and rationales for most drugs within a single class are similar although drug dosages may differ. Be sure to consult a pharmacology text or drug handbook for more information on a specific drug.

Bronchodilators. Bronchodilators increase bronchiolar smooth muscle relaxation. They have no effect on inflammatory processes. Thus when a patient with asthma has airflow obstruction by both bronchospasm and inflammation, at least two types of drug therapy are needed. Some bronchodilators work by stimulating the beta₂-adrenergic receptors on bronchial smooth muscle in much the same way that the sympathetic nervous system transmitters *epinephrine* and *norepinephrine* do; others work by blocking the parasympathetic nervous system. Bronchodilators include beta₂ agonists and cholinergic antagonists.

Beta₂ agonists bind to the beta₂-adrenergic receptors and cause an increase in the intracellular level of a substance called *cyclic adenosine monophosphate (cAMP)*. This substance sets pathways into motion that trigger smooth muscle relaxation.

Short-acting beta₂ agonists (SABAs) provide rapid but short-term relief. These inhaled drugs are most useful when an attack begins (as relief) or as premedication when the patient is about to begin an activity that is likely to induce an attack (GINA, 2010). Such agents include albuterol (Proventil, Ventolin), bitolterol (Tornalate), levalbuterol (Xopenex), pirbuterol (Maxair), and terbutaline (Brethaire). When inhaled from either a metered dose inhaler (MDI) or a dry powder inhaler (DPI), the drug is delivered directly to the site of action and systemic effects are minimal (unless the agent is overused). Teach the patient the correct technique for using an inhaled drug to achieve the greatest benefit. Chart 32-8 describes the proper way to use an MDI. Fig. 32-5 shows a patient using a “spacer” with an MDI. Spacer use increases

the amount of drug delivered to the lungs. Chart 32-9 describes the proper care and use of a DPI. Fig. 32-6 shows a patient using a DPI.

Dry powder inhalers indicate the amount of remaining drug; however, aerosol inhalers (MDIs) do not. Demonstrate how to check approximate aerosol inhaler drug levels by placing the inhaler in water (Fig. 32-7). Full inhalers sink to the bottom. An empty inhaler floats on its side. *This technique is controversial because it is only a general approximation.* The more recommended technique is for the patient to count the number of doses as they are used; however, many patients have difficulty keeping the dose count accurate.

Long-acting beta₂ agonists (LABAs) are also delivered by inhaler directly to the site of action—the bronchioles. Proper

CHART 32-8 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

How to Use an Inhaler Correctly*

With a Spacer (Preferred Technique)

1. Before each use, remove the caps from the inhaler and the spacer.
2. Insert the mouthpiece of the inhaler into the non-mouthpiece end of the spacer.
3. Shake the whole unit vigorously three or four times.
4. Place the mouthpiece into your mouth, over your tongue, and seal your lips tightly around it.
5. Press down firmly on the canister of the inhaler to release one dose of medication into the spacer.
6. Breathe in slowly and deeply. If the spacer makes a whistling sound, you are breathing in too rapidly.
7. Remove the mouthpiece from your mouth, and, keeping your lips closed, hold your breath for at least 10 seconds and then breathe out slowly.
8. Wait at least 1 minute between puffs.
9. Replace the caps on the inhaler and the spacer.
10. At least once a day, clean the plastic case and cap of the inhaler by thoroughly rinsing in warm, running tap water; at least once a week, clean the spacer in the same manner.

Without a Spacer (Primary Method)

1. Before each use, remove the cap and shake the inhaler according to the instructions in the package insert.
2. Tilt your head back slightly, and breathe out fully.
3. Open your mouth, and place the mouthpiece 1 to 2 inches away.
4. As you begin to breathe in deeply through your mouth, press down firmly on the canister of the inhaler to release one dose of medication.
5. Continue to breathe in slowly and deeply (usually over 3-5 sec).
6. Hold your breath for at least 10 seconds to allow the medication to reach deep into the lungs, and then breathe out slowly.
7. Wait at least 1 minute between puffs.
8. Replace the cap on the inhaler.
9. At least once a day, remove the canister and clean the plastic case and cap of the inhaler by thoroughly rinsing in warm, running tap water.

Without a Spacer (Alternative Method)

1. Follow steps 1 and 2 of the primary method for using an inhaler without a spacer.
2. Place the mouthpiece into your mouth, over your tongue, and seal your lips tightly around it.
3. Follow steps 4 to 9 of the primary method for using an inhaler without a spacer.

*Avoid spraying in the direction of the eyes.

! NURSING SAFETY PRIORITY

Action Alert

Teach the patient with asthma to always carry the relief drug inhaler with him or her and to ensure that enough drug remains in the inhaler to provide a quick dose when needed.

FIG. 32-5 Patient using an aerosol inhaler with a spacer.

CHART 32-9 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

How to Use a Dry Powder Inhaler (DPI)

For Inhalers Requiring Loading

- First load the drug by:
 - Turning the device to the next dose of drug, or
 - Inserting the capsule into the device, or
 - Inserting the disk or compartment into the device

After Loading the Drug and for Inhalers That Do Not Require Drug Loading

- Read your doctor's instructions for how fast you should breathe for your particular inhaler.
- Place your lips over the mouthpiece, and breathe in forcefully (there is no propellant in the inhaler; only your breath pulls the drug in).
- Remove the inhaler from your mouth as soon as you have breathed in.
- *Never exhale (breathe out) into your inhaler.* Your breath will moisten the powder, causing it to clump and not be delivered accurately.
- *Never wash or place the inhaler in water.*
- *Never shake your inhaler.*
- Keep your inhaler in a dry place at room temperature.
- If the inhaler is preloaded, discard the inhaler after it is empty.
- Because the drug is a dry powder and there is no propellant, you may not feel, smell, or taste it as you inhale.

FIG. 32-6 Patient using a dry powder inhaler (DPI).

use of the long-acting agonists can decrease the need to use reliever (rescue) drugs as often. Unlike short-acting agonists, long-acting drugs need time to build up an effect but the effects are longer lasting. *Thus these drugs are useful in preventing an asthma attack but have no value during an acute attack. Therefore teach patients not to use LABAs alone to relieve (rescue) them during an attack or when wheezing is getting worse but, instead, to use a SABA. Relying on LABAs during an attack can lead to worsening of symptoms and death (Aschenbrenner, 2010).* Examples of LABAs include formoterol (Foradil) and salmeterol (Serevent). *These drugs are never prescribed as the **only** drug therapy for asthma. Teach the patient to use these control drugs daily as prescribed, even when no symptoms are present.*

FIG. 32-7 Checking the approximate drug level in an aerosol inhaler by placing it in water.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

A client reaches for the salmeterol (Serevent) inhaler with the onset of an asthma attack. What is the nurse's best action?

- Instruct the client to use the albuterol (Proventil) inhaler instead.
- Assist the client to use oxygen for three breaths between the two puffs of the inhaled drug.
- Instruct the client to attach the spacer to the inhaler before using it and inhale as rapidly as possible.
- Remind the client to take a deep breath, hold it for 15 seconds, and then exhale before using the inhaler.

*Cholinergic antagonists, also called **anticholinergic drugs**, are similar to atropine and block the parasympathetic nervous system. This blockade allows the sympathetic nervous system to dominate, resulting in increased bronchodilation and decreased pulmonary secretions. The most common drug in this class is ipratropium (Atrovent), which is used as an inhalant. Most cholinergic antagonists are short acting and must be used several times a day, although long-acting agents such as tiotropium (Spiriva) are available for use once a day. These drugs are not as effective as beta₂ agonists and are recommended as first-line asthma control therapy only for those patients who cannot tolerate the side effects of beta₂ agonists.*

Xanthines, such as theophylline and aminophylline, are used only when other types of management are ineffective. These drugs are given systemically, and the dosage that is effective is close to the dosage that produces many dangerous side effects. Blood levels must be monitored closely to ensure the drug level is within the therapeutic range.

Anti-Inflammatory Agents. Anti-inflammatory agents decrease the inflammatory responses in the airways. Those given systemically have more side effects. Others are used as inhalants and have fewer systemic side effects.

Corticosteroids decrease inflammatory and immune responses in many ways, including by preventing the synthesis of mediators. Inhaled corticosteroids (ICSs) can be helpful in controlling (preventing) the manifestations of asthma. Newer high-potency steroid inhalers, such as fluticasone (Flovent), budesonide (Pulmicort), and mometasone (Asmanex), may be used once per day for maintenance. Systemic corticosteroids, because of severe side effects, are

avoided for mild to moderate intermittent asthma and are used on a short-term basis for moderate asthma. For some patients with severe asthma, daily oral corticosteroids may be needed. *Both inhaled corticosteroids and those taken orally are control drugs (preventive). They are not effective in reversing symptoms during an asthma attack and should not be used as reliever (rescue) drugs. Teach patients the difference between ICSs and relief drug inhalers. Control drugs must be used on a scheduled basis, even when asthma symptoms are not present.*

Cromones, both those that are inhaled and those that are taken orally, are useful as *preventive* asthma therapy when taken on a scheduled basis. These agents have different mechanisms of action to reduce airway inflammation. Nedocromil (Tilade) inhibits the release of inflammatory mediators from respiratory cells and WBCs. Mast cell stabilizers, such as cromolyn sodium (Intal), prevent mast cell membranes from opening when an allergen binds to IgE. Thus these drugs help prevent atopic asthma attacks but are not useful during an acute episode. *The inhaled cromones are not effective in reversing symptoms during an asthma attack and should not be used as reliever (rescue) drugs.*

Leukotriene modifiers are oral drugs that work in several ways to prevent an asthma episode when taken on a scheduled basis. Montelukast (Singulair) and zafirlukast (Accolate) block the leukotriene receptor. Zileuton (Zyflo) prevents leukotriene synthesis. *These drugs do not reverse symptoms during an asthma attack and should not be used as reliever (rescue) drugs.*

Anti-IgE agents are monoclonal antibodies directed against part of the immunoglobulin E (IgE) structure. When these agents bind to IgE molecules that have allergens attached to them, the complex cannot bind to mast cells and basophils. This action prevents the IgE-allergen complex from triggering the release of mediators from mast cells and basophils. Thus these drugs help *prevent* atopic asthma attacks but are not useful during an acute episode. Omalizumab (Xolair) is currently the only drug in this class and is used only for people with asthma who have high blood levels of IgE. It is injected subcutaneously every 2 to 3 weeks.

! NURSING SAFETY PRIORITY

Drug Alert

There is a high risk for anaphylaxis from omalizumab. Administer it only in a setting capable of managing this type of reaction.

Exercise/Activity

Regular exercise is a recommended part of asthma therapy (Holcomb, 2008). Aerobic exercise assists in maintaining cardiac health, enhancing skeletal muscle strength, and promoting ventilation and perfusion. Teach patients with asthma to examine the conditions that trigger an attack and adjust the exercise routine as needed. Some may need to premedicate with inhaled SABAs before beginning activity. For others, adjusting the environment may be needed (e.g., changing from outdoor ice-skating in cold, dry air to indoor ice-skating).

Oxygen Therapy

Supplemental oxygen is often used during an acute asthma attack. Oxygen is delivered by mask, nasal cannula, or endotracheal tube. High flow rates or concentrations may be needed when bronchospasms are severe and limit flow of

oxygen through the bronchiole tubes. Heliox, a mixture of helium and oxygen (often 50% helium and 50% oxygen), can help improve oxygen delivery to the alveoli. This gas mixture is lower in density than oxygen alone or room air and flows even when airway resistance is high.

! NURSING SAFETY PRIORITY

Action Alert

Ensure that no open flames (e.g., cigarette smoking, fireplaces, burning candles) or other combustion hazards are in rooms where oxygen is in use.

Status Asthmaticus

Status asthmaticus is a severe, life-threatening acute episode of airway obstruction that intensifies once it begins and often does not respond to usual therapy. The patient arrives in the emergency department with extremely labored breathing and wheezing. Use of accessory muscles for breathing and distention of neck veins are observed. *If the condition is not reversed, the patient may develop pneumothorax and cardiac or respiratory arrest.* IV fluids, potent systemic bronchodilators, steroids (to decrease inflammation), epinephrine, and oxygen are administered immediately to reverse the acute condition. Prepare for emergency intubation. Sudden absence of wheezing may indicate complete airway obstruction and require a tracheotomy. When breathing improves and wheezing decreases, management is similar to that for any patient with asthma.

? DECISION-MAKING CHALLENGE

Patient-Centered Care; Evidence-Based Practice; Safety

The patient is a 22-year-old college student who has had asthma since childhood. She is being managed with fluticasone (Flovent) 50 mcg/puff, 2 puffs twice daily; salmeterol (Serevent) 1 puff twice daily; albuterol (Ventolin) 1-2 puffs every 4-6 hours as needed for wheezing. She reports that she is using the fluticasone and salmeterol as prescribed but needs to use the albuterol about every 2 hours. She also tells you that she is having difficulty sleeping and feels "like my heart is skipping some beats." Her vital signs are BP, 136/88; P, 96 and irregular; R, 30, with slight wheezing on exhalation. Her oxygen saturation is 92%, and you notice that she has a slight tremor in both hands.

1. What additional physical manifestations should you assess?
2. What questions should you ask?
3. Should you administer oxygen? Why or why not?
4. At what "step" is her current asthma management?
5. What information indicates this step is effective or ineffective?

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Pathophysiology

Chronic obstructive pulmonary diseases (COPD) include emphysema and chronic bronchitis. Although these are separate disorders with different pathologic processes, many patients with emphysema also have chronic bronchitis at the same time (Fig. 32-8).

Emphysema

The two major changes that occur with emphysema are loss of lung elasticity and hyperinflation of the lung (see Fig. 32-1). These changes result in dyspnea and the need for an increased respiratory rate.

In the healthy lung, protein degrading enzymes called *proteases* are present to destroy and eliminate particulates and organisms inhaled during breathing. If these proteases are present in higher-than-normal levels, they damage the alveoli and the small airways by breaking down elastin. High protease levels cause the alveolar sacs to lose their elasticity and the small airways to collapse or narrow. Some alveoli are destroyed, and others become large and flabby, with decreased area for effective gas exchange.

An increased amount of air is trapped in the lungs. Causes of air trapping are loss of elastic recoil in the alveolar walls, overstretching and enlargement of the alveoli into air-filled spaces called *bullae*, and collapse of small airways (bronchioles). These changes greatly increase the work of breathing. The hyperinflated lung flattens the diaphragm (Fig. 32-9), weakening the effect of this muscle. As a result, the patient with emphysema needs to use additional muscles (accessory muscles) in the neck, chest wall, and abdomen to inhale and exhale. This increased effort increases the need for oxygen, making the patient work harder and have an “air hunger”

FIG. 32-8 The interaction of chronic bronchitis and emphysema in chronic obstructive pulmonary disease (COPD).

sensation. Often, inhalation starts before exhalation is completed, resulting in an uncoordinated pattern of breathing.

Oxygenation is affected by the increased work of breathing and the loss of alveolar tissue. Although some alveoli enlarge, the curves of alveolar walls decrease and less surface area is available for gas exchange. Often the patient adjusts by increasing the respiratory rate, so arterial blood gas (ABG) values may not show gas exchange problems until the patient has advanced disease. Then carbon dioxide is produced faster than it can be eliminated, resulting in carbon dioxide retention and chronic respiratory acidosis (see Chapter 14). The patient with late-stage emphysema also has a low arterial oxygen (P_{aO_2}) level, because it is difficult for oxygen to move from diseased alveoli into the blood.

Emphysema is classified as *panlobular*, *centrilobular*, or *paraseptal* depending on the pattern of destruction and dilation of the gas-exchanging units (acini) (see Fig. 32-1). Each type can occur alone or in combination in the same lung. Most are associated with smoking or chronic exposure to other inhalation irritants.

Chronic Bronchitis

Bronchitis is an inflammation of the bronchi and bronchioles caused by exposure to irritants, especially cigarette smoke. The irritant triggers inflammation, vasodilation, mucosal edema, congestion, and bronchospasm. Bronchitis affects only the airways, not the alveoli.

Chronic inflammation increases the number and size of mucous glands, which produce large amounts of thick mucus. The bronchial walls thicken and impair airflow. This thickening, along with excessive mucus, blocks some of the smaller airways and narrows larger ones. Smaller airways are involved first. In addition, the increased mucus provides a breeding ground for microorganisms and leads to chronic low-grade infection.

Chronic bronchitis hinders airflow and gas exchange because of mucus plugs and infection narrowing the airways.

FIG. 32-9 Diaphragm shape and lung inflation in the normal patient and in the patient with chronic airflow limitation (CAL), especially chronic obstructive pulmonary disease (COPD).

As a result, the Pao_2 decreases (hypoxemia) and the arterial blood carbon dioxide ($Paco_2$) level increases (respiratory acidosis).

Etiology and Genetic Risk

Cigarette smoking is the greatest risk factor for COPD. The patient with an 8-pack-year history usually has obstructive lung changes but no manifestations of disease. The patient with a 20-pack-year history or longer often has early-stage COPD with changes in pulmonary function tests (PFTs).

The harmful effects of tobacco occur because inhaled smoke triggers the release of excessive amounts of the proteases from cells in the lungs. These enzymes break down elastin, the major component of alveoli. By impairing the action of cilia, smoking also inhibits the cilia from clearing the bronchi of mucus, cellular debris, and fluid.

In addition to the increased risk for COPD from active smoking, passive smoking (or secondhand smoke), as well as smoke that clings to hair and clothing (sometimes called “thirdhand” smoke), contributes to upper and lower respiratory problems. The risk is greater when exposure occurs in small, confined spaces.

CULTURAL AWARENESS

The prevalence of smoking remains higher among African Americans, blue-collar workers, and less educated people than in the overall population of the United States. Smoking prevalence is highest among Northern Plains American Indians and Alaskan Natives. Development of culturally appropriate smoking-cessation programs as well as research examining barriers to cessation in these populations may help reduce this disparity.

Alpha₁-antitrypsin deficiency is a less common but important risk factor for COPD. A special enzyme, alpha₁-antitrypsin (AAT), is normally present in the lungs. One purpose of AAT is to regulate the proteases that are present to break down inhaled pollutants and organisms. AAT, a protease inhibitor, prevents the proteases from working on lung structures.

The production of normal amounts of AAT depends on the inheritance of a pair of normal gene alleles for this protein. The AAT gene is recessive. Thus if one of the pair of alleles is faulty and the other allele is normal, the person makes enough AAT to prevent COPD unless there is significant exposure to cigarette smoke and other precipitating factors. This person, however, is a carrier for AAT deficiency. If both alleles are faulty, COPD develops at a fairly young age even when the person is not exposed to cigarette smoke or other irritants.

About 100,000 Americans have severe AAT deficiency, and many more have mild to moderate deficiencies (Nussbaum et al., 2007). Although an AAT deficiency also can cause problems in the skin and liver, lung diseases are more common.

GENETIC/GENOMIC CONSIDERATIONS

The gene for AAT has many known mutations, some of which increase the risk for emphysema. Variation of mutations (polymorphisms) results in different levels of AAT deficiency. This variation is one reason why the disease is more severe for some people than for others. The most serious mutation for an increased risk for emphysema is the Z mutation, although others also increase the risk but to a lesser degree. Table 32-1 shows the most common AAT mutations increasing the risk for emphysema.

TABLE 32-1 CHARACTERISTICS ASSOCIATED WITH THE MOST COMMON ALPHA₁-ANTITRYPSIN GENE MUTATIONS

MUTATION GENOTYPE	LEVEL OF SERUM ALPHA ₁ -ANTITRYPSIN (% OF NORMAL)	DISEASE SEVERITY
M/S	80%	No detectable disease
S/S	50%-60%	Minimal to no disease expression
M/Z	50%-55%	Minimal to no disease expression
S/Z	30%-35%	Pulmonary disease, early age
Z/Z	10%-15%	Severe COPD, extra-pulmonary involvement

From Workman, M.L., & Winkelman, C. (2008). Genetic influences in common respiratory disorders. *Critical Care Nursing Clinics of North America*, 20(2), 171-189. COPD, Chronic obstructive pulmonary disease.

Incidence/Prevalence

The prevalence of chronic bronchitis and emphysema in the United States has been estimated at about 13.5 million (for chronic bronchitis) and 2 million (for emphysema). Chronic obstructive pulmonary disease (COPD) is the fourth leading cause of morbidity and mortality in the United States ([Global Initiative for Chronic Obstructive Lung Disease \[GOLD\]](#), 2009).

Complications

COPD affects *oxygenation* of all tissues. Complications can result in tissue anoxia and death. Major problems occur, such as hypoxemia, acidosis, respiratory infection, cardiac failure, and dysrhythmias.

Hypoxemia and acidosis occur because the patient with COPD has reduced gas exchange, leading to decreased oxygenation and increased carbon dioxide levels. These problems reduce cellular function.

Respiratory infection risk increases because of the increased mucus and poor oxygenation. Bacterial infections with *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis* are common. Acute lung infections make COPD manifestations worse by increasing inflammation and mucus production and inducing more bronchospasm. Airflow becomes even more limited, the work of breathing increases, and dyspnea results.

Cardiac failure, especially **cor pulmonale** (right-sided heart failure caused by pulmonary disease), occurs with bronchitis or emphysema. Air trapping, airway collapse, and stiff alveolar walls increase the lung tissue pressure, making blood flow through lung vessels more difficult. The increased pressure creates a heavy workload on the right side of the heart, which pumps blood into the lungs. As the disease progresses, the amount of oxygen in the blood decreases, causing major blood vessels in the lung to constrict. To pump blood through these narrowed vessels, the right side of the heart generates high pressures. In response to this heavy workload, the right chambers of the heart enlarge and thicken, causing right-sided heart failure with backup of blood into the general venous system. [Chart 32-10](#) lists key features of cor pulmonale.

CHART 32-10 KEY FEATURES

Cor Pulmonale

- Hypoxia and hypoxemia
- Increasing dyspnea
- Fatigue
- Enlarged and tender liver
- Warm, cyanotic hands and feet, with bounding pulses
- Cyanotic lips
- Distended neck veins
- Right ventricular enlargement (hypertrophy)
- Visible pulsations below the sternum
- GI disturbances, such as nausea or anorexia
- Dependent edema
- Metabolic and respiratory acidosis
- Pulmonary hypertension

Cardiac dysrhythmias are common in patients with COPD. They result from hypoxemia (from decreased oxygen to the heart muscle), other cardiac disease, drug effects, or acidosis.

Health Promotion and Maintenance

The incidence and severity of COPD would be greatly reduced by smoking cessation. COPD is rare among people who have never smoked cigarettes. Disease progression can be slowed by smoking cessation. Urge all people who smoke to quit smoking. [Chart 32-4](#) provides tips to teach people about smoking cessation.

Other measures to reduce the incidence of COPD are to avoid inhalation irritants in all environments. Teaching all people to use masks when working in areas with high levels of particulate matter can reduce individual exposure. Proper venting of workplaces and recreation areas that have airborne or particulate matter also reduces exposure.

PATIENT-CENTERED COLLABORATIVE CARE

The Concept Map on p. 615 addresses assessment and nursing care issues related to COPD.

ASSESSMENT**History**

Ask about risk factors such as age, gender, occupational history, and ethnic-cultural background. COPD is seen more often in older men. Some types of emphysema occur in families, especially those with α_1 -antitrypsin (AAT) deficiency.

Obtain a thorough smoking history, because tobacco use is a major risk factor. Ask about the length of time the patient has smoked and the number of packs smoked daily. Use these data to determine the pack-year smoking history.

Ask the patient to describe his or her breathing problems. Assess whether the patient has any difficulty breathing while talking. Can he or she speak in complete sentences, or is it necessary to take a breath between every one or two words? Ask about the presence, duration, or worsening of wheezing, coughing, and shortness of breath. Determine what activities trigger these problems. Assess the patient's cough, and ask whether sputum is clear or colored and how much is produced each day. Ask about the time of day when sputum production is greatest. Smokers often have a productive

FIG. 32-10 Orthopnea positions that patients with chronic obstructive pulmonary disease (COPD) often assume to ease the work of breathing.

cough when they get up in the morning; nonsmokers generally do not. Ask whether sputum production has increased or changed during the past year.

Check the relationship between activity tolerance and dyspnea by asking the patient to compare the activity level and shortness of breath now with those of a month ago and a year ago. Ask about any difficulty with eating and sleeping. Many patients sleep in a semi-sitting position because breathlessness is worse when lying down (**orthopnea**). Ask about usual daily activities and any difficulty with sleeping, bathing, dressing, or sexual activity. Document this initial assessment to personalize the intervention plan.

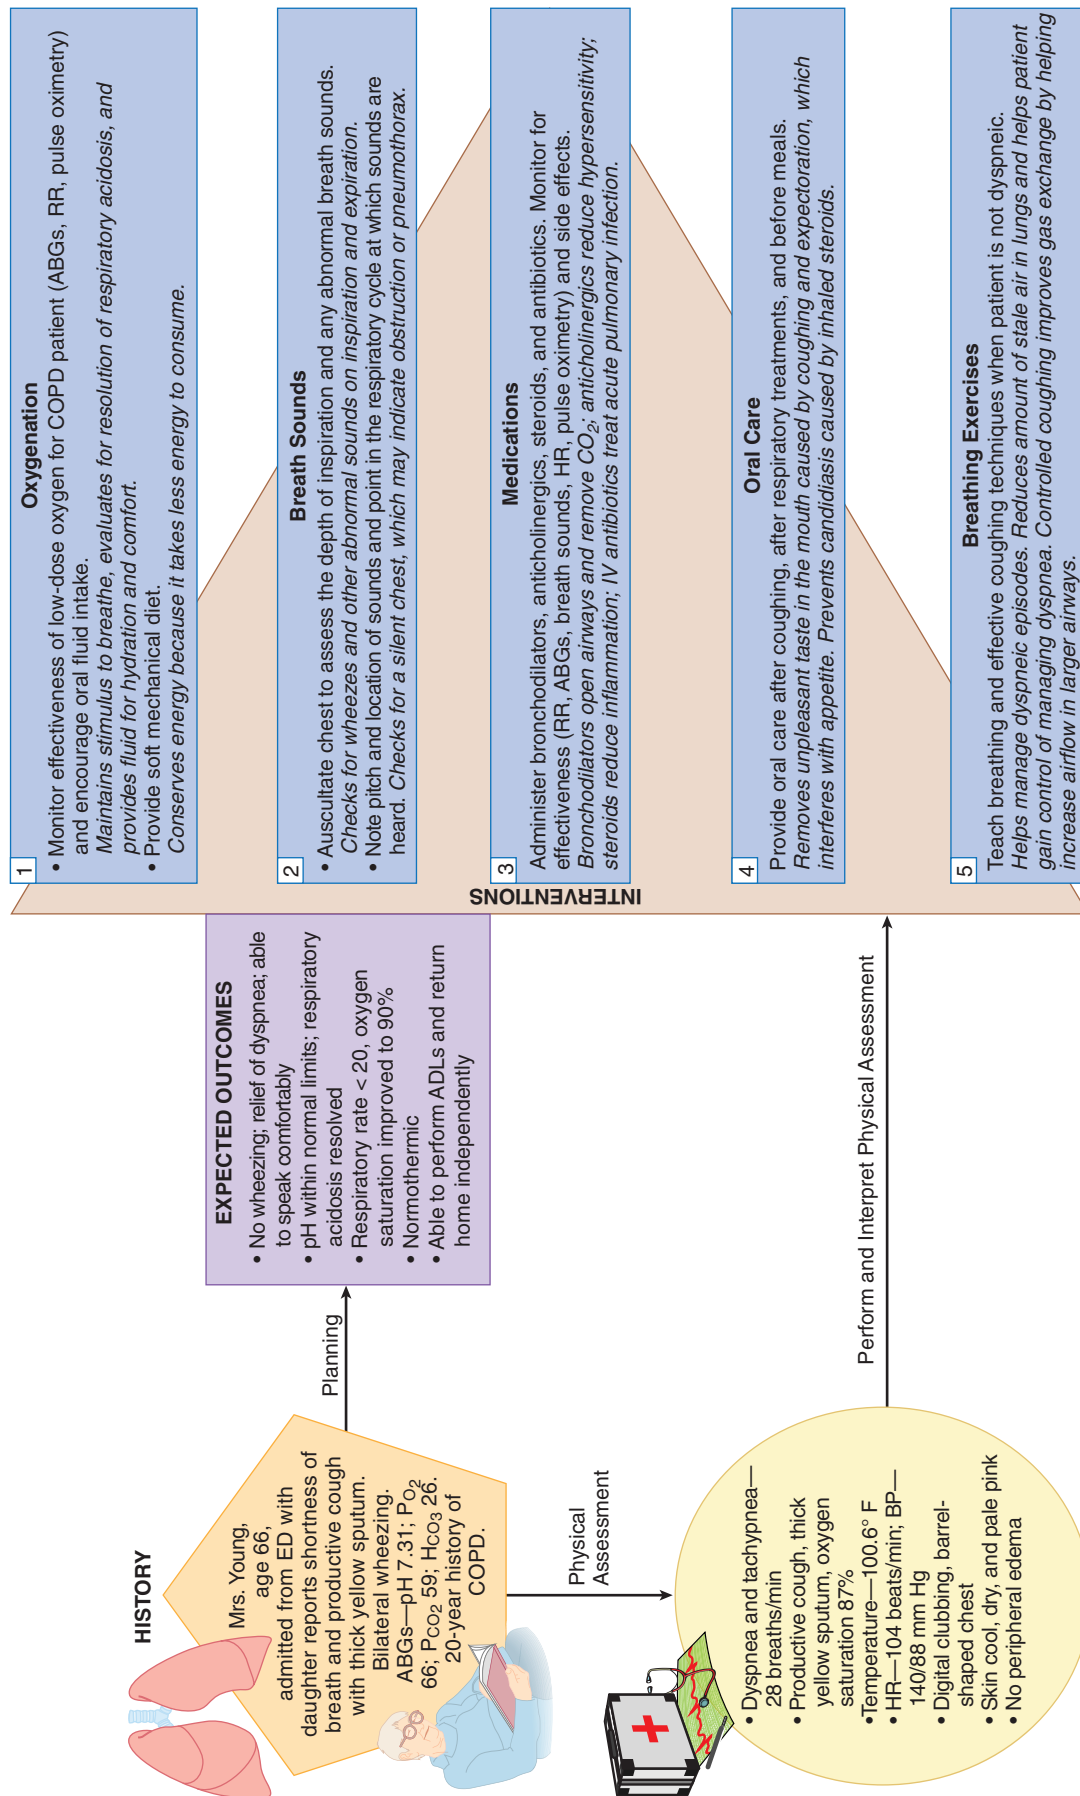

Weigh the patient, and compare this weight with previous weights. Unplanned weight loss is likely when COPD severity increases, because the work of breathing increases metabolic needs. Dyspnea and mucus production often result in poor food intake and inadequate nutrition. Ask the patient to recall a typical day's meals and fluid intake. When heart failure is present with COPD, general edema with weight gain may occur.

Physical Assessment/Clinical Manifestations

General appearance can provide clues about the patient's respiratory status and energy level. Observe weight in proportion to height, posture, mobility, muscle mass, and overall hygiene. The patient with increasingly severe COPD is thin, with loss of muscle mass in the extremities, although the neck muscles may be enlarged. He or she tends to be slow moving and slightly stooped. Usually the person sits with a forward-bending posture, sometimes with the arms held forward, a position known as the *orthopneic* or *tripod position* ([Fig. 32-10](#)). When dyspnea becomes severe, activity intolerance may be so great that bathing and general grooming are neglected.

Respiratory changes occur as a result of obstruction, changes in chest size, and fatigue. Inspect the chest to assess the breathing rate and pattern. The patient with respiratory

Concept Map: Respiratory Acidosis (COPD-Related)

muscle fatigue breathes with rapid, shallow respirations, and may have an abnormal breathing pattern in which the abdominal wall is sucked in during inspiration, or may use accessory muscles in the abdomen or neck. The respiratory rate could be as high as 40 to 50 breaths/min. The breathing patterns often seen with respiratory muscle fatigue use abdominal muscles and the intercostal muscles more than the diaphragm. Respiratory movement is jerky and appears uncoordinated.

Check the patient's chest for abnormal retractions and for asymmetric chest expansion. The patient with emphysema has limited diaphragmatic movement (excursion) because the diaphragm is flattened and below its usual resting state. Chest vibration (fremitus) is often decreased and the chest sounds hyperresonant on percussion because of trapped air.

Auscultate the chest to assess the depth of inspiration and any abnormal breath sounds. Wheezes and other abnormal sounds occur with emphysema and chronic bronchitis, often on inspiration and expiration, although crackles are usually not present. Reduced breath sounds are common, especially with emphysema. Note the pitch and location of the sound and the point in the respiratory cycle at which the sound is heard. A silent chest may indicate serious airflow obstruction or pneumothorax.

Assess the degree of dyspnea using an assessment tool called a *Visual Analog Dyspnea Scale (VADS)*. The VADS is a straight line with verbal anchors at the beginning and end of a 100-mm line. Ask the patient to place a mark on the line to indicate his or her perceived breathing difficulty (Fig. 32-11). Document the response, and use this scale to assess dyspnea, determine the therapy effectiveness, and pace the patient's activities.

Examine the patient's chest for the presence of a "barrel chest" (see Fig. 32-3). With a barrel chest, the ratio between the anteroposterior (AP) diameter of the chest and its lateral diameter is 2:2 rather than the normal ratio of 1:1.5. This shape change results from lung overinflation and diaphragm flattening.

The patient with chronic bronchitis often has a cyanotic, or blue-tinged, dusky appearance and has excessive sputum production. Assess for cyanosis, delayed capillary refill, and finger clubbing (Fig. 32-12), which indicate chronically decreased arterial oxygen levels.

Cardiac changes occur as a result of the anatomic changes associated with COPD. Assess the patient's heart rate and rhythm. Check for swelling of the feet and ankles (dependent edema) or other manifestations of right-sided heart failure. Examine nail beds and oral mucous membranes.

FIG. 32-11 A visual analog scale to assess dyspnea.

The patient with later-stage emphysema may have pallor or frank cyanosis.

Psychosocial Assessment

COPD affects all aspects of a person's life. Socialization may be reduced when friends and family avoid the patient with COPD because of annoying coughs, excessive sputum, or dyspnea. The patient may be isolated because dyspnea causes fatigue or because of embarrassment from coughing and excessive sputum production.

Ask the patient about interests and hobbies to assess whether socialization has decreased or whether hobbies cause exposure to irritants. Ask about home conditions for exposure to smoke or crowded living conditions that promote transmission of respiratory infections.

Economic status may be affected by the disease through changes in income and health insurance coverage. Severe COPD may require role changes that have a negative impact on self-image. Drugs, especially the metered dose inhalers (MDIs) and dry powder inhalers (DPI), are expensive, and many patients with limited incomes may use them only during exacerbations and not as prescribed on a scheduled basis.

Anxiety and fear related to dyspnea and feelings of breathlessness may reduce the patient's ability to participate in a full life. Work, family, social, and sexual roles can be affected. Encourage the patient and family to express their feelings about the limitations on lifestyle and disease progression. Assess their awareness and use of support groups and services.

Laboratory Assessment

Arterial blood gas (ABG) values identify abnormal oxygenation, ventilation, and acid-base status. Compare serial or repeated ABG values to assess changes in the patient's respiratory status. Once baseline ABG values are obtained, pulse oximetry can gauge the response to treatment. As COPD worsens, the amount of oxygen in the blood decreases (**hypoxemia**) and the amount of carbon dioxide in the blood increases (**hypercarbia**). Chronic respiratory acidosis (increased arterial carbon dioxide [PaCO_2]) then results; metabolic alkalosis (increased arterial bicarbonate) occurs as compensation by kidney retention of bicarbonate. This change is seen on ABGs as an elevation of HCO_3^- , although

FIG. 32-12 Late digital clubbing (on left) compared with a normal digit (on right).

pH remains lower than normal. Not all patients with COPD are carbon dioxide retainers, even when hypoxemia is present. Carbon dioxide diffuses more easily across lung membranes than does oxygen. Hypercapnia is a problem in advanced emphysema (because the alveoli are affected) rather than in bronchitis (wherein the airways are affected). For more detailed information about acidosis, see [Chapter 14](#).

Sputum samples are obtained for culture from hospitalized patients with an acute respiratory infection. The infection is treated on the basis of manifestations and the common bacterial organisms. A WBC count helps confirm the presence of infection.

Other blood tests include hemoglobin and hematocrit to determine *polycythemia* (a compensatory increase in red blood cells [RBCs] in the chronically hypoxic patient). Serum electrolyte levels are examined because acidosis can change electrolyte values. Low phosphate, potassium, calcium, and magnesium levels reduce muscle strength. In patients with a family history of COPD, serum AAT levels may be drawn.

Imaging Assessment

Chest x-rays are used to rule out other lung diseases and to check the progress of patients with respiratory infections or chronic disease. With advanced emphysema, chest x-rays show hyperinflation and a flattened diaphragm.

Other Diagnostic Assessments

COPD is classified from mild to severe on the basis of manifestations and pulmonary function test (PFT) changes ([Table 32-2](#); see also [Table 29-6](#) in [Chapter 29](#)). Airflow

rates and lung volume measurements help distinguish airway disease (obstructive disease) from interstitial lung disease (restrictive diseases). PFTs determine lung volumes, flow volume curves, and diffusion capacity. Each test is performed before and after the patient inhales a bronchodilator agent. The person being tested for COPD usually has some manifestations and may be anxious about the potential diagnosis. Encourage the patient to express his or her feelings about testing and the potential impact of the results. Explain the preparations for the procedures (if any), whether pain or discomfort will be involved, and any needed follow-up care.

The lung volumes measured for COPD are vital capacity (VC), residual volume (RV), and total lung capacity (TLC) (see [Table 29-6](#) in [Chapter 29](#)). RV is most profoundly affected, although all volumes and capacities change to some degree in COPD. The RV increase reflects the trapped, stale air remaining in the lungs.

Flow volume curves measure the patient's ability to move air into and out from the lungs. The rate of airflow out of the lungs during a rapid, forceful, and complete exhalation from TLC to RV (forced expiratory volume [FEV]) indirectly measures the flow resistance of the lung. A diagnosis of COPD is based mostly on the FEV₁ (the FEV in the first second of exhalation). FEV₁ can also be expressed as a percentage of the forced vital capacity (FVC). As the disease progresses, the ratio of FEV₁ to FVC becomes smaller ([Smith & Tasota, 2011](#)).

The diffusion test measures how well a test gas (carbon monoxide) diffuses across the alveolar-capillary membrane and combines with the hemoglobin of red blood cells. In emphysema, alveolar wall destruction decreases the large surface area for diffusion of gas into the blood, leading to a decreased diffusion capacity. In bronchitis, even though lung volumes are increased, the diffusion capacity is usually normal.

The patient with COPD has decreased oxygen saturation, often much lower than 90%. Changes in pulse oximetry results below the patient's usual saturation require medical attention.

Peak expiratory flowmeters are used to monitor the effectiveness of the prescribed drugs to relieve obstruction. Peak flow rates increase as obstruction resolves. Teach the patient to self-monitor the peak expiratory flow rates at home and adjust drugs as needed.

TABLE 32-2 CLASSIFICATION OF COPD SEVERITY

STAGE	MANIFESTATIONS	PULMONARY FUNCTION TEST RESULTS
0 (At risk)	±Chronic cough ±Chronic sputum production +Exposure to environmental risk factors	Normal
I (Mild)	+Chronic cough ±Sputum production	FEV ₁ /FVC <70% FEV ₁ <80% of predicted
II (Moderate)	±Dyspnea ±Chronic cough ±Sputum production	FEV ₁ /FVC <70% FEV ₁ <80% but at least <50% of predicted
III (Severe)	+Dyspnea +Chronic cough +Sputum production	FEV ₁ /FVC <70% FEV ₁ <50% but at least <30% of predicted
IV (Very severe)	++Dyspnea ++Chronic cough ++Sputum production	FEV ₁ /FVC <70% FEV ₁ <30% of predicted OR FEV ₁ <50% of predicted with respiratory failure

Data from Global Initiative for Chronic Obstructive Lung Disease (GOLD). (2009). *Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease*. Medical Communications Resources, Inc. FEV₁, Volume of air blown out as hard and fast as possible during the first second of the most forceful exhalation after the greatest full inhalation; FVC, functional vital capacity.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

The client with severe dyspnea has all of the following ABG results. Which one does the nurse report immediately to the health care provider?

- A. pH = 7.18
- B. HCO₃⁻ = 31 mEq/L
- C. PaCO₂ = 68 mm Hg
- D. PaO₂ = 68 mm Hg

ANALYSIS

The priority problems for patients with chronic obstructive pulmonary disease (COPD) are:

1. Hypoxemia with hypercapnia related to alveolar-capillary membrane changes, reduced airway size, ventilatory muscle fatigue, excessive mucus production,

airway obstruction, diaphragm flattening, fatigue, and decreased energy

2. Weight loss related to dyspnea, excessive secretions, anorexia, and fatigue
3. Anxiety related to dyspnea, a change in health status, and situational crisis
4. Activity Intolerance related to fatigue, dyspnea, and an imbalance between oxygen supply and demand
5. Potential for pneumonia or other respiratory infections

DECISION-MAKING CHALLENGE

Patient-Centered Care; Teamwork and Collaboration

The patient is a 55-year-old man who has moderate to severe COPD and is being seen for a regularly scheduled checkup in the clinic. He tells you that he has had to give up a few more of his favorite activities and then tells you that life “isn’t fair.” When you ask him about this, he tells you that he did smoke cigarettes for about 10 years during his 20s but quit when his first child was born. He then explains that his mother, a nonsmoker, died at age 62 of COPD but his father, who smoked his entire life, has only mild COPD at age 80. The patient goes on to say that his younger brother, also a smoker, is 58 and does not have COPD but that his identical twin brother, who never smoked, does have the disease. When you ask whether anyone else on either side of his family has or had COPD, he indicates that the following people had been diagnosed with COPD:

- Mother’s younger brother (older brother and younger sister not affected)
 - Mother’s father
 - Mother’s mother’s brother
 - Father’s two sisters, but none of their children
1. Draw this patient’s family pedigree based on the information you have already received.
 2. What, if any, pattern of inheritance can be identified from the pedigree?
 3. What additional information regarding the possibility of genetic risk should you ask this patient?
 4. Could genetic counseling be helpful to this patient? If so, what genetics professional should be consulted and why?

PLANNING AND IMPLEMENTATION

Improving Oxygenation and Reducing Carbon Dioxide Retention

Planning: Expected Outcomes. The patient with COPD is expected to attain and maintain gas exchange at a level within his or her usual baseline values. Indicators include that the patient:

- Maintains SpO_2 of at least 88%
- Is not cyanotic
- Maintains cognitive orientation
- Coughs and clears secretions effectively
- Maintains a respiratory rate and rhythm appropriate to his or her activity level

Interventions. Most patients with COPD use nonsurgical management to improve or maintain gas exchange. Surgical management requires that the patient meet strict criteria.

Nonsurgical Management. The mainstays of nursing management for patients with COPD include airway maintenance, monitoring, breathing techniques, positioning, effective coughing, oxygen therapy, exercise conditioning, suctioning, hydration, and use of a vibratory positive-pressure device. Nursing priorities are teaching the patient how to be a partner in COPD management by participating

in therapies to improve ventilation and by adhering to prescribed drug therapy.

Before any intervention, assess the patient to determine the breathing pattern, especially the rate, rhythm, depth, and use of accessory muscles. The patient with COPD relies more on accessory muscles than on the diaphragm for breathing. These muscles, however, are less efficient than the diaphragm, and the work of breathing increases. Determine whether any factors are contributing to the increased work of breathing, such as respiratory infection. *Airway maintenance is the most important focus of interventions to improve gas exchange.* Keep the patient’s head, neck, and chest in alignment.

Monitoring. Monitoring for changes in respiratory status is key to providing prompt interventions to reduce complications. Assess the hospitalized patient with COPD at least every 2 hours, even when the purpose of hospitalization is not COPD management. Provide the prescribed oxygen, assess the patient’s response to therapy, and prevent complications.

If the patient’s condition worsens despite treatment, more aggressive therapy is needed. Intubation and mechanical ventilation may be needed for patients in respiratory failure, including those who are unable to sustain spontaneous breathing patterns.

Breathing Techniques. Diaphragmatic or abdominal and pursed-lip breathing may be helpful for managing dyspneic episodes. Teach the patient to use these techniques, shown in [Chart 32-11](#), during all activities. The amount of stale air in the lungs is reduced, and he or she gains confidence and control in managing dyspnea (Thomas, 2009). Teach these techniques when the patient is free of dyspnea.

In diaphragmatic breathing, the patient consciously increases movement of the diaphragm. Lying on the back allows the abdomen to relax. Breathing through pursed lips uses the mild resistance of partially closed lips to prolong exhalation and to increase airway pressure. This technique delays airway compression and reduces air trapping. Pursed-lip breathing can be used during diaphragmatic or abdominal breathing.

Positioning. Placing the patient in an upright position with the head of the bed elevated can help alleviate dyspnea by increasing chest expansion, relaxing the chest muscles, and placing the diaphragm in the proper position to contract. This position also conserves energy by supporting the patient’s arms and upper body. Assist the patient who can tolerate sitting in a chair out of bed for 1-hour periods two to three times a day. This position helps move secretions and keeps the diaphragm in a better position for ventilation.

Effective Coughing. Coughing effectively can improve gas exchange by helping increase airflow in the larger airways. The patient with COPD often has difficulty with removal of secretions, which results in compromised breathing and poor oxygenation. Excessive mucus also increases the risk for respiratory infections.

Controlled coughing at specific times of the day is helpful in removing excessive mucus. Teach the patient to cough on arising in the morning to eliminate mucus that collected during the night. Coughing to clear mucus before mealtimes may make meals more pleasant. Coughing before bedtime may ensure clear lungs for a less interrupted night’s sleep.

To cough effectively, teach the patient to sit in a chair or on the side of a bed with feet placed firmly on the floor. Instruct him or her to turn the shoulders inward and to bend

CHART 32-11 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Breathing Exercises

Diaphragmatic or Abdominal Breathing

- If you can do so comfortably, lie on your back with your knees bent. If you cannot lie comfortably, perform this exercise while sitting in a chair.
- Place your hands or a book on your abdomen to create resistance.
- Begin breathing from your abdomen while keeping your chest still. You can tell if you are breathing correctly if your hands or the book rises and falls accordingly.

Pursed-Lip Breathing

- Close your mouth, and breathe in through your nose.
- Purse your lips as you would to whistle. Breathe out slowly through your mouth, without puffing your cheeks. Spend at least twice the amount of time it took you to breathe in.
- Use your abdominal muscles to squeeze out every bit of air you can.
- Remember to use pursed-lip breathing during any physical activity. Always inhale before beginning the activity and exhale while performing the activity. Never hold your breath.

the head slightly downward, hugging a pillow against the stomach. The patient then takes a few breaths, attempting to exhale more fully. After the third to fifth breath (in through the nose, out through pursed lips), instruct him or her to take a deeper breath and bend forward slowly while coughing two or three times (“mini” coughs) from the same breath. Observe the color, consistency, odor, and amount of secretions. On return to a sitting position, the patient takes a comfortably deep breath. The entire coughing procedure is repeated at least twice.

Oxygen Therapy. Oxygen is prescribed for relief of *hypoxemia* (decreased blood oxygen levels) and *hypoxia* (decreased

tissue oxygenation). The need for oxygen therapy and its effectiveness can be determined by arterial blood gas (ABG) values and oxygen saturation by pulse oxymetry. The patient with COPD may need an oxygen flow of 2 to 4 L/min via nasal cannula or up to 40% via Venturi mask. Ensure that there are no open flames or other combustion hazards in rooms in which oxygen is in use. More information on oxygen therapy is found in [Chapter 30](#).

! NURSING SAFETY PRIORITY

Critical Rescue

The patient who is hypoxemic and also has chronic hypercarbia requires lower levels of oxygen delivery, usually 1 to 3 L/min via nasal cannula. A low arterial oxygen level is this patient's primary drive for breathing. If a higher rate is needed to maintain oxygen saturation at the prescribed level, check the patient at least every 30 minutes for a decreased respiratory rate. If the rate drops below 10 breaths per minute in a patient with COPD, attempt to arouse him or her. If he or she does not arouse easily, reduce the oxygen flow and re-assess. If the respiratory rate does not increase or if the SpO₂ drops, call the Rapid Response Team.

Drug Therapy. Drugs used to manage COPD are the same drugs as for asthma and include beta-adrenergic agents, cholinergic antagonists, xanthines, corticosteroids, and cromones (see [Chart 32-7](#)). The focus is on long-term control therapy with longer-acting drugs, such as arformoterol (Brovana) and tiotropium (Spiriva). The patient with COPD is more likely to be taking systemic agents (in addition to inhaled drugs) than is the patient with asthma. An additional drug class for COPD is the mucolytics, which thin the thick secretions, making them easier to cough up and expel. Nebulizer treatments with normal saline or with a mucolytic agent such as acetylcysteine (Mucosil, Mucomyst ) or dornase alfa (Pulmozyme) and normal saline help thin secretions. Guaifenesin (Organidin, Naldecon Senior EX) is a systemic mucolytic that is taken orally. A combination of guaifenesin and dextromethorphan (Mucinex DM) also raises the cough threshold.

Stepped therapy, which adds drugs as COPD progresses, is recommended for patients with chronic bronchitis or emphysema, although the patient's response to drug therapy is the best indicator of when drugs or their dosages need changing. A desired outcome is that the patient is more aware of the disease and participates in management strategies. Teach patients and family members the correct techniques for using inhalers and to care for them properly.

Exercise Conditioning. Exercise for conditioning and pulmonary rehabilitation can improve function and endurance in patients with COPD. Patients often respond to the dyspnea of COPD by limiting their activity, even basic ADLs. Over time, the muscles used in breathing weaken and are less efficient in the use of oxygen. The result is increased dyspnea with lower activity levels.

Pulmonary rehabilitation involves education and exercise training to prevent general and pulmonary muscle deconditioning. Each patient's exercise program is personalized to reflect his or her current limitations and planned outcomes. The simplest plan involves having the patient walk (indoors or outdoors) daily at a self-paced rate until symptoms limit further walking, followed by a rest period, and then

continue walking until 20 minutes of actual walking has been accomplished. As the time during rest periods decreases, the patient can add 5 more minutes of walking time. The benefits of this type of exercise have been shown even for people with severe COPD (GOLD, 2009). Teach patients whose symptoms are severe to modify the exercise by using a walker with wheels or, if needed, to use oxygen therapy during the exercise period. Remind patients that improvement is more likely if exercise is performed at least 2 or 3 times weekly. Formal pulmonary rehabilitation programs can be beneficial even for patients who are severely impaired.

Additional exercise techniques to retrain ventilatory muscles include isocapnic hyperventilation and resistive breathing. Isocapnic hyperventilation, in which the patient hyperventilates into a machine that controls the levels of oxygen and carbon dioxide, increases endurance. In resistive breathing, the patient breathes against a set resistance. Resistive breathing increases ventilatory muscle strength and endurance.

Suctioning. Perform suctioning only when needed—not on a routine schedule. For the patient with a weak cough, weak pulmonary muscles, and inability to expectorate effectively, the nurse or respiratory therapist performs nasotracheal suctioning. Assess the patient for dyspnea, tachycardia, and dysrhythmias during the procedure. Assess for improved breath sounds after suctioning. Suctioning is discussed in detail in Chapter 30.

Hydration. Maintaining hydration may thin the thick, tenacious (sticky) secretions, making them easier to remove by coughing. Unless hydration needs to be avoided for other health problems, teach the patient with COPD to drink at least 2 to 3 L/day. Humidifiers may be useful for those living in a dry climate or those who use dry heat during the winter. Instruct the patient to clean the humidifier daily to prevent the growth of mold spores.

Positive Expiratory Pressure Device. The use of a vibratory positive expiratory pressure device can help assist patients to remove airway secretions. The device is a small, handheld plastic pipe with a short, fat stem and a perforated lid over the bowl (Fig. 32-13). A free-moving steel ball is inside the bowl. The patient inhales deeply and then exhales through the device, causing the ball to move and set up vibrations that are transmitted to the patient's chest and airways. The vibrations loosen secretions and allow them to be coughed out more easily.

FIG. 32-13 The FLUTTER® flutter valve mucus clearance device, a type of vibratory positive-pressure device.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

Which assessment finding indicates to the nurse that the client with chronic obstructive pulmonary disease (COPD) needs to be suctioned?

- A. Documentation indicates the client was last suctioned 12 hours ago.
- B. The client is unable to speak more than six words without clearing the throat.
- C. Although the client is coughing, breath sounds indicate continued presence of secretions in the airways.
- D. The oxygen saturation, as measured by pulse oximetry, decreases while the client performs controlled coughing.

Surgical Management. Lung transplantation and lung reduction surgery can improve gas exchange in the patient with COPD. Transplantation is a relatively rare procedure because of cost and the scarce availability of donor lungs. For these reasons, the few transplants performed for COPD are usually single lung (GOLD, 2009). The more common surgical procedure for patients with emphysema is lung reduction surgery.

The purpose of lung reduction surgery is to improve gas exchange through removal of hyperinflated lung tissue. These areas of the lungs are filled with stagnant air that is not renewed with some atmospheric air (containing oxygen) during each respiratory cycle. Instead, this stagnant air continues to receive carbon dioxide until the level of carbon dioxide in the hyperinflated alveolus is the same as that in the capillary and no gas exchange occurs. After successful lung reduction, most patients have increased forced expiratory volume and decreased total lung capacity and residual volume. Activity tolerance increases, and oxygen therapy may no longer be needed.

Preoperative Care. Patients who are selected for this procedure have end-stage emphysema, minimal chronic bronchitis, and stable cardiac function. They also must be ambulatory; not ventilator dependent; free of pulmonary fibrosis, asthma, or cancer; and not have smoked for at least 6 months. Pulmonary rehabilitation is completed before surgery to the stage that the patient is able to walk, without stopping, for 30 minutes at 1 mile/hr and maintain a 90% or better oxygen saturation level.

In addition to standard preoperative testing, the patient having lung reduction surgery has tests to determine the location of greatest lung hyperinflation and poorest lung blood flow. These tests include pulmonary plethysmography, gas dilution, and perfusion scans.

Operative Procedures. Usually, lung reduction is performed on both lungs either by median sternotomy or, more frequently now, by the minimally invasive surgical technique of video-assisted thoracoscopic surgery (VATS) (Shah & D'Amico, 2009). Each lung is deflated separately and examined for color and texture differences. Normal lung tissue darkens to purple or gray when deflated and becomes more dense or rubbery in texture. Hyperinflated areas do not deflate and remain pink with a spongy texture. The surgeon removes as much of this tissue as possible, sealing off and reinforcing the remaining normal lung tissue.

Postoperative Care. After lung reduction surgery, the patient needs close monitoring for continuing respiratory problems as well as for usual postoperative complications. In

addition to the usual care required after thoracotomy (see Surgical Management [Lung Cancer], pp. 634-638), bronchodilator and mucolytic therapies are maintained. Pulmonary hygiene includes incentive spirometry 10 times per hour while awake, chest physiotherapy starting on the first day after surgery, and hourly pulmonary assessment.

Pain is usually managed by epidural delivery of opioids during the early period after surgery. This type of analgesic delivery reduces pain, limits sedation and cognitive dysfunction, and allows the patient to more fully participate in pulmonary hygiene measures.

Preventing Weight Loss

Planning: Expected Outcomes. The patient with COPD is expected to achieve and maintain a body weight within 10% of ideal. Indicators include that the patient:

- Maintains an appropriate weight/height ratio
- Maintains serum albumin or prealbumin within the normal range

Interventions. The patient with COPD often has food intolerance, nausea, *early satiety* (feeling too “full” to eat), loss of appetite, and meal-related dyspnea. The increased work of breathing raises calorie and protein needs, which can lead to protein-calorie malnutrition. Malnourished patients lose muscle mass and strength, lung elasticity, and alveolar-capillary surface area, all of which reduce effective breathing.

Identify patients at risk for or who have this complication and request that a registered dietitian perform a nutritional assessment. Monitor weight and other indicators of nutrition, such as skin condition and serum prealbumin levels.

Dyspnea management is needed because shortness of breath interferes with eating. Dyspnea during mealtimes can be reduced by resting before meals. Teach the patient to plan the biggest meal of the day for the time when he or she is most hungry and well rested. Four to six small meals a day may be preferred to three larger ones. Remind patients to use pursed-lip and abdominal breathing and to use the prescribed bronchodilator 30 minutes before meals to reduce bronchospasm.

Food selection can help prevent weight loss and improve appetite. Abdominal bloating and a feeling of fullness often prevent the patient from eating a complete meal. Collaborate with the dietitian to teach about foods that are easy to chew and not gas-forming (Bauldoff, 2009). Advise the patient to avoid dry foods that stimulate coughing and caffeine-containing drinks that increase urine output and may lead to dehydration.

Urge the patient to eat high-calorie, high-protein foods. Dietary supplements, such as Pulmocare, provide nutrition with reduced carbon dioxide production. If early satiety is a problem, advise him or her to avoid drinking fluids before and during the meal.

Minimizing Anxiety

Planning: Expected Outcomes. The patient with COPD is expected to have decreased anxiety. Indicators include that the patient consistently demonstrates these behaviors:

- Identifies factors that contribute to anxiety
- Identifies activities to decrease anxiety
- States anxiety is reduced or absent

Interventions. Patients with COPD often have increased anxiety during acute dyspneic episodes, especially if they feel as though they are choking on excessive secretions. Also, anxiety has been shown to cause dyspnea.

Help the patient understand that anxiety can increase dyspnea, and have a plan for dealing with anxiety. Together with the patient, develop a written plan that states exactly what he or she should do if symptoms flare. Having a plan provides confidence and control in knowing what to do, which often helps reduce anxiety. Stress the use of pursed-lip and diaphragmatic breathing techniques during periods of anxiety or panic.

Family, friends, and support groups can be helpful. Recommend professional counseling, if needed, as a positive suggestion. Stress that talking with a counselor can help identify techniques to maintain control over the dyspnea and feelings of panic.

Explore other approaches to help the patient control dyspneic episodes and panic attacks, such as progressive relaxation, hypnosis therapy, and biofeedback. At times, anti-anxiety drug therapy may be needed for severe anxiety.

Improving Activity Tolerance

Planning: Expected Outcomes. The patient with COPD is expected to increase activity to a level acceptable to him or her. Indicators include that the patient:

- Maintains his or her baseline Sao_2 with activity
- Performs ADLs with no or minimal assistance
- Performs selected activities with minimal dyspnea or tachycardia
- Participates in family, work, or social activities as desired

Interventions. The patient with COPD often has chronic fatigue. While in the acute phases of the illness, he or she may need extensive help with the ADLs of eating, bathing, and grooming. As the acute problem resolves, encourage the patient to pace activities and provide as much self-care as possible. Teach him or her to not rush through morning activities, because rushing increases dyspnea, fatigue, and hypoxemia. As activity gradually increases, assess the patient's response by noting skin color changes, pulse rate and regularity, blood pressure, oxygen saturation, and work of breathing. Suggest the use of supplemental oxygen during periods of high energy use, such as bathing or walking.

Energy conservation is the planning and pacing of activities for maximum tolerance and minimum discomfort. Once the forced expiratory volume that can be exhaled in the first 1 second of exhalation (FEV_1) falls below 50% predicted, the patient's ability to perform ADLs is limited. Ask the patient to describe a typical daily schedule. Each activity is divided into its smaller parts to determine whether that task can be performed in a different way or at a different time of the day. Assist him or her to plan and pace daily activities. Rest periods are paced between activities. Help the patient develop a personal chart outlining the day's activities and planned rest periods.

Encourage the patient to avoid working with the arms raised. Activities involving the arms decrease exercise tolerance because the accessory muscles of ventilation are then used to stabilize the arms and shoulders. Many activities involving the arms can be done sitting at a table leaning on the elbows. Teach the patient to adjust work heights to reduce

back strain and fatigue. Remind him or her to keep arm motions smooth and flowing to prevent jerky motions that waste energy. Work with the occupational therapist to teach the patient and family about the use of adaptive tools for housework, such as long-handled dustpans, sponges, and dusters, to reduce bending and reaching.

Suggest how the patient can organize work spaces so that items used most often are within easy reach. Measures such as dividing laundry or groceries into small parcels that can be handled easily, using disposable plates to save washing time, and letting dishes dry in the rack also conserve energy. Talking requires energy and use of the lungs; therefore teach the patient to not talk when engaged in other activities that require energy, such as walking. In addition, teach him or her to avoid breath-holding while performing any activity.

Preventing Respiratory Infection

Planning: Expected Outcomes. The patient with COPD is expected to remain free from serious respiratory infection. Indicators include that the patient consistently demonstrates these behaviors:

- Reports clinical manifestations of respiratory infection
- Describes respiratory infection-monitoring procedures
- Uses prevention activities such as pneumonia and influenza vaccination and crowd avoidance
- Seeks medical assistance when manifestations of respiratory infection first appear

Interventions. Pneumonia is one of the most common complications of COPD. Patients who have excessive secretions or who have artificial airways are at increased risk for respiratory tract infections. The risk is greatly increased for older adults. Teach patients to avoid large crowds, and stress the importance of receiving a pneumonia vaccination and a yearly influenza vaccine.

Community-Based Care

Home Care Management

Most patients with COPD are managed in the ambulatory care setting and cared for at home. When pneumonia or a severe exacerbation of the disease develops, the patient usually returns home after hospitalization. For those with advanced disease, however, 24-hour care may be needed for ADLs and for monitoring for acute episodes or illness progression. Patients may not be able to enjoy work or leisure activities because of severe dyspnea and fatigue. If home care is not possible, placement in a long-term care setting may be needed.

Patients with hypoxemia may use oxygen at home. It may be needed only during periods of exercise or sleep if hypoxemia occurs only during these times. Continuous, long-term oxygen therapy can reverse tissue hypoxia and decrease pulmonary vascular resistance. It can also improve cognitive ability and well-being. For more information on home oxygen therapy, see [Chapter 30](#).

Many patients can benefit from a structured pulmonary rehabilitation program. The overall focus of these collaborative programs is to increase a person's ability to live with COPD. The patient with COPD is referred to a pulmonary rehabilitation program before illness becomes severe.

Collaborate with the case manager to obtain the equipment needed for care at home. Patient needs may include oxygen therapy, a hospital-type bed, a nebulizer, a tub transfer bench, and visits from a home care nurse to continue moni-

toring the health status, review the drug regimen, and evaluate home care needs.

The patient with COPD faces a lifelong disease with remissions and exacerbations. Explain to the patient and family that he or she may have periods of anxiety, depression, and ineffective coping. The person who was a smoker may also have self-directed anger.

Financial concerns often increase anxiety. The disease may worsen to the point that the patient cannot work. Disability benefits through Social Security or private disability insurance plans can help ease the financial burden. Medicare or other health insurers may assist with payment for home oxygen therapy and nebulizer treatments. Coordinate with the social worker or case manager to help the patient make the needed arrangements.

Teaching for Self-Management

Patients with COPD need to know as much about the disease as possible so that they can better manage it and themselves. Patients and families should be able to discuss drug therapy, manifestations of infection, avoidance of respiratory irritants, the nutrition therapy regimen, and activity progression. Instruct them to identify and avoid stressors that can worsen the disease.

Teach the patient techniques of pursed-lip breathing, diaphragmatic breathing, positioning, relaxation therapy, energy conservation, and coughing and deep breathing. With shortened lengths of hospital stays, teaching about all of the needed topics during a single hospitalization may not be realistic. Coordinate teaching with the home care or clinic staff.

Health Care Resources

Provide appropriate referrals as needed. Home care visits may be warranted, particularly if the patient must use home oxygen therapy for the first time. [Chart 32-12](#) lists assessment areas for the patient with COPD at home. Referral to assistance programs, such as Meals on Wheels, can be helpful. Provide a list of support groups, as well as Better Breather clubs sponsored by the American Lung Association. If the patient wants to quit smoking, make the appropriate referrals.

NCLEX EXAMINATION CHALLENGE

Psychosocial Integrity

A client with moderate chronic obstructive pulmonary disease (COPD) is preparing to go home and has thrown away the information regarding smoking cessation. He states, "Why should I quit now after I have already caused this disease." What is the nurse's best response?

- "You are not responsible for this disease. It is a matter of a gene-environment interaction."
- "Choosing to quit smoking can slow the progression of COPD and make you feel better about yourself."
- "Blaming yourself is counterproductive and is likely to make your anxiety and depressive symptoms worse."
- "You shouldn't be so negative. After all, COPD is manageable, not like lung cancer."

EVALUATION: OUTCOMES

Evaluate the care of the patient with COPD based on the identified priority patient problems. The expected outcomes of care are that the patient should:

CHART 32-12 HOME CARE ASSESSMENT

The Patient with Chronic Obstructive Pulmonary Disease**Assess Respiratory Status and Adequacy of Ventilation**

- Measure rate, depth, and rhythm of respirations.
- Examine mucous membranes and nail beds for evidence of hypoxia.
- Determine use of accessory muscles.
- Examine chest and abdomen for paradoxical breathing.
- Count number of words patient can speak between breaths.
- Determine need and use of supplemental oxygen. (How many liters per minute is the patient using?)
- Determine level of consciousness and presence/absence of confusion.
- Auscultate lungs for abnormal breath sounds.
- Measure oxygen saturation by pulse oximetry.
- Determine sputum production, color, and amount.
- Ask about activity level.
- Observe general hygiene.
- Measure body temperature.

Assess Cardiac Status

- Measure rate, quality, and rhythm of pulse.
- Check dependent areas for edema.
- Check neck veins for distention with the patient in a sitting position.
- Measure capillary refill.

Assess Nutritional Status

- Weight maintenance, loss, or gain
- Food and fluid intake
- Use of nutritional supplements
- General condition of the skin
- Assess patient's and caregiver's adherence and understanding of illness and treatment, including:
 - Correct use of supplemental oxygen
 - Correct use of inhalers
 - Drug schedule and side effects
 - Manifestations to report to the health care provider indicating the need for acute care
 - Increasing severity of resting dyspnea
 - Increasing severity of usual symptoms
 - Development of new symptoms associated with poor oxygenation
 - Respiratory infection
 - Failure to obtain the usual degree of relief with prescribed therapies
 - Unusual change in condition
 - Use of pursed-lip and diaphragmatic breathing techniques
 - Scheduling of rest periods and priority activities
 - Participation in rehabilitation activities

- Attain and maintain gas exchange at a level within his or her chronic baseline values
- Achieve an effective breathing pattern that decreases the work of breathing
- Maintain a patent airway
- Achieve and maintain a body weight within 10% of his or her ideal weight
- Have decreased anxiety
- Increase activity to a level acceptable to him or her
- Avoid serious respiratory infections

Specific indicators for these outcomes are listed for each priority patient problem under the **Planning and Implementation** section (see earlier).

CYSTIC FIBROSIS**Pathophysiology**

Cystic fibrosis (CF) is a genetic disease that affects many organs and lethally impairs pulmonary function. Although this disorder is present from birth and usually is first seen in early childhood, almost half of all people with cystic fibrosis in the United States are adults (*Cystic Fibrosis Foundation, 2009*). Some adults are not diagnosed with CF until they have a child who is first diagnosed with the disease (*Lomas & Fowler, 2010*).

The underlying problem of CF is blocked chloride transport in the cell membranes (McCance et al., 2010). The error in chloride transport causes the formation of mucus that has little water content and is thick. The thick, sticky mucus causes problems in the lungs, pancreas, liver, salivary glands, and testes. The mucus plugs up the airways in the lungs and the glandular tissues in the nonpulmonary organs, causing atrophy and organ dysfunction. Nonpulmonary problems include pancreatic insufficiency with malnutrition and intestinal obstruction, poor growth, male sterility, and cirrhosis of the liver. These primary problems cause many additional health problems in young adulthood, especially osteoporosis and diabetes mellitus (*Cystic Fibrosis Foundation, 2009*). Respiratory failure is the main cause of death.

The pulmonary problems of CF result from the constant presence of thick, sticky mucus and are the most serious complications of the disease. The mucus narrows airways, reducing airflow and interfering with *oxygenation*. The constant presence of mucus results in chronic respiratory tract infections, chronic bronchitis, and chronic dilation of the bronchioles (bronchiectasis). Lung abscesses are common. Over time, the bronchioles distend and have increased numbers (hyperplasia) of mucus-producing cells and increased mucus-producing cell size (hypertrophy). Complications include pneumothorax, arterial erosion and hemorrhage, and respiratory failure.

CF is most common among white people, and about 4% are carriers. It is rare among African Americans and Asians. Males and females are affected equally.

GENETIC/GENOMIC CONSIDERATIONS

CF is an autosomal recessive disorder in which both gene alleles must be mutated for the disease to be expressed. The CF gene is located on chromosome 7 and produces a protein that controls chloride movement across cell membranes (Nussbaum et al., 2007). The severity of CF varies greatly; however, life expectancy is always considerably reduced, with an average of 32 years. People with one mutated allele are carriers and have few or no symptoms of CF but can pass the abnormal allele on to their children. More than 1700 different mutations have been identified (*OMIM, 2010*). The inheritance of different mutations is responsible for variation in disease severity.

PATIENT-CENTERED COLLABORATIVE CARE**ASSESSMENT**

Usually, cystic fibrosis (CF) is diagnosed in childhood. The major diagnostic test is sweat chloride analysis. Additional genetic testing can be performed to determine which specific

mutation a person may have. This distinction can be important because different mutations result in different degrees of disease severity. The defect in chloride movement prevents absorption of sodium chloride in the sweat glands; thus more chloride than normal is present in the sweat. The sweat chloride test is positive for CF when the chloride level in the sweat ranges between 60 and 200 mEq/L (mmol/L), compared with the normal value of 5 to 35 mEq/L.

Nonpulmonary manifestations include abdominal distention, gastroesophageal reflux, rectal prolapse, foul-smelling stools, and **steatorrhea** (excessive fat in stools). The patient is often malnourished and has many vitamin deficiencies, especially of the fat-soluble vitamins (e.g., vitamins A, D, E, K). As pancreatic function decreases, diabetes mellitus develops with loss of insulin production. In addition, the adult with CF is usually smaller and thinner than average.

Pulmonary manifestations caused by CF are progressive. Respiratory infections are frequent or chronic with exacerbations. Patients usually have chest congestion, limited exercise tolerance, cough, sputum production, use of accessory muscles, and decreased pulmonary function (especially forced vital capacity [FVC] and forced expiratory volume in the first second of exhalation [FEV₁]). Chest x-rays show persistent infiltrate and an increased anteroposterior (AP) diameter.

During an acute exacerbation or when the disease progresses to end stage, the patient has increased chest congestion, reduced activity tolerance, increased crackles, increased cough, increased sputum production (often with hemoptysis), and severe dyspnea. Fatigue increases in proportion with the dyspnea. Arterial blood gas (ABG) studies show acidosis with greatly reduced partial pressure of arterial oxygen (Pao₂), increased partial pressure of arterial carbon dioxide (Paco₂), increased bicarbonate levels, and low pH.

When infection is present, the patient has fever, an elevated white blood cell count, and decreased oxygen saturation. Other manifestations of infection include tachypnea, tachycardia, intercostal retractions, weight loss, and increased fatigue.

INTERVENTIONS

The patient with CF needs daily therapy to slow disease progress and enhance gas exchange. There is no cure for CF.

Nonsurgical Management

The management of the patient with CF is complex and lifelong. Nutritional management focuses on weight maintenance, vitamin supplementation, diabetes management, and pancreatic enzyme replacement. Pulmonary management is focused on preventive maintenance and management of pulmonary exacerbation. Priority nursing interventions focus on teaching about drug therapy, infection prevention, pulmonary hygiene, nutrition, and vitamin supplementation.

Preventive/maintenance therapy involves the use of positive expiratory pressure, active cycle breathing technique, and an individualized regular exercise program. Unlike for chronic obstructive pulmonary disease, a regimen of daily chest physiotherapy with postural drainage has proven benefit for the patient with CF. As shown in [Fig. 32-14](#), this therapy combines chest percussion, chest vibration, and dependent drainage positions to loosen secretions and promote their drainage. Pulmonary function tests (PFTs), especially FEV₁, are

monitored regularly. Maintenance drugs include bronchodilators, anti-inflammatory agents, mucolytics, and antibiotics.

Exacerbation therapy is needed when the patient with CF has a change in manifestations from baseline. Such changes include increased chest congestion, decreased activity tolerance, increased or new-onset crackles, and at least a 10% decrease in FEV₁. Other manifestations occurring with exacerbation include increased sputum production with bloody or purulent sputum, increased frequency and duration of coughing, decreased appetite, weight loss, fatigue, decreased Sao₂, and ventilatory muscle retractions. Often infection is present, and the patient also has fever, increased lung infiltrate on chest x-ray, and an elevated white blood cell count.

Every attempt is made to avoid having the patient with CF mechanically ventilated. Treatment focuses on airway clearance, increased oxygenation, and antibiotic therapy. Supplemental oxygen is prescribed on the basis of Sao₂ levels. Heliox delivery of 50% oxygen and 50% helium may improve gas exchange and oxygen saturation. The respiratory therapist initiates airway clearance techniques (ACTs) four times a day. Bronchodilator and mucolytic therapies are intensified (higher doses given more frequently than for maintenance). Steroidal agents are started or increased.

Depending on the severity of the exacerbation, a 10- to 14-day course of oral antibiotics may be prescribed. If the exacerbation is more severe, aerosolized tobramycin may be prescribed. If oral/inhaled antibiotics are not effective or if the exacerbation is very severe, IV antibiotics are used, usually an aminoglycoside (such as tobramycin and colistin) or meropenem (Merrem).

A serious bacterial infection for patients with CF is *Burkholderia cepacia*. The organism lives in the respiratory tracts of patients with CF and becomes resistant to antibiotic therapy relatively quickly. It is spread by casual contact from one CF patient to another. For this reason, the Cystic Fibrosis Foundation bans infected patients from participating in any foundation-sponsored events. It is also possible for *B. cepacia* to be transmitted to a CF patient during clinic and hospital visits; thus special infection control measures that limit close contact between people with CF are needed. These measures include separating CF patients on hospital units and seeing them in the clinic on different days. Strict CF Foundation-approved procedures are used when cleaning clinic rooms, pulmonary function laboratories, and respiratory therapy equipment to reduce the risk for contamination. Drug therapy for this infection usually includes co-trimoxazole (a combination of trimethoprim and sulfamethoxazole [Bactrim, Septra]) along with the usual drugs used for exacerbation therapy (Avgeri et al., 2008).

Teach patients about protecting themselves by avoiding direct contact of bodily fluids such as saliva and sputum. Teach them to not routinely shake hands or kiss people in social settings. Handwashing is critical because the organism also can be acquired indirectly from contaminated surfaces, such as sinks and tissues.

As specialized treatment for CF improves and life span increases, other problems may occur. Patients may have bronchiole bleeding from lung arteries. Interventional radiology may be needed to embolize the bleeding arterial branches. Patients with CF may undergo this procedure repeatedly to control hemoptysis. See [Chapter 38](#) for information on interventional radiology vascular procedures.

FIG. 32-14 Chest physiotherapy (chest PT) and postural drainage. *Left*, Percussion and vibration techniques. One or two hands are used with vibration, which is performed when the patient exhales or coughs. *Right*, Positions for postural drainage of respiratory secretions.

Other problems that occur in patients with CF over time include severe gastroesophageal reflux disease (GERD), osteoporosis, and sensorineural hearing loss. GERD appears related to increased pulmonary pressures needed for ventilation (Newton, 2009). Hearing loss appears related to antibiotic use (Cheng et al., 2009). Osteoporosis development with bone density loss may be related to multiple factors, including drug therapy with corticosteroids and the smaller stature of patients who have more severe disease. Regardless of the cause, it increases the patient's risk for bone fractures.

Surgical Management

The surgical management of the patient with CF involves lung and/or pancreatic transplantation. The patient has reduced manifestations but is at continuing risk for lethal pulmonary infections, especially with anti-rejection drug

therapy. Transplantation may extend life for some years, depending on other factors, although life span is not increased to the level expected in the general population. A major problem is a relatively high rate of transplant rejection, possibly caused by poor intestinal absorption of anti-rejection drugs (Song et al., 2008).

Fewer lung transplants are performed compared with transplantation of other solid organs. The problem is related to the scarcity of available lungs. In addition, many of the people who could benefit from lung transplantation have serious problems in other organs that make extended surgical procedures dangerous.

Lung transplant procedures include two lobes or a single lung transplantation, as well as double-lung transplantation. The type of procedure is determined by the patient's age and overall condition, the cause of the lung problem, and the life

expectancy after transplantation. Usually, the patient with CF has a bilateral lobe transplant from either a cadaver donor or living-related donor.

Preoperative Care. Many factors are considered before lung transplantation surgery. Recipient and donor criteria vary from one program to another, but some criteria are universal.

Recipient criteria for the person who will receive the transplant include that the recipient must have severe, irreversible lung damage. It is important, however, that the patient be well enough to survive the surgery. Usually only those younger than 55 years receive transplants, although transplantation is considered on an individual basis. Exclusion criteria are:

- Severe psychiatric disorders or self-destructive tendency
- Proven history of noncompliance or poor compliance with medical regimens
- Current cancer or cancer within the past 5 years
- Systemic infection
- Irreversible heart, kidney, or liver damage/disease
- Presence of any problem that would be made worse by immunosuppression

Donor criteria, regardless of whether the lung tissue is obtained from a cadaver or from a living-related donor, include:

- Infection free
- Cancer free
- Healthy lung tissue
- Close tissue match with the recipient
- Same blood type as the recipient

When the donor is living-related, additional criteria are:

- Age is younger than 55 years.
- Donor has normal cardiac function.
- Pulmonary function is expected to remain adequate after tissue removal.
- The donor has had no previous chest surgery.
- Donor is psychologically stable.
- Donor has not been coerced into this situation.

The two nursing priorities before surgery are teaching the patient the expected regimen of pulmonary hygiene to be used in the period immediately after surgery and assisting the patient in a pulmonary muscle strengthening/conditioning regimen.

Operative Procedures. The patient may or may not need to be placed on cardiopulmonary bypass, depending on the exact procedure. Those having single-lung or lobe transplantation usually do not need bypass; those having double-lung transplantation usually do.

The most common incision used for lung transplantation is a transverse thoracotomy (“clamshell”). The diseased lung or lungs are removed. The new lobes, lung, or lungs are placed in the chest cavity with proper connections made to the trachea, mainstem bronchus, or secondary bronchus and blood vessels. Usually, lung transplantation surgery is completed within 4 to 6 hours.

Postoperative Care. The patient is intubated for at least 48 hours. In addition, chest tubes and arterial lines are in place. Much of the care needed is the same as that for any thoracic surgery.

Major problem areas after lung transplantation are bleeding, infection, and transplant rejection. Bleeding is most common in patients who had cardiopulmonary bypass with anticoagulation. Usually the patient remains in the ICU for several days after transplantation.

Anti-rejection drug regimens must be started immediately after surgery, which increases the risk for infection. The drugs used for long-term rejection suppression after organ transplantation are combinations of very specific immunosuppressants (cyclosporine [Sandimmune]), less specific immunosuppressants (azathioprine [Imuran] or mycophenolate mofetil [CellCept]), and one of the corticosteroids, such as prednisone (Apo-Prednisone ☛, Deltasone ☛) or prednisolone (Delta-Cortef). Corticosteroids are avoided in the first 10 to 14 days after surgery because of their negative impact on the healing process. (See Chapter 19 for details about anti-rejection therapy.)

PULMONARY ARTERIAL HYPERTENSION

Pathophysiology

General pulmonary hypertension can occur as a complication of other lung disorders. Primary pulmonary arterial hypertension (PAH) (also known as idiopathic pulmonary hypertension) occurs in the absence of other lung disorders, and its cause is unknown although exposure to some drugs increases the risk. This disorder is rare and occurs mostly in women between the ages of 20 and 40 years (McCance et al., 2010; Widlitz et al., 2007).

GENETIC/GENOMIC CONSIDERATIONS

About 50% of patients with pulmonary arterial hypertension (PAH) have a genetic mutation in the *BMPR2* gene, which codes for a growth factor receptor (Weber et al., 2011). Excessive activation of this receptor allows increased growth of arterial smooth muscle in the lungs, making these arteries thicker. Many more people have mutations in this gene than have PAH. It is thought that these mutations increase the susceptibility to PAH when other, often unknown, environmental factors also are present. Often PAH is not diagnosed until late in the disease process when the lungs and heart have already been significantly damaged. Teach people, especially women, who have a first-degree relative (parent or sibling) with PAH to have regular health checks and to consult a health care provider whenever pulmonary problems are present.

The pathologic problem in PAH is blood vessel constriction with increasing vascular resistance in the lung. Pulmonary blood pressure rises and blood flow decreases, leading to poor perfusion and hypoxemia. Eventually, the right side of the heart fails (cor pulmonale) from the continuous workload of pumping against the high pulmonary pressures. Without treatment, death usually occurs within 2 years after diagnosis.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The most common early manifestations are dyspnea and fatigue in an otherwise healthy adult. Some patients also have angina-like chest pain. Table 32-3 lists the classification of PAH.

Diagnosis is made from the results of right-sided heart catheterization showing elevated pulmonary pressures. Other test results suggesting pulmonary hypertension include abnormal ventilation-perfusion scans, pulmonary function tests (PFTs) showing reduced functional pulmonary volumes with reduced diffusion capacity, and computed tomography (CT).

TABLE 32-3 SEVERITY CLASSIFICATION FOR PRIMARY PULMONARY ARTERIAL HYPERTENSION

CLASS	MANIFESTATIONS
I	Pulmonary hypertension diagnosed by pulmonary function tests and right-sided cardiac catheterization No limitation of physical activity Moderate physical activity does not induce dyspnea, fatigue, chest pain, or light-headedness
II	No manifestations at rest Mild to moderate physical activity induces dyspnea, fatigue, chest pain, or light-headedness
III	No or slight manifestations at rest Mild (less than ordinary) activity induces dyspnea, fatigue, chest pain, or light-headedness
IV	Dyspnea and fatigue present at rest Unable to carry out any level of physical activity without manifestations Manifestations of right-sided heart failure apparent (dependent edema, engorged neck veins, enlarged liver)

Data from Donahue, D. (2010). Managing pulmonary arterial hypertension. *Nursing* 2010, 40(1), 52-54.

INTERVENTIONS

Drug therapy can reduce pulmonary pressures and slow the development of cor pulmonale by dilating pulmonary vessels and preventing clot formation. Warfarin (Coumadin) therapy is taken daily to achieve an international normalized ratio (INR) of 1.5 to 2.0. Calcium channel blockers, such as nifedipine (Procardia) and diltiazem (Cardizem), have been used to dilate blood vessels. Endothelin-receptor antagonists, such as bosentan (Tracleer), induce blood vessel relaxation and decrease pulmonary arterial pressure. These agents, however, cause general vessel dilation and some degree of hypotension. Natural and synthetic prostacyclin agents provide the best specific dilation of pulmonary blood vessels. Continuous infusion of epoprostenol (Flolan) or treprostinil (Remodulin) through a small IV pump reduces pulmonary pressures and increases lung blood flow. Treprostinil also can be delivered by continuous subcutaneous infusion. These continuous infusions of prostacyclin drugs can be performed by the patient at home and in other settings. Some patients are able to continue working while undergoing this therapy. Another prostacyclin drug, iloprost (Ilomedin, Ventavis), can be delivered by inhalation. A drug given along with prostacyclins is sildenafil (Revatio, Viagra) administered orally or IV (Vacca, 2009).

! NURSING SAFETY PRIORITY

Critical Rescue

A critical nursing priority for a patient undergoing therapy with IV prostacyclin agents is that, although it is very effective, deaths have been reported if the drug delivery is interrupted even for a matter of minutes. Teach the patient to always have backup drug cassettes and battery packs. If these are not available or if the line is disrupted, the patient should go to the emergency department immediately.

Another critical nursing priority is working with the patient receiving IV prostacyclin therapy to prevent sepsis. The continuous central line IV setup provides an access for organisms to directly enter the bloodstream. Teach the patient to

use strict aseptic technique in all aspects of manipulating the drug delivery system. Also teach him or her to notify the pulmonologist at the first sign of any respiratory or systemic infection.

When the heart has undergone some hypertrophy and cardiac output has fallen, the patient may be started on a regimen of digoxin (Lanoxin) and diuretics. Oxygen therapy is used when dyspnea is continuous or uncomfortable. These therapies do not cure the disorder; they just improve function and reduce symptoms.

Surgical management of primary pulmonary hypertension involves single-lung or whole-lung transplantation. When cor pulmonale also is present, the patient may need a combined heart-lung transplantation (Vacca, 2009). It is not known whether the process of pulmonary vasoconstriction can begin again in the transplanted lungs or if the transplant is a “cure.”

INTERSTITIAL PULMONARY DISEASES

The category of interstitial pulmonary diseases contains a variety of lung disorders, also called *fibrotic lung diseases*, that have some features in common. All affect the alveoli, blood vessels, and surrounding support tissue of the lungs rather than the airways. Thus these disorders are **restrictive** (preventing good expansion and recoil of the gas exchange unit) rather than obstructive. With restrictive disease, the lung tissues thicken, causing reduced gas exchange and “stiff” lungs that do not expand well (Pruitt, 2008). Unlike obstructive problems, air trapping does not occur and the patient does not develop a “barrel chest.” Often the onset of these disorders is slow and dyspnea is the most common manifestation.

SARCOIDOSIS

Pathophysiology

Sarcoidosis is a granulomatous disorder of unknown cause that can affect any organ, but the lung is involved most often. It develops over time with growths called **granulomas** forming in the lungs. Granulomas contain lymphocytes, macrophages, epithelioid cells, and giant cells.

Pulmonary sarcoidosis involves autoimmune responses in which the normally protective T-lymphocytes increase and cause damaging actions in lung tissue. Alveolar cells are the targets of the damaging actions. No single cause for T-lymphocyte activation has been identified, although infection and genetic predisposition may play a role (LaRue, 2009). Alveolar inflammation (**alveolitis**) occurs from the presence of immune cells in the alveoli. Chronic inflammation causes **fibrosis** (scar tissue formation in the lungs). The fibrosis reduces **lung compliance** (elasticity) and the ability to exchange gases. **Cor pulmonale** (right-sided cardiac failure) is often present, because the heart can no longer pump effectively against the stiff, fibrotic lung.

The disease affects young adults. Manifestations include enlarged lymph nodes in the hilar area of the lungs, lung infiltrate on chest x-ray, skin lesions, and eye lesions. The first indication of disease may be an abnormal chest x-ray in an otherwise healthy patient. The most common symptoms include cough, dyspnea, hemoptysis, and chest discomfort. In many patients, the illness resolves permanently. Others

may have progressive pulmonary fibrosis and severe systemic disease.

PATIENT-CENTERED COLLABORATIVE CARE

Sarcoidosis is suspected in the patient who has a cough, dyspnea, and abnormal chest x-ray but is otherwise asymptomatic. Other conditions to rule out before diagnosing sarcoidosis are lung infections and cancer. Bronchoscopy with biopsy may be used in the diagnosis of this disorder (see Chapter 29).

Sarcoidosis is staged on the basis of x-ray findings. Higher stages have greater damage and widespread disease. Pulmonary function studies often show a restrictive pattern of decreased lung volumes and impaired diffusing capacity. Irreversible lung changes occur in 10% to 15% of patients. Patients who have severe restrictive disease may develop secondary pulmonary hypertension.

The focus of therapy is to lessen symptoms and prevent fibrosis. Management varies. If the patient is asymptomatic and has normal pulmonary function, no treatment is given. Decreased total lung capacity (TLC), diffusing capacity, or forced vital capacity (FVC); involvement of other organs; and hypercalcemia are indicators for treatment.

Corticosteroids are the main type of therapy. Dosages vary from 40 to 60 mg daily with tapering doses over 6 to 8 weeks, to a maintenance dose of 10 to 15 mg daily for 6 months. Further therapy may continue over 12 months. Drugs under study for management of this disease include thalidomide (Thalomid) and infliximab (Remicade) (LaRue, 2009). Follow-up and monitoring include assessment of symptom severity, pulmonary function studies, chest x-rays, a complete blood count, serum creatinine, serum calcium, and urinalysis. Teach the patient about side effects of steroid therapy and other aspects of physical care as indicated.

IDIOPATHIC PULMONARY FIBROSIS

Pathophysiology

Idiopathic pulmonary fibrosis is a common restrictive lung disease. The typical patient is an older adult with a history of cigarette smoking or chronic exposure to inhalation irritants such as metal particles, dust, organic chemicals, wood fires, or exposure to the drug *amiodarone* (Cordarone) (Roberts, 2010). Unlike sarcoidosis, pulmonary fibrosis is highly lethal. Most patients have progressive disease with few remission periods. Even with proper treatment, patients usually survive less than 5 years after diagnosis.

Pulmonary fibrosis is an example of excessive wound healing. Once lung injury occurs, an inflammatory process begins tissue repair. The inflammation continues beyond normal healing time, causing fibrosis and scarring. These changes thicken alveolar tissues, making gas exchange difficult.

PATIENT-CENTERED COLLABORATIVE CARE

The onset of disease is slow, with early symptoms of mild dyspnea on exertion. Pulmonary function tests show decreased FVC. As the fibrosis progresses, the patient becomes

more dyspneic and hypoxemia becomes severe. Eventually, he or she needs high levels of oxygen and often is still hypoxic. Respirations are rapid and shallow.

The goal of therapy is to slow the fibrotic process and manage dyspnea. Corticosteroids and other immunosuppressants are the mainstays of therapy. Immunosuppressant drugs include cytotoxic drugs such as cyclophosphamide (Cytoxan, Neosar, Procytox), azathioprine (Imuran), chlorambucil (Leukeran), or methotrexate (Folex). These drugs have many side effects, including immunosuppression, nausea, and lung and liver damage, and have shown limited benefit. New studies using the combination therapy of corticosteroids, azathioprine, interferon gamma 1b, and *N*-acetylcysteine show promise of slowing disease progression. Starting drug therapy early is critical, even though not all patients respond to therapy. Even among those who have a response to therapy, the disease eventually continues to progress and leads to death by respiratory failure.

Lung transplantation is a curative therapy; however, the selection criteria, cost, and availability of organs make this option unlikely for most patients.

The patient and family need support and help with community resources after diagnosis. Nursing care focuses on assisting the patient and family in understanding the disease process and maintaining hope for control of the fibrosis. It is important to prevent respiratory infections. Teach the patient and family about the manifestations of infection, and encourage them to avoid respiratory irritants, crowds, and other people with known infections.

Home oxygen is needed by the time the patient becomes symptomatic because significant fibrosis has already occurred. Teach him or her about oxygen use as a continuous therapy. Fatigue is a major problem. Teach the patient and family about energy conservation measures (see discussion of activity tolerance on pp. 621-622 in the *Chronic Obstructive Pulmonary Disease* section). Activity limitations and rest help reduce the work of breathing and oxygen consumption.

Support the patient's need to be as independent as possible, and encourage him or her to pace activities and accept assistance as needed. The disease is costly because the patient is often unable to work and may need home care.

In the later stages of the disease, the focus is to reduce the sensation of dyspnea. This is often accomplished with the use of oral, parenteral, or nebulized morphine. Provide information about hospice, which supports and coordinates resources to meet the needs of the patient and family when the prognosis for survival is less than 6 months.

OCCUPATIONAL PULMONARY DISEASE

Pathophysiology

Exposure to occupational or environmental fumes, dust, vapors, gases, bacterial or fungal antigens, and allergens can result in a variety of respiratory disorders. Depending on the degree, frequency, and intensity of exposure and on the specific disease, patients may have acute reversible effects or chronic lung disease. All occupational pulmonary diseases are made worse by cigarette smoking; thus smoking-cessation efforts are very important.

Many occupational diseases have an onset of symptoms long after the initial exposure to the offending agent. The patient's personal history can provide clues about the

CHART 32-13 KEY FEATURES

Common Occupational Pulmonary Diseases

DISEASE AND CATEGORY	CAUSES AND MANIFESTATIONS
Occupational Asthmas	
Latency (allergic) asthma	Airway narrowing related only to workplace exposures Atopic allergic response to industrial irritants Develops after a period of exposure (from several weeks to several years) Characterized by airflow limitation Usually resolves when exposure ceases Obstructive disease
Irritant-induced asthma	Manifestations appear only in the workplace First onset usually occurs within 24 hours of exposure Common irritants are chlorine, ammonia, and phosgene Characterized by sloughing of epithelium, thickening of the basement membranes, and mucosal inflammation Early manifestations include cough, wheeze, and dyspnea High exposures can lead to pulmonary edema, ARDS, and death Most tissue changes are permanent Obstructive and restrictive disease
Pneumoconiosis	
Silicosis	Chronic fibrosis from long-term inhalation of silica dust Found among people working in mines, stone quarries, and foundries. Also found in people working in these industries: glass making, pottery, sandblasting, tile and brick making, soap and polishes, and manufacture of filters Characterized by nodule formation between alveoli leading to fibrosis Manifestations include dyspnea on exertion, fatigue, weight loss, reduced lung volume, and upper lobe fibrosis Restrictive disease
Coal Miner's Disease (Black Lung Disease)	Massive deposits of coal dust in the lungs leading to diffuse fibrosis Develops earlier among miners who smoke Early manifestations are similar to bronchitis Emphysema is a late development Restrictive disease
Diffuse Interstitial Fibrosis	
Asbestosis	Occurs among people who work in asbestos mines, building construction/remodeling, and shipyards Characterized by diffuse pleural thickening and diaphragmatic calcification Restrictive disease
Talcosis	Occurs among people who work in industries that manufacture paint, ceramics, roofing materials, cosmetics, and rubber goods Restrictive disease
Berylliosis	Occurs among people who work in industries in which metal is heated (steel mills, welding) or metal is machined, creating dust Has a genetic component for increased susceptibility to disease after beryllium exposure Restrictive disease
Extrinsic Allergic Alveolitis	
"Farmer's Lung"	Hypersensitivity pneumonitis as an immunologic response to inhaling dust or chemical that contains bacterial or fungal antigens
"Bird Fancier's Lung"	
"Machine Operator's Lung"	Characterized by formation of granulomas with central necrosis in the alveoli and surrounding blood vessels Restrictive disease

ARDS, Acute respiratory distress syndrome.

presence and cause of occupational pulmonary diseases. Common occupational pulmonary diseases include occupational asthma, pneumoconiosis, diffuse interstitial fibrosis, and extrinsic allergic alveolitis. [Chart 32-13](#) lists the key features of these disorders.

PATIENT-CENTERED COLLABORATIVE CARE

Consider an occupational cause for patients with new-onset asthma or dyspnea. Ask about occupational exposure and onset of symptoms because there may or may not be a latency

period between exposure and onset of symptoms. Determine whether the symptoms are acute or chronic. Ask about the use of inhalation protection and about cigarette smoking.

Prevention is important to avoiding disability from occupation-related disease. Teach about the importance of using special respirators and ensuring adequate ventilation when working in potentially harmful environments.

The patient with occupational asthma with a latency period should be removed from the site of exposure, transferred to a job without exposure, and treated with asthma drugs. Nursing care is similar to the care for asthma not caused by the workplace environment. Refer the patient to a

social worker, who provides information regarding compensation and pensions.

Nursing interventions for patients with occupational lung restrictive disease are the same as for those with emphysema. Hypoxemic patients require supplemental oxygen. In addition, respiratory therapies to promote sputum clearance are essential.

BRONCHIOLITIS OBLITERANS ORGANIZING PNEUMONIA

Pathophysiology

Bronchiolitis obliterans organizing pneumonia (BOOP) is an inflammatory process that allows connective tissue plugs to form in the lower airways and the tissue between the alveoli. The luminal inflammation triggers white blood cell clumping with fibroblast (connective cell) growth that occludes and eventually obliterates these airways and leads to restricted lung volume with decreased vital capacity. Fibrosis is not part of the pathology of BOOP. It is not a true pneumonia, but the manifestations resemble respiratory infection.

The cause of BOOP has not been established although many personal and environmental conditions are associated with it. Suggested triggers include infectious organisms, drugs (chemotherapy agents, certain antibiotics [sulfa-based drugs, cephalosporins, amphotericin B], antiseizure drugs, cocaine, and amiodarone), or the presence of another connective tissue disorder, such as rheumatoid arthritis or systemic lupus erythematosus. It is also associated with chest radiation therapy for cancers in the breast or lung.

BOOP is most common in people between 30 and 60 years and affects both genders. It is not associated with cigarette smoking, and is more common among patients who have received solid organ transplants. Depending on how fast the problem progresses and the degree to which it interferes with gas exchange, BOOP can lead to death.

PATIENT-CENTERED COLLABORATIVE CARE

An event or condition triggers excessive inflammation in the lumens of lower airways, causing dyspnea, fever, mild cough, flu-like symptoms, and crackles on auscultation. In some patients, the problem resolves spontaneously. In others, the problem can rapidly progress and be fatal within 3 days of the appearance of manifestations. Usually, manifestations are present for weeks or months and do not improve with standard antibiotic therapy.

Diagnosis of BOOP is difficult because manifestations are similar to many other respiratory problems. Chest x-rays do not differentiate BOOP from any other respiratory problem. Computed tomography (CT) scans can show widespread changes in pulmonary tissue that only suggest BOOP, not confirm it. Biopsy with histologic findings is needed to confirm a BOOP diagnosis.

The most effective treatment for BOOP is corticosteroid therapy. A short course of the drug for acute disease can reduce manifestations, and the patient may never have a relapse. For those patients with more severe disease and those with any type of additional health problem, a year of corticosteroid therapy may be needed. In this population, BOOP

is more of a chronic disease with some degree of permanent restrictive disease. Exacerbations can occur.

LUNG CANCER

Pathophysiology

Lung cancer is a leading cause of cancer-related deaths worldwide. In the United States, more deaths from lung cancer occur each year than from prostate cancer, breast cancer, and colon cancer combined. The American Cancer Society estimates that more than 186,000 new cases of lung cancer are diagnosed each year and that more than 165,000 deaths occur each year from it ([American Cancer Society, 2011](#)). The overall 5-year survival for all patients with lung cancer is only 14%. This poor long-term survival is because most lung cancers are diagnosed at a late stage, when metastasis is present. Only 15% of patients have small tumors and localized disease at the time of diagnosis ([American Cancer Society, 2011](#)).

Despite many advances in cancer treatment, the overall prognosis for lung cancer remains poor unless the tumor can be removed completely by surgery. Treatment of lung cancer is often aimed toward relieving symptoms ([palliation](#)) rather than cure because of metastasis.

Most primary lung cancers arise from the bronchial epithelium. These cancers are collectively called *bronchogenic carcinomas*. Lung cancers can be classified according to their histologic cell type as small cell lung cancer (SCLC), epidermoid (squamous cell) cancer, adenocarcinoma, and large cell cancer. The last three types are now referred to as *non-small cell lung cancer (NSCLC)* because of their similar responses to treatment ([Walker, 2008](#)). [Chapter 23](#) discusses the general mechanisms and processes of cancer development.

Metastasis (spread) of lung cancer occurs by direct extension, through the blood, and by invading lymph glands and vessels. Tumors in the bronchial tubes can grow and obstruct the bronchus partially or completely. Tumors in other areas of lung tissue can grow so large that they can compress and obstruct the airway. Compression of the alveoli, nerves, blood vessels, and lymph vessels can occur and also interfere with *oxygenation*. The patterns of metastasis depend on the type of tumor cell and the location of the tumor. Lung lymph nodes, distant lymph nodes, and other tissues including bone, liver, brain, and adrenal glands can be invaded.

Additional manifestations, known as *paraneoplastic syndromes*, complicate certain lung cancers. The paraneoplastic syndromes are caused by hormones secreted by tumor cells ([McClelland, 2010](#)). Paraneoplastic syndrome commonly occurs with SCLC. [Table 32-4](#) lists the endocrine paraneoplastic syndromes that may occur, most commonly with SCLC.

Staging of lung cancer is performed to assess the size and extent of the disease. These factors are related to survival. Lung cancer staging is based on the TNM system (T, primary tumor; N, regional lymph nodes; M, distant metastasis). See [Table 23-6](#) in [Chapter 23](#) for a cancer staging system. Higher numbers represent later stages and less chance for cure or long-term survival.

Incidence/Prevalence

Lung cancers occur as a result of repeated exposure to inhaled substances that cause chronic tissue irritation or inflammation. Cigarette smoking is the major risk factor and is responsible for 85% of all lung cancer deaths ([American](#)

TABLE 32-4 ENDOCRINE PARANEOPLASTIC SYNDROMES ASSOCIATED WITH LUNG CANCER

ECTOPIC HORMONE	MANIFESTATION
Adrenocorticotrophic hormone (ACTH)	Cushing's syndrome
Antidiuretic hormone	Syndrome of inappropriate antidiuretic hormone (SIADH) Weight gain General edema Dilution of serum electrolytes
Follicle-stimulating hormone (FSH)	Gynecomastia
Parathyroid hormone	Hypercalcemia
Ectopic insulin	Hypoglycemia

Cancer Society, 2011). The risk for lung cancer is directly related to the total exposure to cigarette smoke as determined by the number of years of smoking and number of packs of cigarettes smoked per day (pack-years). Pipe and cigar smoking also increase risk. The incidence of lung cancer decreases when smoking stops, although it remains higher than among people who have never smoked.

Etiology and Genetic Risk

Nonsmokers exposed to “passive,” or “secondhand,” smoke also have a greater risk for lung cancer than do nonsmokers who are minimally exposed to cigarette smoke. Passive smoke has many of the carcinogens found in inhaled, or “mainstream,” tobacco smoke.

Other lung cancer risk factors include chronic exposure to asbestos, beryllium, chromium, coal distillates, cobalt, iron oxide, mustard gas, petroleum distillates, radiation, tar, nickel, and uranium. Air pollution with benzopyrenes and hydrocarbons also increases the risk for lung cancer.

GENETIC/GENOMIC CONSIDERATIONS

Lung cancer development varies among people with similar smoking histories, suggesting that genetic factors can influence susceptibility. Differences in a gene product that activates carcinogens (a cancer susceptibility gene) and another gene product that clears carcinogens from the body (a cancer resistance gene) are associated with differences in personal susceptibility to lung cancer. More recent evidence supports the possibility that differences in a gene that regulates cell division, the *Tp53* gene, may be the most important genetic susceptibility link for lung cancer development. Mutations in the alleles of this gene are known to increase the susceptibility to a wide variety of cancers both with and without exposure to environmental risks, including lung cancer development among smokers and nonsmokers.

Health Promotion and Maintenance

Primary prevention for lung cancer is directed at reducing tobacco smoking. Educational strategies start in childhood to discourage children from beginning to smoke. Nurses are actively involved in encouraging nonsmokers to not begin to smoke, in promoting smoking-cessation programs, and in establishing a smoke-free environment. Encourage nonsmokers to avoid passive, or secondhand, smoke by avoiding environmental exposure.

Teach workers in industrial settings about safety precautions, such as wearing specialized masks and protective

TABLE 32-5 WARNING SIGNALS ASSOCIATED WITH LUNG CANCER

- Hoarseness
- Change in respiratory pattern
- Persistent cough or change in cough
- Blood-streaked sputum
- Rust-colored or purulent sputum
- Frank hemoptysis
- Chest pain or chest tightness
- Shoulder, arm, or chest wall pain
- Recurring episodes of pleural effusion, pneumonia, or bronchitis
- Dyspnea
- Fever associated with one or two other signs
- Wheezing
- Weight loss
- Clubbing of the fingers

clothing, to reduce exposure. Encourage people who are at high risk for lung cancer to have frequent health examinations. Urge patients being treated for lung cancer to quit smoking. The actual diagnosis of the disease and its treatment time represent “teachable moments.”

Secondary prevention by early detection has not been considered feasible in the past with earlier detection not making a difference in long-term survival rates. New data from recent studies indicate that screening people at risk for lung cancer using annual CT scans can detect cancers at stage I, when cure is probable and long-term survival (longer than 5 years) is very likely.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Ask the patient about risk factors, including smoking, hazards in the workplace, and warning signals (Table 32-5). Have the patient describe how many packs of cigarettes per day he or she has smoked and for how many years to determine the pack-year smoking history.

Ask about the presence of lung cancer manifestations, such as hoarseness, cough, sputum production, hemoptysis, shortness of breath, or change in endurance. Assessing for and documenting these manifestations provide information about the extent of nursing care and teaching the patient needs now and can be used later to determine therapy effectiveness. Many manifestations are common and may have been present for years. Ask the patient to describe any recent changes in symptoms or if position affects symptoms.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

The client is a 62-year-old man who has smoked one pack of cigarettes per day from the time he was 13 years old until he was 19 and then smoked two packs of cigarettes per day from age 19 to the present. How should the nurse calculate this client's pack-year smoking history?

- 62 pack-years
- 55 pack-years
- 92 pack-years
- 99 pack-years

Assess for chest pain or discomfort, which can occur at any stage of tumor development. Chest pain may be localized or on just one side and can range from mild to severe. Ask about any sensation of fullness, tightness, or pressure in the chest, which may suggest obstruction. A piercing chest pain or pleuritic pain may occur on inspiration. Pain radiating to the arm results from tumor invasion of nerve plexuses in advanced disease.

Physical Assessment/Clinical Manifestations—Pulmonary

Manifestations of lung cancer are often nonspecific and appear late in the disease process. Specific manifestations depend on the type and location of the tumor. Chills, fever, and cough may be related to pneumonitis or bronchitis that occurs with obstruction. Assess sputum quantity and quality. Blood-tinged sputum may occur with bleeding from a tumor. Hemoptysis is a later finding in the course of the disease. If infection or necrosis is present, sputum may be purulent and copious.

Breathing may be labored or painful. Obstructive breathing may occur as prolonged exhalation alternating with periods of shallow breathing. Rapid, shallow breathing occurs with pleuritic chest pain and an elevated diaphragm. Inspiratory efforts are reduced in advanced disease. Look for and document abnormal retractions, the use of accessory muscles, flared nares, stridor, and asymmetric diaphragmatic movement on inspiration. Dyspnea and wheezing may be present with airway obstruction. Ask about the level of dyspnea at rest, with activity, and in the supine position (orthopnea). Determine how much the dyspnea interferes with his or her participation in ADLs, work, recreational activities, and family responsibilities. Ask the patient to compare his or her participation in activities during the past week with that of a month ago and a year ago.

Areas of tenderness or masses may be felt when palpating the chest wall. Increased vibrations felt on the chest wall (**fremitus**) indicate areas of the lung where air spaces are replaced with tumor or fluid. Fremitus is decreased or absent when the bronchus is obstructed. The trachea may be displaced from midline if a mass is present in the area.

Lung areas with masses sound dull or flat rather than hollow or resonant on chest percussion. Breath sounds may change with the presence of a tumor. Wheezes indicate partial obstruction of airflow in passages narrowed by tumors. Decreased or absent breath sounds indicate complete obstruction of an airway by a tumor or fluid. Increased loudness or sound intensity of the voice while listening to breath sounds indicates increased density of lung tissue from tumor compression. A pleural friction rub may be heard when inflammation also is present.

Physical Assessment/Clinical Manifestations—Nonpulmonary

Many other systems can be affected by lung cancer and have changes at the time of diagnosis. Heart sounds may be muffled by a tumor or fluid around the heart (*cardiac tamponade*). Dysrhythmias may occur as a result of hypoxemia or direct pressure of the tumor on the heart. Cyanosis of the lips and fingertips or clubbing of the fingers may be present (see Fig. 32-12).

Bones lose density with tumor invasion and break easily. The patient may have bone pain or pathologic fractures.

Handle the patient carefully. Thin bones can fracture with little pressure and without trauma. Even heavy coughing can break a rib.

Late manifestations of lung cancer usually include fatigue, weight loss, anorexia, dysphagia, and nausea and vomiting. *Superior vena cava syndrome may result from tumor pressure in or around the vena cava. This syndrome is an emergency (see Chapter 24) and requires immediate medical attention.* The patient may have confusion or personality changes from brain metastasis. Bowel and bladder tone or function may be affected by tumor spread to the spine and spinal cord.

Psychosocial Assessment

The poor prognosis for lung cancer has made it a much-feared disease. Dyspnea and pain add to the patient's fear and anxiety. The patient with a history of cigarette smoking may feel guilt and shame. Convey acceptance, and interact with the patient in a nonjudgmental way. Encourage the patient and family to express their feelings about the possible diagnosis of lung cancer.

Few patients with stage III or higher lung cancer are cured or live longer than 5 years after diagnosis. Many are given limited treatment for symptom relief. Fear of pain and death is common.

Diagnostic Assessment

The diagnosis of lung cancer is made by examination of cancer cells. Cytologic testing of early-morning sputum specimens may identify tumor cells; however, cancer cells may not be present in the sputum. When pleural effusion is present, fluid is obtained by thoracentesis for cytology.

Most commonly, lung lesions are first identified on chest x-rays. Computed tomography (CT) examinations are then used to identify the lesions more clearly.

Fiberoptic bronchoscopy provides direct visibility of the tracheobronchial tree. Specimens and bronchial brushings can be obtained with this technique, especially when lesions are located within or close to an airway. Needle biopsy during bronchoscopy may be used to obtain cancer cells.

A thoracoscopy may be performed through a video-assisted thoracoscope entering the chest cavity via small

DECISION-MAKING CHALLENGE

Patient-Centered Care; Teamwork and Collaboration

The patient is a 47-year-old woman who was treated for breast cancer 7 years ago with combination chemotherapy and chest irradiation. Her chest MRI shows a lesion that was thought to be metastatic breast cancer. However, a biopsy reveals stage I lung cancer. She smoked as much as two packs per day in college but has not smoked since age 25. She is distraught, saying she would much rather have breast cancer because there are more treatment options for breast cancer and all people with lung cancer die of the disease. She does not want her husband or children to know the lung cancer diagnosis. Then she asks whether her breast cancer could have caused her lung cancer.

1. Is her new cancer diagnosis related to her previous cancer diagnosis?
2. What should you tell her about her previous smoking history?
3. How should you immediately respond to her distress?
4. What should you tell her about stage I lung cancer?
5. Should you respect her wishes about not revealing a lung cancer diagnosis to her family? Why or why not?

incisions through the chest wall. This procedure allows direct viewing of the lung tissue. To identify metastasis in mediastinal lymph nodes, a mediastinoscopy may be performed through a small chest incision.

Other diagnostic studies may be needed to determine how widely the cancer has spread. Such tests include needle biopsy of lymph nodes, direct surgical biopsy, and thoracentesis with pleural biopsy. Magnetic resonance imaging (MRI) and radio-nuclide scans of the liver, spleen, brain, and bone help determine the location of metastatic tumors. Pulmonary function tests (PFTs) and arterial blood gas (ABG) analysis help determine the overall respiratory status. Positron emission tomography (PET) scanning is becoming the most thorough way to locate metastases. Together, these tests help determine the extent of the cancer and the best methods to treat it.

INTERVENTIONS FOR CURE

Interventions for the patient with lung cancer can have the purposes of curing the disease, increasing survival time, and enhancing quality of life through palliation. Both nonsurgical and surgical interventions are used to achieve these purposes. Some patients with lung cancer may undergo interventions for all three purposes at different stages in the disease process. Currently, cures are most likely for patients who undergo treatment for stage I or II disease. Cure is rare for patients who undergo treatment for stage III or IV disease, although survival time is increasing (Walker, 2008).

Nonsurgical Management

Chemotherapy is often the treatment of choice for lung cancers, especially small cell lung cancer (SCLC). It may be used alone or as adjuvant therapy in combination with surgery for non-small cell lung cancer (NSCLC). The exact combination of drugs used depends on the response of the tumor and the overall health of the patient; however, most include platinum-based agents.

Side effects that occur with chemotherapy for lung cancer include chemotherapy-induced nausea and vomiting (CINV), **alopecia** (hair loss), open sores on mucous membranes (**mucositis**), immunosuppression with neutropenia, anemia, **thrombocytopenia** (decreased numbers of platelets), and peripheral neuropathy. Some of these side effects are presented briefly below. Consult [Chapter 24](#) for a thorough discussion of the nursing care needs for patients who have these side effects.

Reassure patients that hair loss is temporary. Hair regrowth begins about 1 month after chemotherapy is completed. Hair loss can be disguised by the use of wigs, scarves, and caps.

The chemotherapy agents used for lung cancer treatment are **emetogenic** (inducing nausea and vomiting). Many effective antiemetic drugs are available. Usually one or more antiemetics are given before and after chemotherapy. Drugs used to control chemotherapy-induced nausea and vomiting are listed in [Chart 24-8](#) in [Chapter 24](#).

Frequent mouth assessment and oral hygiene are key in managing mucositis. Stress the importance of good, frequent oral hygiene, including tooth cleaning and mouth rinsing. Teach patients to use a soft-bristled toothbrush or disposable mouth sponges and to avoid using dental floss and water-pressure gum cleaners.

Immunosuppression, which greatly increases the risk for infection, is the major dose-limiting side effect of

chemotherapy for lung cancer. Immunosuppression can be managed by the use of growth factors to stimulate bone marrow production of immune system cells. Teach the patient and family about precautions to take to reduce the patient's chances of developing an infection (see [Chart 24-5](#) in [Chapter 24](#)). (See [Chapter 24](#) for more information about chemotherapy and associated nursing care.)

Targeted therapy is now becoming more common in the treatment of later-stage lung cancer. As discussed in [Chapter 24](#), these agents take advantage of one or more differences in cancer cell growth or metabolism that is either not present or only slightly present in normal cells. These differences are a result of specific gene expression in cancer cells. Agents used as targeted therapies often are antibodies that work to disrupt cancer cell division in one of several ways. Some of these drugs “target” and block growth factor receptors, especially the epithelial growth factor receptors (EGFRs) or the vascular endothelial growth factor receptors (VEGFRs). When a lung cancer cell's growth depends on having the growth factors bind to their specific receptors, blocking the receptors at least slows the cancer cell's growth. Two oral agents most often used for targeted therapy of certain types of non-small cell lung cancer are erlotinib (Tarceva) and gefitinib (Iressa). Neither drug is used alone as therapy for lung cancer.

Radiation therapy can be an effective treatment for locally advanced lung cancers confined to the chest. Best results are seen when radiation is used in addition to surgery or chemotherapy. Radiation may be performed before surgery to shrink the tumor and make resection easier.

Usually radiation therapy for lung cancer is performed daily for a 5- to 6-week period. Only the areas thought to have cancer are positioned in the radiation path. The immediate side effects of this treatment are skin irritation and peeling, fatigue, nausea, and taste changes. Some patients have esophagitis during therapy, making adequate nutrition more difficult. Teach patients to eat foods that are soft, bland, and high in calories. Consult with a dietitian to provide a list of foods that are easier to swallow and nutritious. Suggest that the patient drink liquid nutrition supplements, such as Ensure or Boost, between meals to maintain weight and energy levels.

Skin care in the radiation-treated area can be difficult. If the area has been marked with a dye to outline the areas for radiation, instruct the patient to not wash off the markings. The use of ink or dye markings is rare, with most cancer centers using small permanent tattoos to mark the area. Because skin in the radiation path is more sensitive to sun damage, advise patients to avoid direct skin exposure to the sun during treatment and for at least 1 year after radiation is completed. See [Chapter 24](#) for other nursing care issues associated with radiation therapy.

Photodynamic therapy (PDT) may be used to remove small bronchial tumors when they are accessible by bronchoscopy. This therapy is now used for cure of select lung cancers. The patient is first injected with an agent that sensitizes cells to light. This drug enters all cells but leaves normal cells more rapidly than cancer cells. Usually, within 48 to 72 hours, most of the drug has collected in high concentrations in cancer cells. At this time, the patient goes to the operating room where, under anesthesia and intubation, a laser light is focused on the tumor. The light activates a chemical reaction within those cells retaining the sensitizing drug that induces

irreversible cell damage. Some cells die and slough immediately; others continue to slough for several days.

The photosensitizing drug has many effects that require special patient teaching and care both before and after the laser treatment (Collins & Garner, 2007). Chapter 24 describes these issues in detail. In addition to these general care issues, when PDT is used in the airways, the patient usually requires a stay in the ICU for airway management. The sloughing tissue can block the airway as can airway edema from the inflammatory response of the tissues. In addition, the patient is at risk for bronchial hemorrhage, fistula formation, and hemoptysis. A complicating factor in caring for patients who have undergone bronchial PDT is that they are now super-sensitive to light and will remain so for 30 to 90 days. Thus special precautions are needed along with environmental manipulation to keep patients safe during their hospital stay and during the next 3 months (see Chapter 24 for a more complete discussion of photodynamic therapy).

Surgical Management

Surgery is the main treatment for stage I and stage II NSCLC. Total removal of a non-small cell primary lung cancer is undertaken in hope of achieving a cure. If complete resection is not possible, the surgeon removes the bulk of the tumor. The specific surgery depends on the stage of the cancer and the patient's overall health and functional status. Lung cancer surgery may involve removal of the tumor only, removal of a lung segment, removal of a lobe (**lobectomy**), or removal of the entire lung (**pneumectomy**). These procedures can be performed by open thoracotomy or by thoracoscopy with minimally invasive surgery in select patients.

Preoperative Care. The goals of care before surgery are to relieve anxiety and promote the patient's participation (see Chapter 16 for routine preoperative care). Encourage the patient to express fears and concerns, reinforce the surgeon's explanation of the surgical procedure, and provide education related to what is expected after surgery. Teach about the probable location of the surgical incision or thoracoscopy openings, shoulder exercises, and the chest tube and drainage system (except after pneumectomy).

Operative Procedures. Three types of incisions can be made depending on the location of the cancer: posterolateral, anterolateral, and median sternotomy (Fig. 32-15). The incisions are large and are held open with retractors during surgery, contributing to pain after surgery.

A segmental resection is a lung resection that includes the bronchus, pulmonary artery and vein, and tissue of the involved lung segment or segments of a lobe. A **wedge resection** is removal of the peripheral portion of small, localized areas of disease. A **lobectomy** is the removal of an entire lung lobe. A **pneumectomy** is the removal of an entire lung with severing of the bronchus.

Removal of a lobe or entire lung can be accomplished through video-assisted thoracoscopic surgery (VATS) for select patients. The procedure involves making three small incisions in the chest for placement of the instruments. These same openings are used later for placement of drains and chest tubes. The lung section, lobe, or lung is isolated from its airway, which is surgically closed. The lobe or the lung is closed off from the rest of the lung using a double-stapling technique. The tissue is encapsulated in an impermeable bag to prevent leakage of tumor tissue and possible seeding of the

FIG. 32-15 Common incision locations for partial or total pneumectomy.

cancer and is then removed whole through one of the small incisions.

Postoperative Care. Care after surgery for patients who have undergone thoracotomy (except for pneumectomy) requires closed-chest drainage to drain air and blood that accumulate in the pleural space. A **chest tube**, a drain placed in the pleural space to restore intrapleural pressure, allows re-expansion of the lung (Fig. 32-16). The chest tube also prevents air and fluid from returning to the chest. The drainage system consists of one or more chest tubes or drains, a collection container placed below the chest level, and a water seal to keep air from entering the chest. The drainage system may be a stationary, disposable, self-contained system (Fig. 32-17) or a smaller, portable, disposable, self-contained system that requires no connection to a vacuum source (Fig. 32-18). The nursing care priorities for the patient with a chest tube are to ensure the integrity of the system, promote comfort, ensure chest tube patency, and prevent complications.

Chest Tube Placement and Care. The tip of the tube used to drain air is placed near the front lung apex (see Fig. 32-16). The tube that drains liquid is placed on the side near the base of the lung. After lung surgery, two tubes, anterior and posterior, are used. The puncture wounds are covered with airtight dressings.

The chest tube is connected to about 6 feet of tubing that leads to a collection device placed several feet below the chest. The tubing allows the patient to turn and move without pulling on the chest tube. Keeping the collection device below the chest allows gravity to drain the pleural space. When two chest tubes are inserted, they are joined by a Y-connector near the patient's body; the 6 feet of tubing is attached to the Y-connector.

Stationary chest tube drainage systems usually use a water seal mechanism that acts as a one-way valve to prevent air or liquid from moving back into the chest cavity. The Pleur-evac system is a common device using a one-piece disposable plastic unit with three chambers. The three chambers are connected to one another. The tube(s) from the patient is(are) connected to the first chamber in the series of three. This chamber is the drainage collection container. The second

FIG. 32-16 Chest tube placement.

chamber in the series is the water seal to prevent air from moving back up the tubing system and into the chest. The third chamber, when suction is applied, is the suction regulator.

In setting up the system, chamber one (nearest to the patient) does not at first have fluid in it. The tubing from the patient penetrates shallowly into this chamber, as does the tube connecting chamber one with chamber two.

Chamber one collects the fluid draining from the patient. This fluid is measured hourly during the first 24 hours. *The fluid in chamber one must never fill to the point that it comes into direct contact with either the tube draining from the patient or the tube connecting this chamber to chamber two. If the tubing from the patient enters the fluid, drainage stops and can lead to a tension pneumothorax.*

Chamber two is the water seal that prevents air from re-entering the patient's pleural space. As the trapped air

leaves the pleural space, it will pass through chamber one (drainage collection chamber) before entering chamber two (the water seal chamber), which should always contain at least 2 cm of water to prevent air from returning to the patient. As trapped air from the patient's pleural space passes through the water seal, which serves as a one-way valve, the water will bubble. Once all the air has been evacuated from the pleural space, bubbling of the water seal stops.

! NURSING SAFETY PRIORITY

Action Alert

For a water seal chest tube drainage system, 2 cm of water is the minimum needed in the water seal to prevent air from flowing backward into the patient. Check the water level every shift and add sterile water to this chamber to the level marked on the indicator (specified by the manufacturer of the drainage system) (Durai et al., 2010).

The bubbling of the water in the water seal chamber indicates air drainage from the patient. Bubbling is usually seen when intrathoracic pressure is greater than atmospheric pressure, such as when the patient exhales, coughs, or sneezes. When the air in the pleural space has been removed, bubbling stops. A blocked or kinked chest tube also can cause bubbling to stop. Excessive bubbling in the water seal chamber (chamber two) may indicate an air leak. The water in the narrow column of the water seal chamber normally rises 2 to 4 inches during inhalation and falls during exhalation, a process called *tidaling*. An absence of fluctuation may mean that the lung has fully re-expanded or can mean that there is an obstruction in the chest tube (Bauman & Handley, 2011).

Chamber three is the suction control of the system. There are different types of suction, most commonly wet or dry. With wet suction, the fluid level in chamber three is prescribed by the health care provider (usually -20 cm water). The chamber is connected to wall suction, which is turned up until there is gentle bubbling in the chamber. With dry suction, the health care provider prescribes the suction level to be dialed in on the device. When connected to wall suction, the regulator is set to the amount indicated by the device's manufacturer. For either type of suction, the amount of suction in the system is determined not by the wall suction unit but by the chest tube drainage device.

Chart 32-14 summarizes best safety practices when caring for a patient with a water seal chest tube drainage system. Check hourly to ensure the sterility and patency of any chest drainage system. Tape tubing junctions to prevent accidental disconnections, and keep an occlusive dressing at the chest tube insertion site. Keep sterile gauze at the bedside to cover the insertion site immediately if the chest tube becomes dislodged. Also keep padded clamps at the bedside for use if the drainage system is interrupted. Position the drainage tubing to prevent kinks and large loops of tubing, which can block drainage and prevent lung re-expansion.

Manipulation of the chest tube should be kept to a minimum. Do not vigorously "strip" the chest tube because this can create up to -400 cm of water negative pressure and damage lung tissue. If any tube manipulation is needed, gentle hand-over-hand "milking" of the tube, with stopping between each hand hold, is used to move blood clots and prevent obstruction (Halm, 2007). Follow physician prescriptions, as well as agency policies and guidelines on this action.

FIG. 32-17 Left, The Pleur-evac drainage system, a commercial three-chamber chest drainage device. Right, Schematic of the drainage device.

FIG. 32-18 A portable chest drainage system.

Assess the respiratory status and document the amount and type of drainage hourly. Usually the drainage in chamber one is not emptied unless the container is so full that the fluid is in danger of coming into contact with the chest drainage tube. The self-contained systems have calibrations on the collection chamber. Record the amount of hourly drainage. Notify the physician of drainage if more than 100 mL/hr occurs. After the first 24 hours, assess drainage at least every 8 hours.

Check the water seal chamber for unexpected bubbling created by an air leak in the system. Bubbling is normal during forceful expiration or coughing because air in the chest is being expelled. Continuous bubbling indicates an air leak that must be identified. Notify the physician if bubbling occurs continuously in the water seal chamber. On the physician's prescription, gently apply a padded clamp briefly on the drainage tubing close to the occlusive dressing. If the bubbling stops, the air leak may be at the chest tube insertion site or within the chest, requiring physician intervention. Air bubbling that does not cease when a padded clamp is applied indicates that the air leak is between the clamp and the drainage system. Release the clamp as soon as this assessment is made.

Mobile or portable chest tube drainage systems are “dry” chest drainage systems that do not use water to form a seal to prevent air from re-entering the patient’s lung through the chest tube. Instead, these lightweight devices use a dynamic control “flutter” valve that prevents backflow of air. The flutter valve is a soft rubber tube surrounded by a harder

CHART 32-14 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Management of Chest Tube Drainage Systems

Patient

- Ensure that the dressing on the chest around the tube is tight and intact. Depending on agency policy and the surgeon's preference, reinforce or change loose dressings.
- Assess for difficulty breathing.
- Assess breathing effectiveness by pulse oximetry.
- Listen to breath sounds for each lung.
- Check alignment of trachea.
- Check tube insertion site for condition of the skin. Palpate area for puffiness or crackling that may indicate subcutaneous emphysema.
- Observe site for signs of infection (redness, purulent drainage) or excessive bleeding.
- Check to see if tube "eyelets" are visible.
- Assess for pain and its location and intensity, and administer drugs for pain as prescribed.
- Assist patient to deep breathe, cough, perform maximal sustained inhalations, and use incentive spirometry.
- Reposition the patient who reports a "burning" pain in the chest.

Drainage System

- Do not "strip" the chest tube.
- Keep drainage system lower than the level of the patient's chest.
- Keep the chest tube as straight as possible, avoiding kinks and dependent loops.
- Ensure the chest tube is securely taped to the connector and that the connector is taped to the tubing going into the collection chamber.
- Assess bubbling in the water seal chamber; should be gentle bubbling on patient's exhalation, forceful cough, position changes.
- Assess for "tidaling."
- Check water level in the water seal chamber, and keep at the level recommended by the manufacturer.
- Check water level in suction control chamber, and keep at the level prescribed by the surgeon (unless dry suction system is used).
- Clamp the chest tube only for brief periods to change the drainage system or when checking for air leaks.
- Check and document amount, color, and characteristics of fluid in the collection chamber, as often as needed according to the patient's condition and agency policy.
- Empty collection chamber or change the system before the drainage makes contact with the bottom of the tube.
- When sample of drainage is needed for culture or other laboratory test, obtain it from the chest tube; after cleansing chest tube, use a 20-gauge (or smaller) needle and draw up specimen into a syringe.

Immediately Notify Physician or Rapid Response Team for:

- Tracheal deviation
- Sudden onset or increased intensity of dyspnea
- Oxygen saturation less than 90%
- Drainage greater than 70 mL/hr
- Visible eyelets on chest tube
- Chest tube falls out of the patient's chest (first, cover the area with dry, sterile gauze)
- Chest tube disconnects from the drainage system (first, put end of tube in a container of sterile water and keep below the level of the patient's chest)
- Drainage in tube stops (in the first 24 hours)

plastic tube. When the patient exhales, air is forced from the chest cavity into the chest tube, under pressure. This pressure forces the soft flutter valve open and air moves into the harder surrounding tube shell (which has a vent for air). When the patient inhales, creating negative pressure in the chest tube, the soft sides of the flutter valve collapse on themselves (like the sides of a deflated balloon when a person sucks on the mouthpiece instead of blowing into the mouthpiece), closing the one-way valve. Portable units allow the patient to ambulate more freely and go home with chest tubes still in place.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

The client is 1 day postoperative after an open thoracotomy and has two chest tubes in place on the right side. The nurse notes that the client's trachea is pointing toward the left upper chest. What is the nurse's best first action?

- Immediately notify either the Rapid Response Team or the thoracic surgical resident.
- Check the suction setting for chamber three and compare it with the prescribed setting.
- Assess the client's oxygen saturation, and attempt to reposition the trachea within the midline.
- No action is needed because the trachea is deviated toward the unaffected side rather than the affected side.

Pain Management. Most patients have intense pain after an open thoracotomy for at least the first 24 hours. It is considerably less for the patient after lung cancer surgery using minimally invasive techniques. However, pain control is needed in either case for patient comfort and to assist him or her to participate in techniques to reduce the risk for postoperative complications (see [Chapter 18](#)). Administer the prescribed drugs for pain, and assess the patient's responses to them. Teach patients using patient-controlled analgesia (PCA) devices to self-administer the drug before pain intensity becomes too severe. Monitor vital signs before and after giving opioid analgesics, especially for the patient who is not being mechanically ventilated. Plan care activities around the timing of analgesia to reduce the stimulation of additional pain.

Respiratory Management. Immediately after surgery the patient is mechanically ventilated. See [Chapter 34](#) for nursing care of the patient receiving mechanical ventilation.

Once the patient is breathing on his or her own, the priorities are to maintain a patent airway, ensure adequate ventilation, and prevent complications. Assess the patient at least every 2 hours for adequacy of ventilation and gas exchange. Check the alignment of the trachea. Assess oxygen saturation and the rate and depth of respiration. Listen to breath sounds in all lobes on the nonoperative side, particularly noting the presence of crackles. Assess the oral mucous membranes for cyanosis and the nail beds for rate of capillary refill. Perform oral suctioning as necessary.

Usually the patient receives oxygen by mask or nasal cannula for the first 2 days after surgery. Warm and humidify the oxygen. Assist the patient to a semi-Fowler's position or up in a chair as soon as possible. Encourage him or her to use the incentive spirometer every hour while awake. If coughing is permitted, help him or her cough by splinting any incision and ensuring that the chest tube does not pull

with movement. Ensuring that pain is handled properly increases the patient's ability to cough and deep breathe effectively.

Pneumonectomy Care. After pneumonectomy, the pleural cavity on the affected side is an empty space. The surgeon sometimes inserts a clamped chest tube for only a day because serous fluid may then accumulate in the empty space and create adhesions, which reduce mediastinal shift toward the affected side. Closed-chest drainage is not usually used.

Complications of a pneumonectomy include empyema (purulent material in the pleural space) and development of a bronchopleural fistula (an abnormal duct that develops between the bronchial tree and the pleura). Positioning of the patient after pneumonectomy varies according to surgeon preference and the patient's comfort. Some surgeons want the patient placed on the nonoperative side immediately after a pneumonectomy to reduce stress on the bronchial stump incision. Others prefer to place the patient on the operative side to allow fluids to fill in the space formerly taken up by the lungs.

INTERVENTIONS FOR PALLIATION

Oxygen therapy is prescribed when the patient is hypoxemic. Even if the hypoxemia is not severe, humidified oxygen may be prescribed to relieve dyspnea and anxiety. (See [Chapter 30](#) for issues related to home oxygen therapy.)

Drug therapy with bronchodilators and corticosteroids is prescribed for the patient with bronchospasm to decrease bronchospasm, inflammation, and edema. Mucolytics may be of use to ease removal of thick mucus and sputum. Bacterial infections are treated with antibiotic therapy.

Radiation therapy can help relieve hemoptysis, obstruction of the bronchi and great veins (superior vena cava syndrome), **dysphagia** (difficulty swallowing) from esophageal compression, and pain resulting from bone metastasis. Usually radiation for palliation uses higher doses for shorter periods. Skin care issues and fatigue are the same as those occurring with radiation therapy for cure.

Thoracentesis is performed when pleural effusion is a problem for the patient with lung cancer. The excess fluid

increases dyspnea, discomfort, and the risk for infection. The goal of treatment is to remove pleural fluid and prevent its formation. **Thoracentesis** is fluid removal by suction after the placement of a large needle or catheter into the intrapleural space. Fluid removal temporarily relieves hypoxia; however, the fluid can rapidly re-form in the pleural space. When fluid development is continuous and uncomfortable, a continuously draining catheter may be placed into the intrapleural space to collect the fluid.

Dyspnea management is needed because the patient with lung cancer tires easily and is often most comfortable resting in a semi-Fowler's position. Dyspnea is reduced with oxygen, use of a morphine drip, and positioning for comfort. The severely dyspneic patient may be most comfortable sitting in a lounge chair or reclining chair.

Pain management may be needed for chest pain and pain radiating to the arm. With bone metastasis, the patient may also have bone pain. Perform a complete pain assessment with attention to onset, intensity, quality, duration, and the patient's description of the pain. The purpose of therapy is to help the patient to be as pain-free and as comfortable as possible.

Pharmacologic management with opioid drugs as oral, parenteral, or transdermal preparations is needed. Nonpharmacologic measures, such as positioning, hot or cold compresses, distractions, and guided imagery, may also be helpful. Prescribed analgesics are most effective when given around the clock. Additional PRN analgesics are used for breakthrough pain. Ongoing assessment and evaluation of pain control effectiveness are primary nursing responsibilities.

Hospice care can be beneficial for the patient in the terminal phase of lung cancer. Hospice programs provide support to the terminally ill patient and the family by meeting physical and psychosocial needs, adjusting the palliative care regimen as needed, making home visits, and providing volunteers for errands and respite care. (See [Chapter 9](#) for a more complete discussion of end-of-life issues.) The American Cancer Society may provide assistance through support groups for patients and families or through the use of equipment, such as a hospital bed or bedside commode.

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing inadequate oxygenation and tissue perfusion as a result of chronic obstructive respiratory problems?

- Respirations rapid and shallow
- Decreased oxygen saturation by pulse oximetry
- Skin cyanosis or pallor (in lighter-skinned patients)
- Cyanosis or pallor of the lips and oral mucous membranes (in patients of any skin color)
- Tachycardia
- Patient appears to work hard to inhale and exhale
- Patient is restless or anxious
- Patient's general appearance is thin compared with height
- Muscles of the neck appear thick
- Arm and leg muscles appear thin

- Fingers are clubbed
- Chest is barrel-shaped (has a round rather than an oval shape with the front to back depth increased)
- Ribs are spaced more than a fingerbreadth apart

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate oxygenation and tissue perfusion as a result of an acute critical respiratory problem?

Perform and interpret physical assessment, including:

- Taking vital signs
- Auscultating all lung fields
- Monitoring oxygen saturation by pulse oximetry

NURSING CONCEPT REVIEW—cont'd

- Checking the accuracy of pulse oximetry readings
- Assessing cognition (Mini-Mental State Examination [MMSE])
- Assessing for the presence and characteristics of sputum production
- Assessing the patient's ability to cough and clear the airway

Interpret laboratory values, including:

- Elevated red blood cell count, hematocrit, and hemoglobin
- Elevated white blood cell count
- Arterial blood gas values: pH lower than 7.35, HCO_3^- greater than 24 mEq/L, PaCO_2 greater than 45 mm Hg; PaO_2 lower than 80 mm Hg

Respond by:

- Assisting the patient to an upright position, with arms resting on a table or armrests
- Performing or assisting the patient to perform chest physiotherapy/pulmonary hygiene

- Ensuring that oxygen delivery is kept low enough to maintain respirations of no fewer than 16 breaths per minute
- Prioritizing and pacing activities to prevent fatigue
- Administering prescribed inhaled drugs
- Administering respiratory therapy treatments or collaborating with the respiratory therapist to administer these treatments
- Re-assessing respiratory status after respiratory therapy treatment
- Ensuring a fluid intake of at least 3 liters per day

On what should you REFLECT?

- Observe patient for evidence of improved oxygenation (see [Chapter 29](#)).
- Think about what may have made the patient's dyspnea worse and what steps could be taken to prevent a similar episode.
- Think about what patient teaching focus could help reduce the intensity of dyspnea in the future.

GET READY FOR THE NCLEX® EXAMINATION!**KEY POINTS**

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Avoid high liter flow rates of oxygen for patients with COPD.
- Ensure there are no open flames or combustion hazards in rooms where oxygen is in use.
- Protect the patient with cystic fibrosis from hospital-acquired pulmonary infections.
- Ensure proper function of chest tube drainage equipment.

Health Promotion and Maintenance

- Teach patients who come into contact with inhalation irritants in their workplaces or leisure-time activities to use a mask to avoid respiratory contact with these substances.
- Teach anyone who smokes that smoking increases the risk for development of many pulmonary problems.
- Encourage all patients older than 50 years and anyone with a respiratory problem to receive a yearly influenza vaccination.
- Teach all patients who smoke the warning signs of lung cancer.

Psychosocial Integrity

- Assess the degree to which breathing problems interfere with the patient's ability to perform ADLs, work, and leisure-time activities.

- Encourage the patient and family to express their feelings regarding the diagnosis of cancer or the treatment regimen.
- Explain all diagnostic procedures, restrictions, and follow-up care to the patient scheduled for tests.
- Help patients use strategies to improve their appearance when alopecia occurs.
- Refer patients and family members to local cancer resources and support groups.

Physiological Integrity

- Monitor the rate and depth of respiration at least every hour for any patient with hypercarbia and CO_2 narcosis who is receiving oxygen by mask or nasal cannula.
- Assess the airway and breathing effectiveness for any patient who experiences shortness of breath or any change in mental status.
- Apply oxygen to anyone who is hypoxemic.
- Ensure that oxygen therapy delivered to the patient is humidified.
- Monitor arterial blood gases and oxygen saturation of all patients receiving oxygen therapy.
- Teach patients receiving radiation therapy how to care for the skin in the radiation path (see [Chart 24-2](#) in [Chapter 24](#)).

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Explain the pathophysiology of communicable respiratory diseases and the airborne and droplet modes of organism transmission.
2. Apply principles of infection control (e.g., hand hygiene, Isolation Precautions, Airborne Precautions) when providing care to patients with respiratory infections.
3. Use the “ventilator bundle” interventions to prevent ventilator-associated pneumonia.
4. Educate the patient and family about infection control practices for care of a patient who has tuberculosis and lives at home.
5. Prepare to participate in disease-containment activities in the event of an outbreak of pandemic influenza.

Health Promotion and Maintenance

6. Identify adults at highest risk for contracting influenza, pneumonia, tuberculosis, and other respiratory infections.
7. Provide information to everyone about immunization against influenza and pneumonia.
8. Teach everyone the use of specific infection control techniques, especially hand hygiene and Centers for

Disease Control and Prevention (CDC) cough/sneeze etiquette, to avoid acquiring and spreading respiratory infections.

Psychosocial Integrity

9. Adjust teaching activities to avoid contributing to patient fatigue.

Physiological Integrity

10. Perform focused respiratory assessment and re-assessment.
11. Recognize manifestations of infectious respiratory diseases.
12. Compare the manifestations of pneumonia in the younger adult with those exhibited by the older adult with pneumonia.
13. Provide information to the patient and family about side effects of anti-tuberculosis (TB) therapy and when to notify the health care provider.
14. Administer oxygen therapy to the patient with hypoxemia, and evaluate the response.
15. Assess the TB test results for a person with normal immune function and a person with compromised immune function.

DISORDERS OF THE NOSE AND SINUSES

RHINITIS

Pathophysiology

Rhinitis, an inflammation of the nasal mucosa, is a common problem of the nose and often also involves the sinuses. It can be caused by infection (viral or bacterial) or contact with allergens. Often an allergic rhinitis will make the mucous membranes more susceptible to invasion, and then infection accompanies the allergy. Regardless of the cause, rhinitis is uncomfortable.

Allergic rhinitis, often called *hay fever* or *allergies*, is triggered by hypersensitivity reactions to airborne allergens, especially plant pollens or molds. Some episodes are “seasonal” because they recur at the same time each year and last a few weeks. *Perennial rhinitis* occurs either intermittently with no seasonal pattern or continuously whenever the person is exposed to an offending allergen such as dust, animal dander, wool, or foods (e.g., seafood). Rhinitis also occurs as a “rebound” nasal congestion from overuse of nose drops or sprays (*rhinitis medicamentosa*) and chronic nasal inhalation of cocaine.

Acute viral rhinitis (**coryza**, or the common cold) is caused by any of over 200 viruses. It spreads from person to person by droplets from sneezing or coughing and by direct contact. Colds are most contagious in the first 2 to 3 days after symptoms appear. Colds are self-limiting unless a bacterial infection occurs at the same time. Complications occur most often in immunosuppressed people and older adults, especially if they live or work in crowded conditions or in group settings.

PATIENT-CENTERED COLLABORATIVE CARE

In both acute and chronic allergic rhinitis, the presence of the allergen causes a release of histamine and other mediators from white blood cells (WBCs) in the nasal mucosa. These mediators bind to blood vessel receptors, causing local blood vessel dilation and capillary leak, leading to local edema and swelling. Manifestations include headache, nasal irritation, sneezing, nasal congestion, rhinorrhea (watery drainage from the nose), and itchy, watery eyes.

Viral or bacterial invasion of the nasal passages causes the same local tissue responses as allergic rhinitis. Often the patient also has systemic manifestations, including a sore, dry throat and a low-grade fever.

Management of the patient with any type of rhinitis focuses on symptom relief and patient education. Teach him or her about correct use of the drug therapy prescribed.

Drug therapy, including antihistamines and decongestants, is prescribed but must be used with caution in the older adult because of side effects such as vertigo, hypertension, and urinary retention. *Antihistamines*, *leukotriene inhibitors*, and *mast cell stabilizers* block the chemicals released by WBCs from binding to receptors in nasal tissues or reduce the amount of mediator present, preventing local edema and itching. *Decongestants* constrict blood vessels and decrease edema. *Antipyretics* are given if fever is present. *Antibiotics* are prescribed only when a bacterial infection

accompanies rhinitis. Rhinitis caused by overuse of nose drops or sprays is treated by discontinuing the drug. Steroid nasal sprays may be used to decrease the rebound nasal congestion during the first week after discontinuing the drug (Regan, 2009).

Complementary and alternative therapies may be used to decrease the severity of acute viral rhinitis for some people early in the course of the problem. Common agents used for this purpose are echinacea, large doses of vitamin C, and zinc preparations such as COLD-EEZE or Zicam. These products may help increase nonspecific immune function.

Supportive therapy can increase the patient's comfort and help prevent spread of the infection. Instruct the patient about the importance of rest (8 to 10 hours a day) and fluid intake of at least 2000 mL/day unless other health problems require fluid restriction. Humidifying the air helps relieve congestion. Humidity can be increased with a room humidifier or by breathing steamy air in the bathroom after running hot shower water.

Teach patients to reduce the risk for spreading colds by thoroughly washing hands, especially after nose blowing, sneezing, coughing, rubbing the eyes, or touching the face. Other precautions include staying home from work, school, or places where people gather; covering the mouth and nose with a tissue when sneezing or coughing; disposing properly of used tissues immediately; and avoiding close contact with other people (e.g., kissing, hugging, handshaking). Stress the need to avoid close contact with people who are more susceptible to infection, such as older adults, infants, and anyone who has a chronic respiratory problem. An uncomplicated cold typically subsides within 7 to 10 days.

SINUSITIS

Pathophysiology

Sinusitis is an inflammation of the mucous membranes of one or more of the sinuses. Swelling can obstruct the flow of secretions from the sinuses, which may then become infected. The disorder often follows rhinitis. Other conditions leading to sinusitis include deviated nasal septum, nasal polyps or tumors, inhaled air pollutants or cocaine, facial trauma, nasal intubation, dental infection, or decreased immune function.

The most common organisms causing sinus infection are *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Diplococcus*, and *Bacteroides*. Sinusitis most often develops in the maxillary and frontal sinuses. Complications include cellulitis, abscess, and meningitis.

Diagnosis is made on the basis of the patient's history and manifestations. *Transillumination* (reflection of light through tissues) of the affected sinus is decreased. This can be assessed by having the patient place a lighted penlight tip into the mouth and closing the lips around it in a darkened room. Non-swollen sinuses reflect light through the skin as seen as a red glow on the cheek between the eye and the lip. Sinuses that are swollen or filled with secretions have a reduced or absent glow. Other tests for sinusitis include sinus x-rays, endoscopic examination, and computed tomography (CT). Bacterial sinusitis is usually indicated by

purulent drainage from one or both nares and lack of response to decongestant therapy.

PATIENT-CENTERED COLLABORATIVE CARE

Assess for manifestations of sinusitis, including nasal swelling and congestion, headache, facial pressure, and pain (usually worse when the head is tilted forward or is in a dependent position). Other manifestations include tenderness to touch over the involved area, low-grade fever, cough, and purulent or bloody nasal drainage.

Nonsurgical Management

Treatment includes the use of broad-spectrum antibiotics (e.g., amoxicillin [Amoxil]), analgesics for pain and fever (e.g., acetaminophen [Tylenol, Abenol, Atasol, Panadol]), decongestants (e.g., phenylephrine [Neo-Synephrine]), steam humidification, hot and wet packs over the sinus area, and nasal saline irrigations. Teach the patient to increase fluid intake unless another medical problem requires fluid restriction. If this treatment plan is not successful, he or she may need to be evaluated with sinus x-rays and CT scans. Surgical intervention may be needed if nonsurgical management fails to provide relief.

Surgical Management

A common procedure used for sinusitis that does not respond to drug therapy is functional endoscopic sinus surgery (FESS). Small endoscopes (sinoscopes) are used to first visualize the area. Instruments attached to the sinoscopes are used to open the nasal ostium and remove infected mucosa or improve the pathway for nasal drainage. A balloon catheter may also be used during FESS to change the shape of the nasal ostium to relieve obstruction and promote drainage (Regan, 2009). The procedures take only minutes, although mucosal healing may take from 4 to 6 weeks. Pain, swelling, and bleeding are much less than for more traditional sinus surgery procedures. Instruct the patient to use saline nasal sprays frequently (every 2 to 4 hours) to prevent mucosal crusting and promote healing. After more traditional nasal surgery or endoscopic surgery, the patient may have difficulty eating for a few days because of pain and swelling. Chart 33-1 describes the best practices for care after these surgeries.

DISORDERS OF THE ORAL PHARYNX AND TONSILS

PHARYNGITIS

Pathophysiology

Pharyngitis, or “sore throat,” is a common inflammation of the pharyngeal mucous membranes that often occurs with rhinitis and sinusitis. It accounts for 1.2% of all office visits each year in the United States (Schappert & Reche-steiner, 2008).

Acute pharyngitis can be caused by bacteria, viruses, other organisms, trauma, dehydration, irritants, and tobacco or alcohol use. A common bacterium causing pharyngitis is group A beta-hemolytic *Streptococcus*, but most adult cases are caused by a virus (Hoyle, 2009).

CHART 33-1 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Postoperative Care for Patients with Sinus Surgery

- Place the patient in the semi-Fowler's position to promote drainage and prevent swelling.
- Perform *gentle* oral hygiene to promote healing and prevent injury to the surgical incision.
- Teach the patient to use ice compresses as prescribed for 24 hours.
- If a “mustache” dressing under the nose is present, teach the patient how to change it and assess the amount of drainage.
- Teach the patient to eat soft foods and increase fluid intake.
- Recommend that the patient sleep in a reclining chair or with pillows to keep his or her head at about a 20-degree angle.
- Recommend the use of a room humidifier at night.
- Teach the patient to limit the Valsalva maneuver (no coughing, blowing the nose, or straining at stool) for at least 2 weeks to prevent bleeding and tissue damage.
- Teach the patient to take his or her temperature twice daily during the first week after surgery and to report an elevation to 100° F or higher to the surgeon.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The patient with pharyngitis has throat soreness and dryness, throat pain, pain on swallowing (*odynophagia*), difficulty swallowing, and fever. Viral and bacterial pharyngitis are often difficult to distinguish on physical assessment. When inspecting a throat infected with either virus or bacteria, mild to severe redness may be seen with or without enlarged tonsils and with or without exudate. Ask about nasal discharge, which varies from thin and watery to thick and purulent. Enlargement of neck lymph nodes occurs with both viral and bacterial pharyngitis.

Bacterial infections are often associated with enlarged red tonsils, exudate, purulent nasal discharge, and local lymph node enlargement. Chart 33-2 compares the manifestations of viral and bacterial pharyngitis. Viral pharyngitis is contagious for 2 to 3 days. Symptoms usually subside within 3 to 10 days after onset, and the disease is usually self-limiting.

Bacterial pharyngitis caused by group A streptococcal infection can lead to serious complications (Table 33-1), including acute glomerulonephritis and rheumatic fever carditis. Acute glomerulonephritis may occur 7 to 10 days after the acute infection, and rheumatic fever may develop 3 to 5 weeks after the acute infection.

Many types of rapid antigen tests (RATs) and screens for group A beta-hemolytic streptococcal antigen are available. These tests vary in specificity and sensitivity and cost about the same as a culture and sensitivity, but the results are available in less than 15 minutes. Two common tests are the Gen-Probe and the Optical Immunoassay (OIA).

In some cases, throat cultures can be important in distinguishing viral from a group A beta-hemolytic streptococcal infection; however, the results are not entirely accurate. False-negative cultures can occur, and 24 to 48 hours are required for results.

CHART 33-2 KEY FEATURES

Acute Viral and Bacterial Pharyngitis

FEATURE	VIRAL PHARYNGITIS	BACTERIAL PHARYNGITIS
Temperature	Low-grade or no fever	High temperature (>101° F [38.3° C], and usually 102°–104° F [38.9°–40° C])*
Ear manifestations	Retracted or dull tympanic membrane	Retracted or dull tympanic membrane
Throat manifestations	Scant or no tonsillar exudate Slight erythema of pharynx and tonsils	Severe hyperemia of pharyngeal mucosa, tonsils, and uvula Erythema of tonsils with yellow exudates
Neck manifestations	Possible lymphadenopathy	Anterior cervical lymphadenopathy and tenderness
Skin manifestations	No rash	Possible scarlatiniform rash Possible petechiae on chest or abdomen or both
Dysphagia, odynophagia	Present	Present
Other symptoms	No cough Rhinitis Mild hoarseness Headache	No cough Voice characterized by pain on voicing and slurred speech Headache Arthralgia Myalgia
Laboratory data	Complete blood count usually normal White blood cell count usually ≤10,000/mm ³ Negative throat culture results	Complete blood count abnormal White blood cell count usually >12,000/mm ³ * Throat culture results positive for beta-hemolytic <i>Streptococcus</i>
Onset	Gradual	Abrupt

*May not be present in adults older than 65 years.

TABLE 33-1 COMPLICATIONS OF GROUP A STREPTOCOCCAL INFECTION

- Rheumatic fever
- Acute glomerulonephritis
- Peritonsillar abscess
- Retropharyngeal abscess
- Otitis media
- Sinusitis
- Mastoiditis
- Bronchitis
- Pneumonia
- Scarlet fever

With either RAT or culture methods, it is essential to obtain throat specimens properly for an accurate test result. The organisms are not uniformly distributed throughout the throat and can be missed during swabbing. To obtain a specimen, rub a sterile cotton swab from a throat culture kit first over the right tonsillar area, moving across the right arch, the uvula, and then across the left arch to the left tonsillar area (Rushing, 2007). Remove the swab without touching the patient's teeth, tongue, or gums. Place the swab back into the tube, cap it, and then crush the glass ampule

in the culture tube. Send it to the laboratory as quickly as possible.

A complete blood count (CBC) is performed when the patient's condition is severe or does not improve. Patients who need a CBC are those who have high fevers, lethargy, or manifestations of complications.

Ask about the patient's recent contacts (within the past 10 days) with people who have been ill. Specifically ask whether he or she has been ill with symptoms of a cold or upper respiratory tract infection recently. Document any history of streptococcal infections, rheumatic fever, valvular heart disease, or penicillin allergy. Because diphtheria (*Corynebacterium diphtheriae*) can cause pharyngitis, ask about and document whether the patient has had a diphtheria immunization.

INTERVENTIONS

Most sore throats in adults are viral, do not require antibiotic therapy, and respond to supportive interventions. Teach the patient to rest, increase fluid intake, humidify the air, and use analgesics for pain. Gargling several times each day with warm saline and using throat lozenges can increase comfort.

Management of bacterial pharyngitis involves antibiotics and the same supportive care as with viral pharyngitis. For streptococcal infection, an oral penicillin or cephalosporin is prescribed. Drugs from the macrolide class (e.g., azithromycin or erythromycin) are used if the patient is allergic to penicillin.

NURSING SAFETY PRIORITY

Action Alert

Teach patients with any bacterial infection the importance of completing the entire antibiotic prescription, even when manifestations improve or subside. This action helps eradicate the organism and prevents development of resistant bacterial strains.

The patient should be re-evaluated if there is no improvement in 3 days or if manifestations are still present after completion of the antibiotic course. Persistent bacterial pharyngitis may occur with immunosuppression. Any patient whose bacterial pharyngitis does not improve with antibiotics should consider human immune deficiency virus (HIV) testing.

A rare complication of pharyngitis in adults is infection of the epiglottis and supraglottic structures (**epiglottitis**). The epiglottis is a flaplike structure that closes over the trachea during swallowing to prevent aspiration. An inflamed epiglottis can swell and obstruct the airway, causing an emergency that inhibits oxygenation and tissue perfusion.

NURSING SAFETY PRIORITY

Critical Rescue

If a patient with pharyngitis develops stridor or other indications of airway obstruction, notify the Rapid Response Team. Teach patients at home to call 911 or go to the nearest emergency department if difficulty breathing, stridor, or drooling occurs.

Teach the patient how to take his or her temperature accurately every morning and evening until the infection resolves. He or she is not contagious after 24 hours of effective

antibiotic therapy. Family members or close contacts who also have a sore throat should be evaluated.

TONSILLITIS

Pathophysiology

Tonsillitis is an inflammation and infection of the tonsils and lymphatic tissues located on each side of the throat. The tonsils are lymphatic tissue shaped like a small almond. They are covered by mucous membranes and have small valleys (*crypts*) across their surface. Tonsils filter organisms and protect the respiratory tract from infection (McCance et al., 2010).

Tonsillitis is a contagious airborne infection. Acute or chronic tonsillitis can occur in any age-group, but it is less common in adults. The disease usually lasts 7 to 10 days and often is caused by bacteria, most commonly *Streptococcus*. Other bacterial causes include *Staphylococcus aureus*, *Haemophilus influenzae*, and *Pneumococcus*. Viruses also cause tonsillitis. Chronic tonsillitis may result from an unresolved acute infection or recurrent infections.

PATIENT-CENTERED COLLABORATIVE CARE

Chart 33-3 lists the manifestations of acute tonsillitis. Diagnostic tests often used to rule out other causes of the sore throat and fever include a rapid antigen test (RAT), CBC, throat culture and sensitivity (C&S) studies, and Monospot test. If respiratory symptoms are present, chest x-rays may be needed. The WBC count usually is elevated in bacterial infections and normal in viral infections.

Antibiotics (usually penicillin or azithromycin) are prescribed for 7 to 10 days. Nursing priorities include teaching the patient about supportive care and stressing the importance of completing antibiotic therapy. Teach him or her to rest, increase fluid intake, humidify the air, use analgesics for pain, gargle several times each day with warm saline, and use throat lozenges.

Surgical intervention for tonsillitis may be needed for recurrent acute infections (especially group A beta-hemolytic streptococcal infections), chronic infections that do not respond to antibiotics, a peritonsillar abscess, and enlarged

tonsils or adenoids that obstruct the airway. It is usually performed after the patient has recovered from an acute tonsillitis and no infection is present (except with an acute peritonsillar abscess). The procedure may involve complete tonsil removal (for chronic infection) or a partial tonsil removal for obstruction without infection. A variety of techniques are used to remove tonsils from adults; however, the dissection and snare technique is still the most common. The adenoids may be removed at the same time. When the patient is an adult, a tonsillectomy and adenoidectomy (T&A) is usually performed with him or her under general anesthesia. After surgery, nursing interventions focus on assessing for airway clearance, providing pain relief, and monitoring for excessive bleeding.

PERITONSILLAR ABSCESS

Peritonsillar abscess (PTA) is a complication of acute tonsillitis. The infection spreads from the tonsil to the surrounding tissue, which forms an abscess. The most common cause of PTA is group A beta-hemolytic *Streptococcus*.

Manifestations include pus behind the tonsil causing one-sided swelling with deviation of the uvula toward the unaffected side. The patient may drool, have severe throat pain radiating to the ear, have a voice change, and have difficulty swallowing. He or she may also have a tonic contraction of the muscles of chewing (*trismus*) and have difficulty breathing. Bad breath is present, and lymph nodes on the affected side are swollen. An intraoral or transcutaneous ultrasound may be used for diagnosis (Hoyle, 2009).

Outpatient management with antibiotic therapy and percutaneous needle aspiration of the abscess is usually needed. Acute care management may include IV opioid analgesics for severe pain and IV steroids to reduce the swelling. The patient usually improves in 36 hours. *Stress the importance of completing the antibiotic regimen and of coming to the emergency department quickly if symptoms of obstruction appear (drooling and stridor).* Teach him or her about comfort measures (e.g., warm saline gargles or irrigations, an ice collar, analgesics). Hospitalization is required when the airway is in jeopardy or when the infection does not respond to antibiotic therapy. Incision and drainage of the abscess and additional antibiotic therapy may be needed. A tonsillectomy may be performed to prevent recurrence.

CHART 33-3 KEY FEATURES

Acute Tonsillitis

- Sudden onset of a mild to severe sore throat
- Fever
- Muscle aches
- Chills
- Dysphagia, odynophagia (painful swallowing of food)
- Pain in the ears
- Headache
- Anorexia
- Malaise
- “Hot potato” voice (thickened voice of poor quality)
- Tonsils visually swollen and red with pus
- Tonsils may be covered with a white or yellow exudate
- Purulent drainage may be expressed by pressing a tonsil
- Uvula visually edematous or inflamed
- Cervical lymph nodes usually tender and enlarged

DISORDERS OF THE LARYNX AND LUNGS

LARYNGITIS

Laryngitis is an inflammation of the mucous membranes lining the larynx and may or may not include edema of the vocal cords. It can occur as a single problem or occur with upper respiratory infections. Laryngitis also can be a manifestation of other problems, such as throat or lung cancer. Common causes include exposure to irritating inhalants (e.g., chemical fumes, tobacco, alcohol, smoke), voice overuse, inhalation of fumes (e.g., glue, paint thinner, butane), or intubation. Recurrent laryngitis may be caused by gastroesophageal reflux disease (GERD).

Assess the patient for hoarseness, dry cough, and difficulty swallowing. Complete but temporary voice loss (*aphonia*) also may occur. A laryngeal mirror is used by a physician or

advanced practice nurse to inspect the larynx and identify inflammation, polyps, edema, or tumor. If suspicious lesions are present, an x-ray, computed tomography, or fiberoptic laryngoscopic examination may be needed. Patients who may have a disorder other than acute laryngitis are referred to an ear, nose, and throat (ENT) specialist (otolaryngologist).

Nursing management focuses on symptom relief and prevention. Treatment consists of voice rest, steam inhalations, increased fluid intake, and throat lozenges. Antibiotic therapy and bronchodilators are prescribed when sinusitis, bronchitis, or other bacterial infection is also present. Teach the patient and family about relief measures, infection prevention, and avoidance of alcohol, tobacco, and pollutants, which can irritate the larynx.

Teach about preventive strategies such as reducing tobacco and alcohol use. Emphasize the need to avoid activities that place an added strain on the larynx, such as singing, cheering, public speaking, heavy lifting, and whispering. Speech-language therapy is used when vocal cord injury occurs with laryngitis. Further evaluation is needed for recurrent bouts of laryngitis.

SEASONAL INFLUENZA

Pathophysiology

Seasonal influenza, or “flu,” is a highly contagious acute viral respiratory infection that can occur in adults of all ages. Epidemics are common and lead to complications of pneumonia or death, especially in older adults or debilitated or immunocompromised patients. Between 5% and 20% of the U.S. population develop influenza each year, and more than 36,000 deaths per year are caused by it (Kapustin, 2008). Hospitalization may be required. Influenza may be caused by one of several virus families, referred to as A, B, and C.

The patient with influenza often has a severe headache, muscle aches, fever, chills, fatigue, and weakness. Adults are contagious from 24 hours before symptoms occur and up to 5 days after they begin. Patients who are immunosuppressed may be contagious for several weeks. Sore throat, cough, and watery nasal discharge generally follow the initial symptoms for a week or longer. Most patients feel fatigued for 1 to 2 weeks after the acute episode has resolved.

Health Promotion and Maintenance

Vaccinations for the prevention of influenza are widely available. The vaccine is changed every year on the basis of which specific viral strains are most likely to pose a problem during the influenza season (i.e., late fall and winter). Usually, the vaccines contain three antigens for the three expected viral strains (trivalent influenza vaccine [TIV]). Influenza vaccinations can be taken as an IM injection (Fluviron, Fluzone) or as a live attenuated influenza vaccine (LAIV) by intranasal spray (FluMist). An **attenuated virus** is a live virus that has been altered to reduce its ability to cause an infection. The intranasal vaccine is live, and some people develop influenza symptoms after its use. It is recommended only for healthy people up to 49 years of age. People recommended to be vaccinated yearly include those older than 50 years, people with chronic illness or immune compromise, those living in institutions, people living with or caring for adults with health problems that put them at risk for severe complications of influenza, and health care personnel providing direct care to

patients (Centers for Disease Control and Prevention [CDC], 2010c).

Teach the patient who is sick to reduce the risk for spreading the flu by thoroughly washing hands, especially after nose blowing, sneezing, coughing, rubbing the eyes, or touching the face. Other precautions include staying home from work, school, or places where people gather; covering the mouth and nose with a tissue when sneezing or coughing; disposing properly of used tissues immediately; and avoiding close contact with other people (e.g., kissing, hugging, handshaking). Although handwashing is a good method to prevent transmitting the virus in droplets from sneezing or coughing, many people cannot wash their hands as soon as they have coughed or sneezed. The technique recommended by the CDC for controlling flu spread is to sneeze or cough into the upper sleeve rather than into the hand (CDC, 2010a). (Respiratory droplets on the hands can contaminate surfaces and be transmitted to other people.)

PATIENT-CENTERED COLLABORATIVE CARE

Viral infections do not respond to traditional antibiotic therapy. Antiviral agents may be effective for prevention and treatment of some types of influenza. Amantadine (Symmetrel) and rimantadine (Flumadine) have been effective in the prevention and treatment of influenza A, although strains of resistant organisms are increasing. Ribavirin (Virazole) has been used for severe influenza B. Two drugs that may shorten the duration of influenza A and influenza B are zanamivir (Relenza), which is used as an oral inhalant, and oseltamivir (Tamiflu), which is an oral tablet. These drugs prevent viral spread in the respiratory tract by inhibiting a viral enzyme (neuraminidase) that allows the virus to penetrate respiratory cells. To be effective, they must be taken within 24 to 48 hours after the onset of manifestations.

Advise the patient to stay in bed for several days and increase fluid intake unless another problem requires fluid restriction. Saline gargles may ease sore throat pain. Antihistamines may reduce the rhinorrhea. Other supportive measures are the same as those for acute rhinitis.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

The 75-year-old client tells the nurse he is not planning to receive a “flu shot” this year because he had one just a year ago. What is the nurse’s best response?

- “Because you are older and your immune system is more fragile, you should have one this year too as a booster.”
- “The virus causing influenza often changes each year and a new influenza vaccination is needed every flu season.”
- “The ‘flu shot’ you had last year should still protect you for seasonal influenza, but you still need a vaccination for H1N1.”
- “The fact that you have been vaccinated by injection just last year makes you a candidate to use the nasal vaccination this year.”

PANDEMIC INFLUENZA

Pathophysiology

Many viral infections among animals and birds are not usually transmitted to humans. A few notable exceptions have occurred when these animal and bird viruses mutated and

became highly infectious to humans. These infections are termed **pandemic** because they have the potential to spread globally. Such pandemics include the 1918 “Spanish” influenza that resulted in at least 40 million deaths worldwide and perhaps as many as 100 million deaths. This virus, the H1N1 strain, also known as “swine flu,” mutated and became highly infectious to humans. Most recently, the 2009 H1N1 influenza A resulted in a pandemic infection that spread to 215 countries. In the United States, the number of people infected with this virus during the pandemic is estimated at 61 million, resulting in more than 12,000 deaths (CDC, 2010b). A vaccine was developed in 2009 as a single antigen (monovalent) and was administered separately from the seasonal influenza vaccine. For the 2010–2011 influenza season, the trivalent seasonal vaccine contained the H1N1 antigen.

A new avian virus is the H5N1 strain, known as “avian influenza” or “bird flu,” that has infected millions of birds, especially in Asia, and now has started to spread by human-to-human contact. World health officials are concerned that this strain could become a pandemic because humans have essentially no naturally occurring immunity to this virus. Thus the infection could lead to a worldwide pandemic with very high mortality rates.

Health Promotion and Maintenance

The prevention of a worldwide influenza pandemic of any virus is the responsibility of everyone. Health officials have been monitoring the situation with human outbreaks and with testing of both wild and domestic bird species throughout the world. Vaccines currently are available for both H1N1 and H5N1; however, the H5N1 vaccine is stockpiled and not part of general influenza vaccination. The recommended early approach to disease prevention with H5N1 is early recognition of new cases and the implementation of community and personal quarantine and social-distancing behaviors to reduce exposure to the virus.

Plans for prevention and containment in North America have been developed with the cooperation of most levels of government. When a cluster of cases is discovered in an area, the stockpiled vaccine is to be made available for immunizations. Because vaccination with this vaccine is a two-step process with the first IM injection followed 28 days later by a second IM injection, additional prevention measures are needed.

The antiviral drugs *oseltamivir* (Tamiflu) and *zanamivir* (Relenza) should be widely distributed. These drugs are not likely to prevent the disease but may reduce the severity of the infection and reduce the mortality rate. The infected patients should be cared for in strict isolation. All nonessential public activities in the area should be stopped. These include public gatherings of any type, attendance at schools, religious services, shopping, and many types of employment. People should stay home and use their emergency preparedness supplies (food, water, and drugs) they have stockpiled for at least 2 weeks (see Chapter 12). Travel to and from the affected area should be stopped.

Urge all people to pay attention to public health announcements and early warning systems for disease outbreaks. Teach them the importance of starting prevention behaviors immediately upon notification of an outbreak. Teach all people to have a minimum of a 2-week supply of all their prescribed drugs and at least a 2-week supply of nonperishable food and

water for each member of the household. They should also have a battery-powered radio (and batteries) to keep informed of updates in an active prevention situation. See Chapter 12 for more information on items to have ready in the home for disaster preparedness. *An influenza pandemic is a disaster, and containing it requires the cooperation of all people.*

PATIENT-CENTERED COLLABORATIVE CARE

Care of the patient with avian influenza focuses on supporting the patient and preventing spread of the disease. Both are equally important. The initial manifestations of avian influenza are similar to other respiratory infections—cough, fever, and sore throat. These progress rapidly to shortness of breath and pneumonia. In addition, diarrhea, vomiting, abdominal pain, and bleeding from the nose and gums occur. *Ask any patient with these symptoms if he or she has recently (within the past 10 days) traveled to areas of the world affected by H5N1. If such travel has occurred, coordinate with the health care team to place the patient in an airborne isolation room with negative air pressure. These precautions remain until the diagnosis of H5N1 is ruled out or the threat of contagion is over.* Diagnosis is made based on clinical manifestations and positive testing. The most rapid test currently approved for testing of H5N1 is the AVantage A/H5N1 Flu Test. It can detect a specific protein (NS1), which indicates the presence of H5N1, from nasal or throat swabs in less than 40 minutes.

When providing care to the patient with avian influenza, personal protective equipment is essential. Coordinate the protection activity by ensuring that anyone entering the patient’s room for any reason wears a fit-tested respirator or a standard surgical mask (“Lessons Learned,” 2010). Use other Airborne Precautions and Contact Precautions as described in Chapter 25. Teach others to self-monitor for disease symptoms, especially of respiratory infection, for at least a week after the last contact with the patient. Use the antiviral drug *oseltamivir* (Tamiflu) or *zanamivir* (Relenza) within 48 hours of contact with the infected patient. All health care personnel working with patients suspected of having avian influenza are recommended to receive the vaccine in the recommended two-step process.

No effective treatment for this infection currently exists. Antibiotics and antiviral drugs cannot kill the virus or prevent its replication. Interventions are supportive to allow the patient’s own immune system to fight the infection. Oxygen is given when hypoxia or breathlessness is present. Respiratory treatments to dilate the bronchioles and move respiratory secretions are used. If hypoxemia is not improved with oxygen therapy, intubation and mechanical ventilation may be needed. Antibiotics are used to treat a bacterial pneumonia that may occur with H5N1.

In addition to the need for respiratory support, the patient with H5N1 may have severe diarrhea and need fluid therapy. The Transmission Precautions may prevent the use of a scale to determine fluid needs by weight changes. Monitor the patient’s hydration status, and carefully measure intake and output. The type of fluid therapy varies with the patient’s cardiovascular status and the osmolality of the blood. The two most important areas to monitor during rehydration are pulse rate and quality and urine output.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

For what reason is pandemic influenza a bigger health threat than seasonal influenza?

- A. No vaccines are available for immunization to prevent pandemic influenza.
- B. Unlike seasonal influenza, pandemic influenza does not respond to antibiotics.
- C. Seasonal influenza viruses are killed by exposure to heat, and pandemic viruses are not.
- D. Pandemic influenzas began from animal viruses, and humans have no natural immunity to them.

PNEUMONIA

Pathophysiology

Pneumonia is an excess of fluid in the lungs resulting from an inflammatory process. The inflammation is triggered by many infectious organisms and by inhalation of irritating agents. Infectious pneumonias are categorized as community-acquired pneumonia (CAP) or health care–associated pneumonia (known as *HAP* or *HAI*), depending on where the patient was exposed to the infectious agent (Dobbins & Howard, 2011). HAPs are more likely to be resistant to some antibiotics than are CAPs.

The inflammation occurs in the interstitial spaces, the alveoli, and often the bronchioles. The process begins when organisms penetrate the airway mucosa and multiply in the alveoli. White blood cells (WBCs) migrate to the area of infection, causing local capillary leak, edema, and exudate. These fluids collect in and around the alveoli, and the alveolar walls thicken. Both events seriously reduce gas exchange and lead to hypoxemia, interfering with oxygenation and possibly leading to death. Red blood cells (RBCs) and fibrin also move into the alveoli. The capillary leak spreads the infection to other areas of the lung. If the organisms move into the bloodstream, sepsis results; if the infection extends into the pleural cavity, *empyema* (a collection of pus in the pleural cavity) results.

The fibrin and edema of inflammation stiffen the lung, reducing compliance and decreasing the vital capacity. Alveolar collapse (atelectasis) further reduces the ability of the lung to oxygenate the blood moving through it. As a result, arterial oxygen levels fall, causing hypoxemia.

Pneumonia may occur as lobar pneumonia with **consolidation** (solidification, lack of air spaces) in a segment or an entire lobe of the lung or as bronchopneumonia with diffusely scattered patches around the bronchi. The extent of lung involvement after the organism invades depends on the host defenses. Bacteria multiply quickly in a person whose immune system is compromised. Tissue necrosis results when an abscess forms and perforates the bronchial wall.

Etiology

Pneumonia develops when the immune system cannot combat the virulence of the invading organisms. Organisms from the environment, invasive devices, equipment and supplies, staff, or other people can invade the body. Risk factors are listed in [Table 33-2](#). Pneumonia can be caused by bacteria, viruses, mycoplasmas, fungi, rickettsiae, protozoa, and helminths (worms). Noninfectious causes of pneumonia include

TABLE 33-2 RISK FACTORS FOR PNEUMONIA

Community-Acquired Pneumonia

- Is an older adult
- Has never received the pneumococcal vaccination or received it more than 6 years ago
- Did not receive the influenza vaccine in the previous year
- Has a chronic health problem or other coexisting condition
- Has recently been exposed to respiratory viral or influenza infections
- Uses tobacco or alcohol or is exposed to high amounts of secondhand smoke

Health Care–Acquired Pneumonia

- Is an older adult
- Has a chronic lung disease
- Has presence of gram-negative colonization of the mouth, throat, and stomach
- Has an altered level of consciousness
- Has had a recent aspiration event
- Has presence of endotracheal, tracheostomy, or nasogastric tube
- Has poor nutritional status
- Has immunocompromised status (from disease or drug therapy)
- Uses drugs that increase gastric pH (histamine [H₂] blockers, antacids) or alkaline tube feedings
- Is currently receiving mechanical ventilation (ventilator-associated pneumonia [VAP])

inhalation of toxic gases, chemical fumes, and smoke and aspiration of water, food, fluid, and vomitus.

Incidence/Prevalence

In the United States, 2 to 5 million cases of pneumonia occur each year and it is the seventh leading cause of death ([Schappert et al., 2008](#)). The incidence is higher among older adults, nursing home residents, hospitalized patients, and those being mechanically ventilated. CAP is more common than HAP and occurs in late fall and winter as a complication of influenza. HAP is commonly acquired as a result of transmission during a hospital stay. A specific type of HAP is ventilator-associated pneumonia (VAP). HAP has a 20% to 50% mortality rate; the highest incidence is in those patients infected with *Pseudomonas aeruginosa*, *Acinetobacter*, *Klebsiella*, other “high-risk” organisms, or secondary bacteremia.

Health Promotion and Maintenance

Antigens from 23 different types of pneumonia organisms are included in the pneumococcal polysaccharide vaccine (PPV23). *Patient education is important in the prevention of pneumonia* ([Chart 33-4](#)). *Especially encourage people older than 65 years and those with a chronic health problem to receive the PPV23*. This vaccine is usually given once; however, some experts believe that older adults and those with chronic health problems could benefit from a second vaccination if more than 5 years have passed since the first vaccination ([American Lung Association \[ALA\], 2010a](#)). Because pneumonia often follows influenza, especially among older adults, urge all people to receive the seasonal influenza vaccination yearly ([Schweon, 2010](#)).

Other prevention techniques include strict handwashing to avoid the spread of organisms and avoiding large gatherings of people during cold and flu season. Teach the patient who has a cold or the flu to see his or her health care provider

CHART 33-4 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Preventing Pneumonia

- Know whether you are at risk for pneumonia (older than 65 years, have a chronic health problem [especially a respiratory problem], or have limited mobility and are confined to a bed or chair during your waking hours).
- Have the annual influenza vaccine after discussing appropriate timing of the vaccination with your primary health care provider.
- Discuss the pneumococcal vaccine with your primary health care provider, and have the vaccination as recommended.
- Avoid crowded public areas during flu and holiday seasons.
- If you have a mobility problem, cough, turn, move about as much as possible, and perform deep-breathing exercises.
- If you are using respiration equipment at home, clean the equipment as you have been taught.
- Avoid indoor pollutants, such as dust, secondhand (passive) smoke, and aerosols.
- If you do not smoke, do not start.
- If you smoke, seek professional help on how to stop (or at least decrease) your habit.
- Be sure to get enough rest and sleep on a daily basis.
- Eat a healthy, balanced diet.
- Drink at least 3 liters of nonalcoholic fluids each day (unless fluid restrictions are needed because of another health problem).

if fever lasts more than 24 hours, if the problem lasts longer than 1 week, or if symptoms worsen.

Hospital respiratory therapy equipment must be well maintained and decontaminated or changed as recommended. Use sterile water rather than tap water in GI tubes, and institute Aspiration Precautions as indicated (see [Chapter 31](#)).

VAP is on the rise, especially among patients with endotracheal tubes in place for mechanical ventilation (American Association of Critical-Care Nurses [AACN], 2008; Luttenberger, 2010). Although just having the tube providing a direct connection between the environment and the patient's lower respiratory passageways increases the risk for VAP, the risk can be reduced with conscientious assessment and meticulous nursing care ([Garcia et al., 2009](#)). Three care actions, known as a “ventilator bundle,” have been shown to reduce the incidence of VAP—hand hygiene, oral care, and head-of-bed elevation. Oral care is critical in reducing the risk because many common organisms causing VAP are translocated from the patient's mouth into the respiratory tract. A variety of commercial products are available as oral care kits and suction kits specifically designed for patients who have an endotracheal tube. In addition, some types of endotracheal tubes have a separate lumen to allow for continuous suction of

! NURSING SAFETY PRIORITY

Action Alert

Assess the oral cavity every 6 hours for patients who are mechanically ventilated and have an endotracheal tube. After assessment, suction the oral cavity, and clean the tissues and gums using agents that reduce organisms and provide moisture every 6 hours. Place the ventilated patient on his or her side during oral care to help reduce the risk for aspiration. If teeth are present, brush them every 12 hours ([Garcia et al., 2009](#)).

CHART 33-5 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Preventing Ventilator-Associated Pneumonia (VAP)

- If possible, perform oral care with a disinfecting oral rinse right *before* the intubation.
- Do not wear hand jewelry, especially rings, when providing care to ventilator patients.
- Wash hands before and after contact with the patient.
- Provide complete oral care at least every 12 hours.
- Remove subglottic secretions frequently (at least every 2 hours) or continuously (when the endotracheal tube has a separate lumen that opens directly above the tube cuff).
- Keep the head of the bed elevated to at least 30 degrees unless another health problem is a contraindication for this position.
- Verify that an initial x-ray has been obtained to confirm the placement of any nasogastric tube before instilling drugs, fluids, or feedings into the tube.
- Avoid turning the patient or placing him or her in the supine position (even briefly) within an hour after a bolus tube feeding.
- Work with the patient and health care team to assist in the weaning process as soon as possible (see [Chapter 34](#)).

Information from Tolentino-DelosReyes, A., Ruppert, S., & Shiao, P. (2007). Evidence-based practice: Use of the ventilator bundle to prevent ventilator-associated pneumonia. *American Journal of Critical Care*, 16(1), 20-27.

subglottic secretions to prevent their aspiration. However, the key to successful prevention of VAP remains nursing vigilance in assessment and oral care ([Ames, 2011](#)). [Chart 33-5](#) lists best practices for preventing VAP.

PATIENT-CENTERED COLLABORATIVE CARE

The Concept Map on p. 649 addresses assessment and nursing care issues related to patients who have pneumonia. The manifestations of pneumonia differ in older patients compared with younger patients.

ASSESSMENT

History

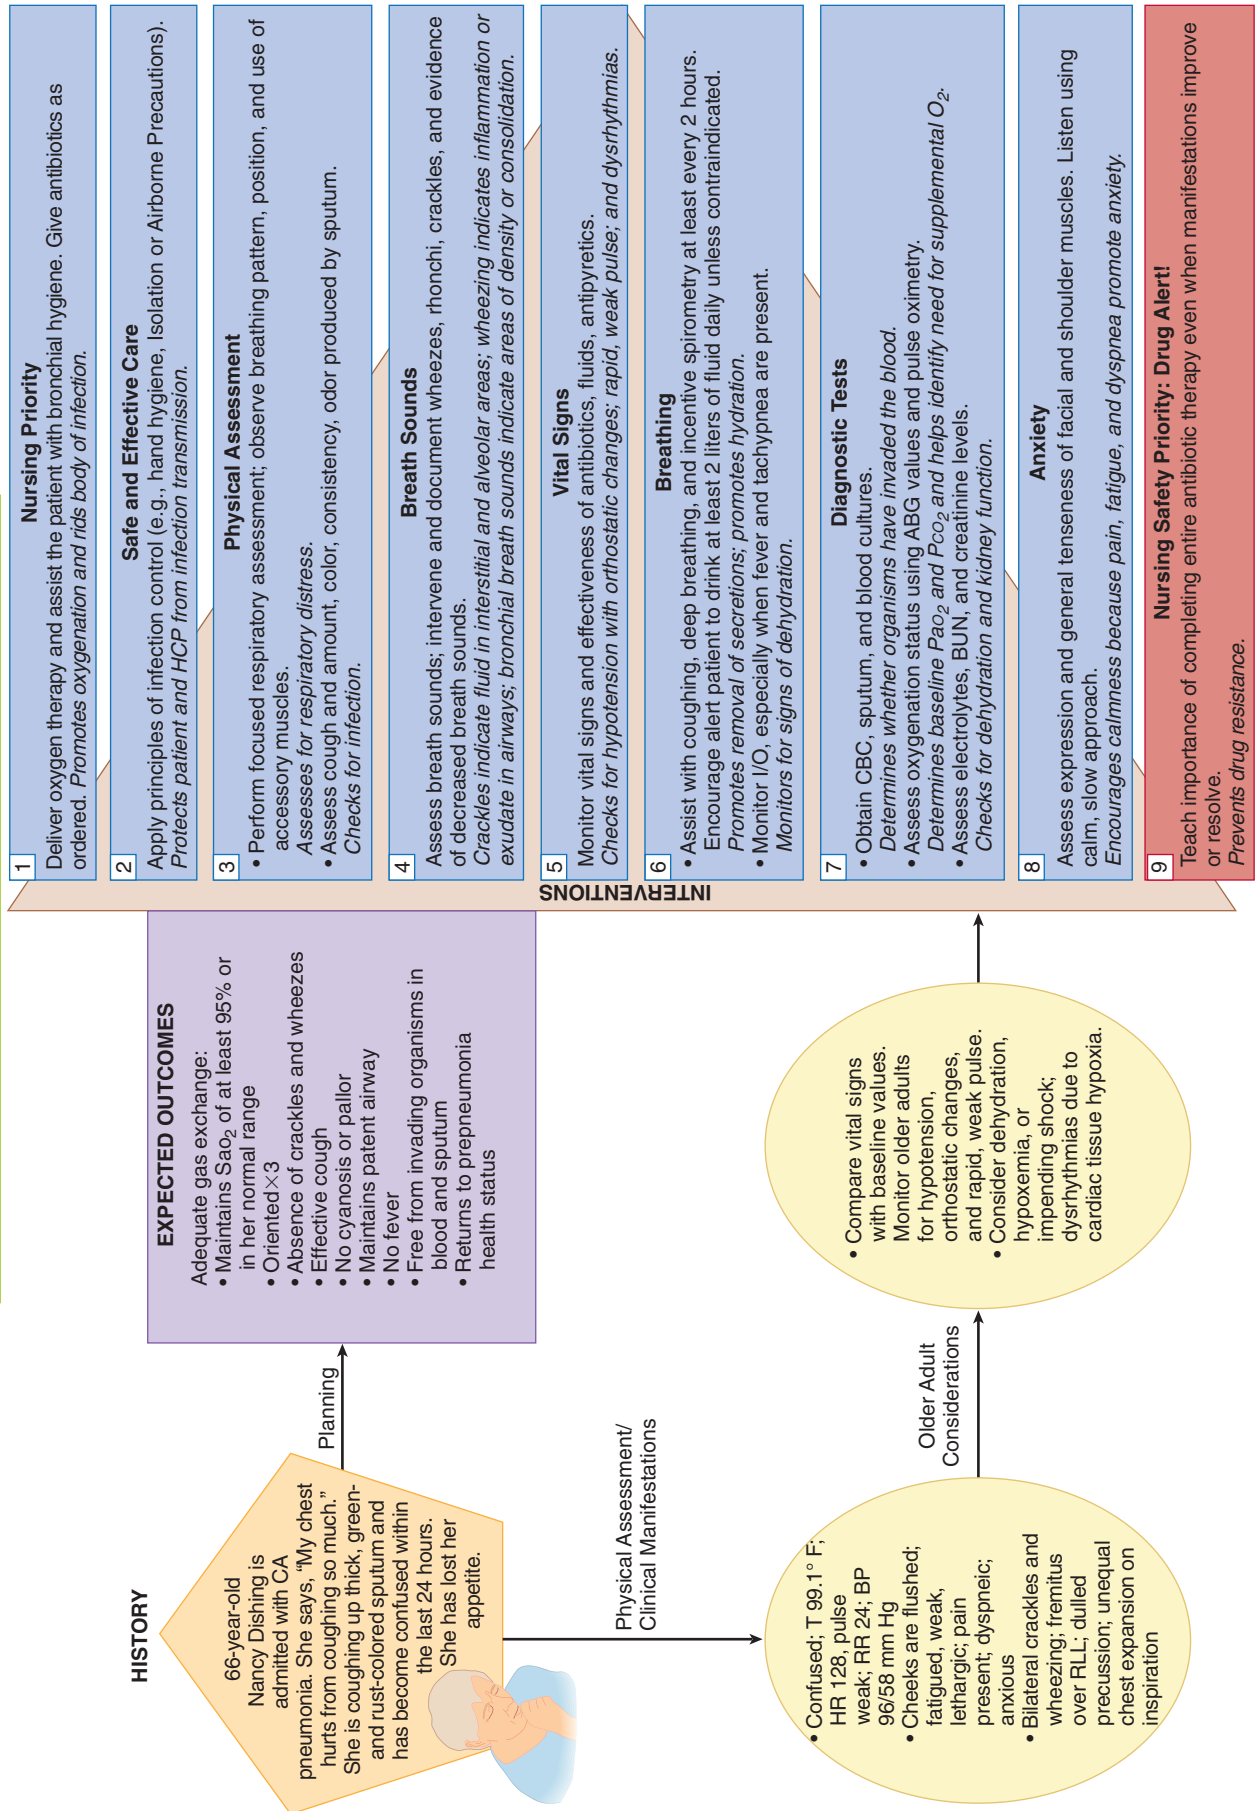

Assess for the risk factors for infection (see [Table 33-2](#)). Obtain the information from a family member if the patient is confused or too dyspneic. Document age; living, work, or school environment; diet, exercise, and sleep routines; swallowing problems; presence of a nasogastrintestinal tube; tobacco and alcohol use; past and current use of “street” drugs; and history of drug addiction and injection drug use. Ask about past respiratory illnesses and whether the patient has been exposed to influenza or pneumonia or has had a recent viral infection. Ask about recent skin rashes, insect bites, and exposure to animals.

If the patient has chronic respiratory problems, ask whether respiratory equipment is used in the home. Assess whether the patient's home cleaning level is adequate to prevent infection. Ask when he or she received the last influenza or pneumococcal vaccine.

Physical Assessment/Clinical Manifestations

Observe the general appearance. Many patients with pneumonia have flushed cheeks, bright eyes, and an anxious expression. The patient may have chest or pleuritic pain or

Concept Map: Community-Acquired (CA) Bacterial Pneumonia

discomfort, myalgia, headache, chills, fever, cough, tachycardia, dyspnea, tachypnea, hemoptysis, and sputum production. Severe chest muscle weakness also may be present from sustained coughing.

Observe the patient's breathing pattern, position, and use of accessory muscles. The hypoxic patient may be uncomfortable in a lying position and will sit upright, balancing with the hands. Assess the cough and the amount, color, consistency, and odor of sputum produced.

Crackles are heard with auscultation when fluid is in interstitial and alveolar areas. Wheezing may be heard if inflammation or exudate is in the airways. Bronchial breath sounds are heard over areas of density or consolidation. Fremitus is increased over areas of pneumonia, and percussion is dulled. Chest expansion may be diminished or unequal on inspiration.

In evaluating vital signs, compare the results with baseline values. The patient with pneumonia is likely to be hypotensive with orthostatic changes as a result of vasodilation and dehydration, especially the older adult. A rapid, weak pulse may indicate hypoxemia, dehydration, or impending shock. Dysrhythmias may be present as a result of cardiac tissue hypoxia. Common pneumonia manifestations and their causes are listed in Table 33-3.

CONSIDERATIONS FOR OLDER ADULTS

The older adult with pneumonia has weakness, fatigue, lethargy, confusion, and poor appetite. Fever and cough may be absent, but hypoxemia is often present. The most common manifestation of pneumonia in the older adult patient is acute confusion from hypoxia. The WBC count may not be elevated until the infection is severe. Waiting to treat the disease until more typical manifestations appear greatly increases the risk for sepsis and death (Touhy & Jett, 2010).

TABLE 33-3 PATHOPHYSIOLOGY OF COMMON CLINICAL MANIFESTATIONS OF PNEUMONIA

CLINICAL MANIFESTATION	PATHOPHYSIOLOGY
Increased respiratory rate/dyspnea	Stimulation of chemoreceptors Increased work of breathing as a result of decreased lung compliance Stimulation of J receptors Anxiety Pain
Hypoxemia	Alveolar consolidation Pulmonary capillary shunting
Cough	Fluid accumulation in the receptors of the trachea, bronchi, and bronchioles
Purulent, blood-tinged, or rust-colored sputum	A result of the inflammatory process in which fluid from the pulmonary capillaries and red blood cells move into the alveoli
Fever	Phagocytes release pyrogens that cause the hypothalamus to increase body temperature
Pleuritic chest discomfort	Inflammation of the parietal pleura causes pain on inspiration

Psychosocial Assessment

The patient with pneumonia often has pain, fatigue, and dyspnea, all of which promote anxiety. Assess anxiety by looking at his or her facial expression and general tenseness of facial and shoulder muscles. Listen to him or her carefully, and use a calm, slow approach. Because of airway obstruction and muscle fatigue, the patient with dyspnea speaks in broken sentences. Keep the interview short if severe dyspnea or breathing discomfort is present.

Laboratory Assessment

Sputum is obtained and examined by Gram stain, culture, and sensitivity testing; however, the responsible organism often is not identified. A sputum sample is easily obtained from the patient who can cough into a specimen container. Extremely ill patients may need suctioning to obtain a sputum specimen. In these situations, a specimen is obtained by sputum trap (Fig. 33-1) during suctioning. A CBC is obtained to assess an elevated WBC count, which is a common finding except in older adults. Blood cultures may be performed to determine whether the organism has invaded the blood.

In severely ill patients, arterial blood gases (ABGs) may be performed to determine baseline arterial oxygen and carbon dioxide levels and help identify a need for supplemental oxygen. Serum electrolyte, blood urea nitrogen (BUN), and creatinine levels also are assessed. A high BUN level may occur as a result of dehydration. Hypernatremia (high blood sodium levels) occurs with dehydration as a result of fever and decreased fluid intake.

Imaging Assessment

Chest x-ray continues to be the most common diagnostic test for pneumonia but may not show changes until 2 or more days after manifestations are present. It usually appears on chest x-ray as an area of increased density. It may involve a lung segment, a lobe, one lung, or both lungs. *In the older adult, the chest x-ray is essential for early diagnosis because pneumonia symptoms are often vague* (Fowler, 2008; Touhy & Jett, 2010).

FIG. 33-1 A Luken's tube for collection of sterile sputum/mucus specimens.

Other Diagnostic Assessment

Pulse oximetry is used to assess for hypoxemia. Invasive tests such as transtracheal aspiration, bronchoscopy, or direct needle aspiration of the lung may be needed. Thoracentesis is most often used in patients who have an accompanying pleural effusion.

ANALYSIS

Priority problems for the patient with pneumonia are:

1. Hypoxemia related to decreased diffusion at the alveolar-capillary membrane
2. Potential for airway obstruction related to excessive tracheobronchial secretions, fatigue, chest discomfort, muscle weakness
3. Potential for sepsis related to the presence of microorganisms in a very vascular area

PLANNING AND IMPLEMENTATION

Managing Hypoxemia

Planning: Expected Outcomes. The patient with pneumonia is expected to have adequate oxygenation. Indicators of adequate oxygenation are:

- Maintenance of Sao_2 of at least 95% or in the patient's normal range
- Absence of cyanosis
- Maintenance of cognitive orientation

Interventions. Interventions to improve oxygenation are similar to those for the patient with chronic airflow limitation (CAL) (see Chapter 32). Nursing priorities include delivery of oxygen therapy and assisting the patient with bronchial hygiene.

Oxygen therapy is usually delivered by nasal cannula or mask unless the hypoxemia does not improve with these devices. The patient who is confused may not tolerate a face-mask. Check the skin under the device and under the elastic band, especially around the ears, for areas of redness or skin breakdown. Actions for oxygen therapy are listed in Chart 30-1 in Chapter 30.

Incentive spirometry is a type of bronchial hygiene used in pneumonia. The objective is to improve inspiratory muscle action and to prevent or reverse atelectasis (alveolar collapse). Instruct the patient to exhale fully, then place the mouthpiece in his or her mouth, and then take a long, slow, deep breath for 3 to 5 seconds. Evaluate technique, and record the volume of air inspired. Teach the patient to perform 5 to 10 breaths per session every hour while awake.

Preventing Airway Obstruction

Planning: Expected Outcomes. The patient with pneumonia is expected to maintain a patent airway. Indicators are:

- Effective cough
- Absence of pallor or cyanosis
- Absence of crackles and wheezes on auscultation
- Pulse oximetry at or above 95%

Interventions. Interventions to avoid airway obstruction in pneumonia are similar to those for chronic obstructive pulmonary disease (COPD) or asthma. Because of fatigue, muscle weakness, chest discomfort, and excessive secretions, the patient often has difficulty clearing secretions. Help him or her cough and deep breathe at least every 2 hours. The alert patient may use an incentive spirometer to facilitate deep breathing and stimulate coughing. Encourage the alert

patient to drink at least 2 liters of fluid daily to prevent dehydration unless another health problem requires fluid restriction. Adequate hydration may help thin secretions and make them easier to remove. Monitor intake and output, oral mucous membranes, and skin turgor to assess for and ensure adequate hydration, especially when fever and tachypnea are present.

Bronchodilators, especially beta₂ agonists (see Chart 32-7 in Chapter 32), are prescribed when bronchospasm is present. They are initially given by nebulizer and then by metered-dose inhaler. Inhaled or IV steroids are used with acute pneumonia when airway swelling is present.

Preventing Sepsis

Planning: Expected Outcomes. The patient with pneumonia is expected to be free of the invading organism and to return to a pre-pneumonia health status. Indicators are:

- Absence of fever
- Absence of pathogens in blood and sputum cultures
- WBC count and differential within normal limits

Interventions. The key to effective treatment of pneumonia is eradication of the organism causing the infection. When sepsis accompanies pneumonia, the risk for death is high (Todd, 2010). Anti-infectives are given for all types of pneumonias except those caused by viruses. Which anti-infective therapy is prescribed is based on how the pneumonia was acquired (i.e., CAP or HAP). The exact drug or drugs and their routes of delivery are determined by the severity of the infection, the organism suspected or identified, and whether the patient has other conditions or factors that increase the risk for complications. Drug therapy choices must reflect the degree of drug resistance in the specific geographic area and in that hospital setting.

If IV drugs are used, the patient may be able to be switched to oral therapy in 2 or 3 days, depending on the response (e.g., stable clinical condition, afebrile). The course of anti-infective therapy varies with the drug used and the organism(s) involved. Usually anti-infectives are used for 5 to 7 days for a

DECISION-MAKING CHALLENGE

Patient-Centered Care; Evidence-Based Practice

The patient is an 80-year-old female nursing home resident who had a stroke 6 months ago. She has been cognitively intact and has left-sided weakness and difficulty swallowing. Several days ago, she was found choking while eating her lunch. Other long-term health problems include diabetes and hypertension. Today, the nursing assistant reported that the patient did not recognize her this morning and had a temperature of 97.2° F. The gerontologic nurse practitioner who examined the patient diagnosed her with pneumonia in the right middle and lower lobes.

1. What risk factors does this patient have for pneumonia?
2. Her record shows that she received the pneumonia vaccination 8 years ago and the seasonal influenza vaccination on admission to the facility. Explain the possibilities for why these immunizations were not effective in preventing the current pneumonia.
3. The nurse practitioner prescribed ceftriaxone (Rocephin) 2 g IV piggyback stat, then 1 g every 12 hours; oxygen at 6 L by nasal cannula; vital signs hourly; and incentive spirometry every 2 hours. Which intervention should be performed first? Provide a rationale for your choice.
4. What could have precipitated this problem and what steps could be taken to prevent it from happening again?

patient with uncomplicated CAP and up to 21 days for an immunocompromised patient or one with HAP.

Drug resistance is becoming increasingly common, especially for infections with *Streptococcus pneumoniae*. This problem is known as *drug-resistant Streptococcus pneumoniae*, or *DRSP*. DRSP is most common among people older than 65 years and among those who became infected as a result of exposure to young children from a day-care environment.

For pneumonia resulting from aspiration of food or stomach contents, interventions focus on preventing lung damage and treating the infection. Aspiration of acidic stomach contents can cause widespread inflammation, leading to acute respiratory distress syndrome (ARDS) and permanent lung damage (Eisenstadt, 2010). In these conditions, steroids and NSAIDs are used with antibiotics to reduce the inflammatory response.

Community-Based Care

The patient needs to continue the anti-infective drugs as prescribed. An important nursing role is to reinforce, clarify, and provide information to the patient and family as indicated.

Home Care Management

No special changes are needed in the home. If the home has a second story, the patient may prefer to stay on one floor for a few weeks, because stair climbing increases fatigue and dyspnea. Toileting needs may be met by using a bedside commode if a bathroom is not located on the level the patient is using. Home care needs depend on the patient's level of fatigue, dyspnea, and family and social support.

The long recovery phase, especially in the older adult, can be frustrating. Fatigue, weakness, and a residual cough can last for weeks. Some patients fear they will never return to a "normal" level of functioning. Prepare them for the disease course, and offer reassurance that complete recovery will occur. After discharge, a home nursing assessment may be helpful (Chart 33-6).

Teaching for Self-Management

Review all drugs with the patient and family, and emphasize completing anti-infective therapy. Teach the patient to notify the health care provider if chills, fever, persistent cough, dyspnea, wheezing, hemoptysis, increased sputum production, chest discomfort, or increasing fatigue recurs or if

symptoms fail to resolve. Instruct him or her to get plenty of rest and increase activity gradually.

An important aspect of education for the patient and family is the avoidance of upper respiratory tract infections and viruses. Teach him or her to avoid crowds (especially in the fall and winter when viruses are prevalent), people who have a cold or flu, and exposure to irritants such as smoke. Stress the importance of following his or her health care provider's recommendations for vaccination against influenza and pneumonia. A balanced diet and adequate fluid intake are essential.

Health Care Resources

Inform patients who smoke that smoking is a risk factor for pneumonia. Provide them with information on local smoking-cessation classes. The health care provider may prescribe nicotine patches. Urge patients to enroll in a smoking-cessation program for increased support. Provide information booklets on pneumonia, and urge the patient who has not already been vaccinated against influenza or pneumonia to take this preventive measure after the pneumonia has resolved.

! NURSING SAFETY PRIORITY

Drug Alert

Warn the patient using nicotine patches or supplements of the danger of myocardial infarction if smoking is continued while using other forms of nicotine.

EVALUATION: OUTCOMES

Evaluate the care of the patient with pneumonia based on the identified priority patient problems. The expected outcomes are that he or she:

- Attains or maintains adequate gas exchange
- Maintains patent airways
- Is free of the invading organism
- Returns to his or her pre-pneumonia health status

Specific indicators for these outcomes are listed for each priority patient problem under the Planning and Implementation section (see earlier).

? DECISION-MAKING CHALLENGE

Evidence-Based Practice

The home care patient recovering from pneumococcal pneumonia asks the visiting nurse about whether he should receive the pneumonia vaccination. His daughter speaks up and says, "No, Dad. You are now immune to pneumonia because you actually had the disease."

1. Is the daughter correct in her statement? Why or why not?
2. If the patient is recommended to receive the pneumonia vaccine, when should this occur? Provide a rationale for your choice.

CHART 33-6 FOCUSED ASSESSMENT

The Patient Recovering from Pneumonia

Ask whether the patient has had any of these:

- New-onset confusion
- Chills
- Fever
- Persistent cough
- Dyspnea
- Wheezing
- Hemoptysis
- Increased sputum production
- Chest discomfort
- Increasing fatigue
- Any other symptoms that have failed to resolve

Assess the patient for:

- Fever
- Diaphoresis
- Cyanosis, especially around the mouth or conjunctiva
- Dyspnea, tachypnea, or tachycardia
- Adventitious or abnormal breath sounds
- Weakness

SEVERE ACUTE RESPIRATORY SYNDROME (SARS)

Pathophysiology

Severe acute respiratory syndrome (SARS) is a newer respiratory infection first identified in China early in November 2002. The cause of SARS is a new virus from a family of virus types known as *coronaviruses*. These viruses have ribonucleic

acid (RNA) as their genetic material and have many projections that look like a halo or “corona.” This family of viruses causes many forms of the common cold. The new virus, known as *SARS Co-V*, is a mutated form of the coronavirus and is more virulent than other coronaviruses. It infects cells of the respiratory tract, triggering inflammatory responses, and stays in the respiratory passageways rather than spreading into the blood.

The virus is easily spread by airborne droplets from infected people through sneezing, coughing, and talking. People at greatest risk for SARS are those in close direct contact with an infected person. The portals of entry are the mucous membranes of the eyes, nose, and mouth.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The manifestations of SARS are the same as those of any respiratory infection. Usually, the patient has a fever higher than 100.4° F (38.0° C), a headache, and general body aches. Mild cold symptoms of a runny nose, sore throat, and watery eyes may also be present. Within 2 to 7 days, the patient develops a dry cough and has difficulty breathing. Hypoxia, with cyanosis, low oxygen saturation, and a feeling of breathlessness, indicates more severe illness. Chest x-rays show a pattern similar to pneumonia. Diagnosis is made by the manifestations and the use of a rapid SARS test that detects SARS-CoV RNA in the blood within 2 days after symptoms begin.

INTERVENTIONS

No known effective treatment for this infection exists at this time. Standard antibiotic agents and antiviral drugs cannot kill the virus or prevent its replication. Interventions are supportive to allow the patient’s own immune system to fight the infection. Oxygen is given when hypoxia or breathlessness is present. Therapies to dilate the bronchioles and move respiratory secretions are used. If oxygenation is not improved with oxygen therapy alone, intubation and mechanical ventilation may be needed. Antibiotics are used for bacterial pneumonia that may occur with SARS.

Prevention of Infection Spread

Isolating the person with SARS and adhering to strict Transmission Precautions are effective in containing the infection and preventing an epidemic. These techniques, promoted by the World Health Organization, were successful in preventing

a SARS pandemic in 2002. No additional cases of SARS have been reported since 2004.

A major nursing responsibility is the prevention of infection spread. Use strict airborne isolation techniques. Handwashing is a key prevention intervention. Use Airborne Precautions and Contact Precautions with patients who are suspected to have SARS. Use gowns and eye protection when coming into direct contact with the patient. When the patient is out of the isolation environment, he or she must wear a mask. If for some reason he or she cannot wear a mask, all other people in the environment should wear a mask.

PULMONARY TUBERCULOSIS

Pathophysiology

Tuberculosis (TB) is a highly communicable disease caused by *Mycobacterium tuberculosis*. It is the most common bacterial infection worldwide (World Health Organization [WHO], 2010). The organism is transmitted via **aerosolization** (i.e., an airborne route) (Fig. 33-2). When a person with active TB coughs, laughs, sneezes, whistles, or sings, droplets become airborne and may be inhaled by others. Far more people are infected with the bacillus than actually develop active TB (Knechel, 2009).

The bacillus multiplies freely when it reaches a susceptible site (bronchi or alveoli). An exudative response occurs, causing pneumonitis. With the development of acquired immunity, further growth of bacilli is controlled in most initial lesions. These lesions usually resolve and leave little or no residual bacilli. Only a small percentage of people initially infected with the bacillus ever develop active TB.

Cell-mediated immunity develops 2 to 10 weeks after infection and is manifested by a positive reaction to a tuberculin test. The primary infection may be so small that it does not appear on a chest x-ray. The process of infection occurs in this order:

1. The granulomatous inflammation created by the tubercle bacillus in the lung becomes surrounded by collagen, fibroblasts, and lymphocytes.
2. **Caseation necrosis**, which is necrotic tissue being turned into a granular mass, occurs in the center of the lesion. If this area shows on x-ray, it is called **Ghon’s tubercle**, or the primary lesion.

Areas of caseation then undergo resorption, degeneration, and fibrosis. These necrotic areas may calcify (**calcification**) or liquefy (**liquefaction**). If liquefaction occurs, the liquid material then empties into a bronchus and the evacuated area becomes a cavity (**cavitation**). Bacilli continue to grow in the necrotic cavity wall and spread via lymph channels into new areas of the lung.

A lesion also may progress by direct extension if bacilli multiply rapidly during inflammation. The lesions may extend through the pleura, resulting in pleural or pericardial effusion. **Miliary** or **hematogenous TB** is the spread of TB throughout the body when a large number of organisms enter the blood. Many tiny nodules scattered throughout the lung are seen on chest x-ray. The brain, liver, kidney, or bone marrow can become infected as a result of this spread.

Initial infection is seen more often in the middle or lower lobes of the lung. The local lymph nodes are infected and enlarged. An asymptomatic period usually follows the

! NURSING SAFETY PRIORITY

Action Alert

When performing procedures for patients with SARS that normally induce coughing or promote aerosolization of particles (e.g., suctioning, using a positive-pressure facemask, obtaining a sputum culture, or giving aerosolized treatments), protect yourself and other health care workers. Wear a disposable particulate mask respirator (e.g., N95, N99, or N100) and protective eyewear during such procedures. Keep the door to the patient’s room closed. Avoid touching your face with contaminated gloves. Wash your hands after you remove the gown, gloves, eyewear, and face shield and whenever you leave the patient’s room. Wear gloves when disinfecting contaminated surfaces or equipment.

FIG. 33-2 Primary TB infection with progression to secondary infection and active disease. *HIV*, Human immune deficiency virus; *M. tuberculosis*, *Mycobacterium tuberculosis*; TB, tuberculosis.

primary infection and can last for years or decades before clinical symptoms develop. *An infected person is not infectious to others until manifestations of disease occur.*

Secondary TB is a reactivation of the disease in a previously infected person. It is more likely when defenses are lowered, such as with older adults and people with HIV disease. The upper lobes are the most common site of reactivation and are referred to as *Simon's foci*.

Etiology

M. tuberculosis is a nonmoving, slow-growing, acid-fast rod transmitted via the airborne route. People who are usually infected are those having repeated close contact with an infectious person who has not yet been diagnosed with TB. The risk for transmission is reduced after the infectious person has received proper drug therapy for 2 to 3 weeks, clinical improvement occurs, and acid-fast bacilli (AFB) in the sputum are reduced.

Incidence/Prevalence

Worldwide, 5.8 million people are diagnosed annually and an additional 8 million people are estimated to have undiagnosed disease (WHO, 2010). The incidence of TB has been steadily decreasing in the United States, although increases in incidence are seen in many other countries (ALA, 2010b). In the United States, the people who are at greatest risk for development of TB are:

- Those in constant, frequent contact with an untreated person
- Those who have decreased immune function or HIV
- People who live in crowded areas such as long-term care facilities, prisons, and mental health facilities
- Older homeless people
- Abusers of injection drugs or alcohol
- Lower socioeconomic groups
- Foreign immigrants (especially from Mexico, the Philippines, and Vietnam)

The incidence of TB among recent immigrants is nearly 10 times that of native-born Americans (ALA, 2010b).

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Early detection of TB depends on subjective findings rather than on observable symptoms. TB has a slow onset, and patients are not aware of symptoms until the disease is advanced. *TB should be considered for any patient with a persistent cough or other symptoms compatible with TB, such as weight loss, anorexia, night sweats, hemoptysis, shortness of breath, fever, or chills.*

History

Assess the patient's past exposure to TB. Ask about his or her country of origin and travel to foreign countries where incidence of TB is high. It is important to ask about the results of any previous tests for TB. Also ask whether the patient has had bacille Calmette-Guérin (BCG) vaccine. The BCG vaccine contains attenuated tubercle bacilli and is used in many countries to produce increased resistance to TB. *Anyone who has received BCG vaccine within the previous 10 years will have a positive skin test that can complicate interpretation.* Usually the size of the skin response decreases each year after BCG vaccination. These patients should be evaluated for TB with a chest x-ray or the QuantiFERON-TB Gold test.

The effectiveness of BCG vaccine in preventing TB is controversial, and it is not used widely for this purpose in the United States or Canada.

Physical Assessment/Clinical Manifestations

The patient with TB has progressive fatigue, lethargy, nausea, anorexia, weight loss, irregular menses, and a low-grade fever. Manifestations may have been present for weeks or

months. Night sweats may occur with the fever. The patient has a cough and mucopurulent sputum, which may be streaked with blood. Chest tightness and a dull, aching chest pain occur with the cough. Ask about, assess for, and document the presence of any of these manifestations to help with diagnosis, to establish a baseline, and to plan nursing interventions.

Physical examination of the chest does not provide conclusive evidence of TB. Dullness with percussion may be heard over the involved lung fields, as may bronchial breath sounds, crackles, and increased transmission of spoken or whispered sounds. Partial obstruction of a bronchus from endobronchial disease or compression by lymph nodes may produce localized wheezing.

Diagnostic Assessment

A new rapid test for tuberculosis has been developed and approved by the [World Health Organization \(2010\)](#). This test is the fully automated nucleic acid amplification test (NAAT) for tuberculosis. Results are available in less than 2 hours. Widespread use of this test is endorsed and should soon replace other diagnostic methods. Currently, diagnosis of TB is suggested by the manifestations and a positive smear for acid-fast bacillus. Sputum is obtained, smeared on a slide, and stained with a red dye. After the slide has dried, it is treated with an acid alcohol to remove the stain. TB does not de-stain with this procedure and remains red. *The acid-fast bacillus test is not specific for TB (other organisms are also acid-fast), but it is used as a quick method to determine whether TB precautions should be started until more definitive testing can be completed with either the purified protein derivative two-step procedure or the QuantiFERON-TB Gold.*

Blood analysis by an enzyme-linked immunosorbent assay using the QuantiFERON-TB Gold (QFT-G) is a relatively rapid test for the presence of *M. tuberculosis*. Results are ready in 24 hours and are most useful in the acute care setting to determine whether a symptomatic patient has TB.

Sputum culture confirms the diagnosis. Enhanced TB cultures and automated mycobacterial cultures require 1 to 4 weeks to determine a positive or negative result. After drugs are started, sputum samples are obtained again to determine therapy effectiveness. Cultures are usually negative after 3 months of treatment.

The tuberculin test (Mantoux test) is the most commonly used reliable test of TB infection. A small amount (0.1 mL) of purified protein derivative (PPD) is placed intradermally in the forearm. An area of induration (localized swelling with hardness of soft tissue), not just redness, measuring 10 mm or greater in diameter 48 to 72 hours after injection indicates exposure to and possible infection with TB (Fig. 33-3). If possible, the site is re-evaluated after 72 hours because the incidence of false-negative readings is greater at 48 hours. *A positive reaction does not mean that active disease is present but indicates exposure to TB or the presence of inactive (dormant) disease.* A reaction of 5 mm or greater is considered positive in people with HIV infection. *A reduced skin reaction or a negative skin test does not rule out TB disease or infection of the very old or anyone who is severely immunocompromised.* Failure to have a skin response because of reduced immune function when infection is present is called **anergy**.

Yearly screening is needed for anyone who comes into contact with people infected with TB. Screening is very

FIG. 33-3 Positive tuberculin skin test with induration.

important for foreign-born people and migrant workers. Participation in screening programs is enhanced when programs are delivered in a culturally sensitive and nonthreatening manner. Urge anyone who is considered high risk to have an annual TB screening test.

Once a person's skin test is positive for TB, a chest x-ray is used to detect active TB or old, healed lesions. Caseation and inflammation may be seen on the x-ray if the disease is active. Instruct anyone who has manifestations of TB to seek medical attention. The chest x-rays of HIV-infected patients may be normal or may show infiltrates in any lung zone and lymph node enlargement.

INTERVENTIONS

Combination drug therapy is the most effective method of treating TB and preventing transmission. Active TB is treated with a combination of drugs to which the organism is sensitive. Therapy continues until the disease is under control. The use of multiple-drug regimens destroys organisms as quickly as possible and reduces the emergence of drug-resistant organisms (Gribble & Williams, 2010). First-line therapy uses isoniazid (INH) and rifampin throughout the therapy; pyrazinamide is added for the first 2 months (Chart 33-7). This protocol shortens the therapy from 6 to 12 months to 6 months. Ethambutol is the recommended fourth drug in first-line therapy. These drugs are now available in two or three drug combinations. Variations of the first-line drugs along with other drug types are used when the patient does not tolerate the standard first-line therapy. Nursing interventions focus on patient teaching for drug therapy adherence and infection control.

Strict adherence to the prescribed drug regimen is crucial for suppressing the disease. Thus your major role is teaching the patient about drug therapy and stressing the importance of taking each drug regularly, exactly as prescribed, for as long as it is prescribed. Provide accurate information in multiple formats, such as pamphlets, videos, and drug-schedule worksheets. An anxious patient may not absorb information well. You may need to repeat the information and obtain the help

! NURSING SAFETY PRIORITY

Drug Alert

The first-line drugs used as therapy for tuberculosis all can damage the liver. Warn the patient to not drink any alcoholic beverages for the entire duration of TB therapy. (Duration of therapy is usually 6 months but can be as long as 2 years for MDR TB.)

CHART 33-7 COMMON EXAMPLES OF DRUG THERAPY

First-Line Treatment for Tuberculosis

DRUG/USUAL DOSAGE	PURPOSE/ACTION	NURSING INTERVENTIONS	RATIONALES
Isoniazid (INH) 200-300 mg orally daily or 600-900 mg orally twice each week	Kills actively growing mycobacteria outside the cell and inhibits the growth of dormant bacteria inside macrophages and caseating granulomas.	Teach the patient to take the drug on an empty stomach (1 hour before or 2 hours after meals) and to avoid antacids. Teach the patient to take a daily multiple vitamin that contains the B-complex vitamins while on this drug. Remind the patient to avoid drinking alcoholic beverages while on this drug. Teach the patient to report darkening of the urine, a yellow appearance to the skin or whites of the eyes, and an increased tendency to bruise or bleed.	Food and antacids slow or prevent absorption of the drug from the GI tract. Drug can deplete the body of this vitamin. The drug can cause liver damage. This effect is potentiated by alcohol. These manifestations may indicate liver toxicity or failure.
Rifampin (RIF) 500-600 mg orally daily or twice each week	Kills slower-growing organisms, even those that reside in macrophages and caseating granulomas.	Teach the patient to expect the drug to stain the skin and urine and expect all other secretions to have a reddish orange tinge; also, soft contact lenses will become permanently stained. Teach women using oral contraceptives to use an additional method of contraception while taking this drug and for 1 month after stopping the drug. Remind the patient to avoid drinking alcoholic beverages while on this drug. Teach the patient to report darkening of the urine, a yellow appearance to the skin or whites of the eyes, and an increased tendency to bruise or bleed. Ask the patient about all other drugs in use.	This is an expected and harmless side effect of the drug and will clear some time after the patient stops taking the drug. This drug reduces the effectiveness of oral contraceptives, increasing the risk for an unplanned pregnancy. The drug can cause liver damage. This effect is potentiated by alcohol. These manifestations may indicate liver toxicity or failure.
Pyrazinamide (PZA) 1000-2000 mg orally daily or 3000-6000 mg orally twice each week	Is not inactivated by the acidic environment of macrophages and can effectively kill organisms residing within them.	Ask whether the patient has ever had gout. Teach the patient to drink at least 8 ounces of water when taking this tablet and to increase fluid intake. Teach the patient to wear protective clothing, a hat, and sunscreen when going outdoors in the sunlight. Remind the patient to avoid drinking alcoholic beverages while on this drug. Teach the patient to report darkening of the urine, a yellow appearance to the skin or whites of the eyes, and an increased tendency to bruise or bleed.	This drug interacts with many drugs. This drug increases uric acid formation and will make gout worse. More fluids help prevent uric acid from precipitating and causing gout or kidney problems. The drug causes photosensitivity and greatly increases the risk for sunburn. The drug can cause liver damage. This effect is potentiated by alcohol. These manifestations may indicate liver toxicity or failure.
Ethambutol (EMB) 750-1500 mg orally daily or 2500-5000 mg orally twice each week	Inhibits bacterial RNA synthesis, thus suppressing bacterial growth. It is slow-acting and is bacteriostatic rather than bactericidal. Thus it must be used in combination with other anti-TB drugs.	Remind the patient to avoid drinking alcoholic beverages while on this drug. Teach the patient to report any changes in vision, such as reduced color vision, blurred vision, or reduced visual fields, immediately to his or her health care provider. Ask whether the patient has ever had gout. Teach the patient to drink at least 8 ounces of water when taking this tablet and to increase fluid intake.	The drug induces severe nausea and vomiting when alcohol is ingested. The drug can cause optic neuritis, especially at high doses, and can lead to blindness. When the problem is discovered early, the eye problems are usually reversed when the drug is stopped. This drug increases uric acid formation and will make gout worse. More fluids help prevent uric acid from precipitating and causing gout or kidney problems.

of family members. To determine whether the patient understands how to take the drugs, ask him or her to describe the treatment regimen, side effects, and when to call the health care agency and physician.

The TB drugs may cause the patient to have nausea. Teach him or her to prevent nausea by taking the daily dose at bedtime. Antiemetics may also prevent this problem. Instruct him or her to eat a well-balanced diet that includes foods that are rich in iron, protein, and vitamins C and B. Collaborate with the dietitian for specialized needs.

The patient with TB has reduced physical stamina and also has concerns about the disease prognosis. Offer a positive outlook for the patient who adheres to the drug regimen. Tell him or her that fatigue will diminish as the treatment progresses. *With current resistant strains of TB, however, emphasize that not taking the drugs as prescribed could lead to an infection that is drug resistant.*

Multidrug-resistant TB (MDR TB) strains are emerging as are strains that are considered extensively drug-resistant (XDR TB), especially among patients who have HIV disease (Ferguson & Rhoads, 2009; Trossman, 2008). MDR TB is an infection that resists INH and rifampin. XDR TB is resistant not only to the first-line anti-tuberculosis drugs but also to the second-line antibiotics, including the fluoroquinolones and at least one of the aminoglycosides. Drug therapy for MDR TB and XDR TB is more limited than standard first-line therapy and requires higher doses for longer periods.

! NURSING SAFETY PRIORITY

Action Alert

Warn patients with extensively drug-resistant TB that absolute adherence to therapy is critical for survival and cure of the disease.

An area to stress when teaching the patient and family with either MDR TB or XDR TB is that the patient is not resistant to the drugs—the organism is. So, a person who acquires the infection and develops TB from a person who is infected with a resistant strain of bacillus will also have drug-resistant disease (Nelson, 2010). Thus teaching infection control strategies is a priority and should be constantly reinforced.

Other care issues for the patient with TB include teaching about infection prevention and what to expect about disease monitoring and participating in activities. TB is often treated outside the acute care setting, with the patient convalescing in the home setting. Airborne Precautions are not necessary in this setting because family members have already been exposed; however, all members of the household need to undergo TB testing. Teach the patient to cover the mouth and nose with a tissue when coughing or sneezing, to place used tissues in plastic bags, and to wear a mask when in contact with crowds until the drugs suppress infection.

Tell the patient that sputum specimens are needed usually every 2 to 4 weeks once drug therapy is initiated. When the results of three consecutive sputum cultures are negative, the patient is no longer infectious and may return to former employment. Remind him or her to avoid exposure to any inhalation irritants because these can cause further lung damage.

The hospitalized patient with active TB is placed on Airborne Precautions (see Chapter 25) in a well-ventilated room that has at least six exchanges of fresh air per minute. All

FIG. 33-4 A high-efficiency particulate air (HEPA) respirator used in the care of patients with active or “rule-out” tuberculosis.

health care workers must wear an N95 or high-efficiency particulate air (HEPA) respirator when caring for the patient (Fig. 33-4). When hand and clothing contamination is a risk, use Standard Precautions with appropriate contact protection (i.e., gowns and gloves). Perform handwashing before and after patient care. Precautions are discontinued when the patient is no longer infectious.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

A client with active tuberculosis who has been taking isoniazid (INH, Nydrazid) and rifampin (RIF, Rifadin) reports having urine that is an orange color. What is the nurse's best action?

- A. Obtain a specimen for culture and test the urine for occult blood.
- B. Reassure the client that this is a normal drug side effect.
- C. Hold the dose and contact the health care provider.
- D. Document the report as the only action.

Community-Based Care

Home Care Management

Most patients with TB are managed outside the hospital; however, patients may be diagnosed with TB while in the hospital for another problem. Discharge may be delayed if the living situation is high risk or if nonadherence is likely. Collaborate with the case manager or social service worker in the hospital or the community health nursing agency to ensure that the patient is discharged to the appropriate environment with continued supervision.

Teaching for Self-Management

Teach the patient to follow the drug regimen exactly as prescribed and always to have a supply on hand. Teach about side effects and ways of reducing them to ensure adherence. Remind him or her that the disease is usually no longer contagious after drugs have been taken for 2 to 3 consecutive weeks and clinical improvement is seen; however, *he or she must continue with the prescribed drugs for 6 months or longer*

as prescribed. **Directly observed therapy (DOT)**, in which a health care professional watches the patient swallow the drugs, may be indicated in some situations. This practice leads to more treatment successes, fewer relapses, and less drug resistance. A variation of this practice, DOTS (directly observed therapy–short course), is attributed to having saved many lives worldwide (The War on Tuberculosis, 2010; WHO, 2010).

The patient who has weight loss and severe lethargy should gradually resume usual activities as these problems decrease during treatment. Proper nutrition is needed to prevent infection recurrence.

To help with concerns about the contagious aspect of the infection, provide the patient with information about TB. A key to preventing transmission is identifying those in close contact with the infected person so that they can be tested and treated if needed. Identified contacts are assessed with a TB test and possibly a chest x-ray to determine infection status. Multidrug therapy may be indicated as a preventive strategy for heavily exposed individuals or for those who have other health problems that reduce the immune response.

Health Care Resources

Teach the patient to receive follow-up care by a health care provider for at least 1 year during active treatment. The American Lung Association (ALA) can provide free information to the patient about the disease and its treatment. In addition, Alcoholics Anonymous (AA) and other health care resources for patients with alcoholism are available if needed. Assist the patient who uses illicit drugs to locate a drug treatment program. Urge smokers to quit, and assist them in finding an appropriate smoking-cessation program.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Safety; Evidence-Based Practice

The patient is a 48-year-old man who is being released from prison after 15 years of incarceration. On his final physical, he is found to be 20 pounds underweight for his height and has a productive cough. He smokes three packs of cigarettes daily and is exposed to a great deal of secondhand smoke in the prison environment. On release, he is going to live with his 70-year-old aunt. A tuberculin skin test injected 3 days ago shows an 8-mm area of induration around the injection site. His records indicate that his last skin test, performed 18 months ago, did not result in any reaction.

1. What risk factors does this patient have for TB?
2. Does the PPD response indicate a negative test, old TB, or currently active TB?
3. What other tests should be performed with this patient?
4. Should he still be released to live with his aunt? Why or why not?
5. If he does have active TB, would directly observed therapy be appropriate for this patient? Why or why not?
6. If he does have active TB, what are the teaching priorities for this patient and his aunt?

LUNG ABSCESS

Pathophysiology

A lung abscess is a localized area of destruction caused by liquefaction necrosis, which is usually related to pyogenic bacteria. Patients with an abscess often have a history of pneumonia, aspiration of stomach contents, or obstruction

as a result of a tumor or foreign body. Other causes of aspiration leading to lung abscesses include any condition that alters the ability to swallow, such as alcoholic blackouts, seizure disorders, neurologic deficits, and swallowing disorders. Bronchial obstruction may cause a necrotizing process in the lung that eventually becomes an abscess.

Multiple abscesses and cavities form in patients with tuberculosis (TB) or fungal infections of the lung. Immunosuppressed patients, such as those receiving cancer chemotherapy or those with acquired immune deficiency syndrome (AIDS), are at high risk for fungal infections.

PATIENT-CENTERED COLLABORATIVE CARE

Ask the patient about any recent history of influenza, pneumonia, febrile illness, cough, and foul-smelling sputum production. Ask about the sputum color and odor and about any **pleuritic chest pain** (a stabbing pain upon taking a deep breath). Often the patient is febrile, pale, fatigued, and cachectic. Auscultation may reveal decreased breath sounds and dullness on percussion in the involved area. Bronchial breath sounds and crackles may be heard over the site of the lesion. A chest x-ray and sputum samples are needed for diagnosis.

Problems and interventions for the patient with pneumonia also apply to the patient with a lung abscess. Management involves antibiotics and drainage of the abscess. Provide frequent mouth care and observe for oral overgrowth of *Candida albicans*, especially in older adults.

INHALATION ANTHRAX

Pathophysiology

Inhalation anthrax (respiratory anthrax) is a bacterial infection caused by the gram-positive organism *Bacillus anthracis*, which lives as a spore in contaminated soil. Infection with this organism occurs through the skin, the intestinal tract, or the lungs. *Inhalation anthrax is a rare natural occurrence in the United States and is nearly 100% fatal without treatment. It is not spread by person-to-person contact.*

NURSING SAFETY PRIORITY

Action Alert

Because inhalation anthrax is so rare, any occurrence is considered an intentional act of bioterrorism. Report the presence of manifestations consistent with inhalation anthrax to hospital authorities immediately.

This organism first forms a **spore**, an encapsulated organism that is inactive. When many spores are inhaled into the deep parts of the lungs, macrophages engulf them. Once inside the macrophage, the organism leaves its capsule and replicates. The active bacteria produce several toxins that are released into the infected tissues and the blood. These toxins make the infection worse by creating massive edema in infected tissues, suppressing neutrophil action, causing hemorrhage, and destroying lung cells and WBCs. The infected macrophages carry the organisms to the lymph nodes. From these nodes, the organisms can enter the blood and spread rapidly, causing sepsis and meningitis.

CHART 33-8 KEY FEATURES

Inhalation Anthrax**Prodromal Stage (early)**

- Fever
- Fatigue
- Mild chest pain
- Dry cough
- No manifestations of upper respiratory infection
- Mediastinal “widening” on chest x-ray

Fulminant Stage (late)

- Sudden onset of breathlessness
- Dyspnea
- Diaphoresis
- Stridor on inhalation and exhalation
- Hypoxia
- High fever
- Mediastinitis
- Pleural effusion
- Hypotension
- Septic shock

PATIENT-CENTERED COLLABORATIVE CARE

Inhalation anthrax is a two-stage illness—prodromal and fulminant. Manifestations may not begin until as long as 8 weeks after exposure to the organism (Chart 33-8).

The prodromal stage is early and difficult to distinguish from influenza or pneumonia. Manifestations include fever, fatigue, mild chest pain, and a dry, harsh cough. A special feature of inhalation anthrax is that it is not accompanied by upper respiratory manifestations of sore throat or rhinitis. Usually the patient starts to feel better and symptoms improve in 2 to 4 days.

Although diagnosis is difficult at this stage, if the patient begins appropriate antibiotic therapy, the likelihood of survival is high. Diagnostic tests may show a slightly elevated WBC count with increasing numbers of band neutrophils. Other indicators that may be detectable at this time are positive Gram stain of the serum and a mediastinal “widening” on chest x-ray as the local lymph nodes greatly enlarge. After several days, blood cultures may be positive for the organism and the genetic material of the bacteria may be detected through the amplification process of the polymerase chain reaction (PCR). Positive results for these more definitive diagnostic tests may not be evident, however, until the disease has progressed to the fulminant stage.

The fulminant stage begins after the patient feels a little better. Usually there is a sudden onset of breathlessness. This sensation rapidly progresses to severe respiratory distress, dyspnea, diaphoresis, stridor, and cyanosis. The patient has a high fever. Mediastinitis and pleural effusions develop. As the disease spreads through the blood, causing septic shock and meningitis, death often occurs within 24 to 36 hours even if antibiotics are started in this stage.

The naturally occurring organism has a cell wall and is sensitive to many antibiotics, including the penicillins and the cephalosporins, which work specifically against bacteria that have a cell wall; however, organisms grown for bioterrorism may have been altered to be resistant to these antibiotics. Therefore the antibiotics used for suspected or diagnosed inhalation anthrax include combination therapy with ciprofloxacin, doxycycline, and amoxicillin (Chart 33-9). The same drugs are used individually in oral form for prophylaxis when people have been exposed to inhalation anthrax but have not developed symptoms.

CHART 33-9 COMMON EXAMPLES OF DRUG THERAPY

Prophylaxis and Treatment of Inhalation Anthrax**PROPHYLAXIS**

Ciprofloxacin (Cipro)
500 mg orally twice daily

Or

Doxycycline (Vibramycin)
100 mg orally twice daily

Or (if organism is proven susceptible to penicillin)

Amoxicillin (Amoxil, Trimox) 500 mg orally every 8 hr

Prophylaxis must continue for 60 days (or longer if exposure was heavy).

TREATMENT

Ciprofloxacin (Cipro IV) 400 mg IV every 12 hr

Or

Doxycycline (Doxy 100) 100 mg IV every 12 hr

Plus one or two of the following secondary agents (parenteral form; dosage based on patient's weight and age):

Rifampin (RIF)
Clindamycin (Cleocin)
Vancomycin (Vancocin, Vancoled)

Treatment with IV drugs continues for at least 7 days. When the response is good and the patient improves, IV drugs are changed to oral agents and are continued for at least 60 days.

Teach patients with any type of lower respiratory infection to be especially vigilant for changes after they think they are getting well. They need to seek medical attention immediately upon having a setback that starts with breathlessness.

PULMONARY EMPYEMA**Pathophysiology**

Pulmonary empyema is a collection of pus in the pleural space. The most common cause of empyema is pulmonary infection, lung abscess, or infected pleural effusion. Pneumonia or lung abscess can spread across the pleura. Lymph node obstruction can cause a **retrograde** (backward) flood of infected lymph into the pleural space. A liver abscess or abdominal abscess can spread through the lymphatic system into the lungs. Chest surgery or trauma can introduce bacteria directly into the pleural space, leading to empyema. Blood from trauma may collect in the pleural space, promoting infection.

PATIENT-CENTERED COLLABORATIVE CARE

Important history findings include recent febrile illness (including pneumonia), chest pain, dyspnea, cough, and trauma. Observe and document the character of the sputum. Chest wall motion may be reduced on physical examination. If a pleural effusion is present, fremitus may be decreased or absent on palpation, percussion may sound flat, and breath sounds are decreased on auscultation. With compression of lung tissue near the effusion, abnormal breath sounds include bronchial breath sounds, egophony, and whispered pectoriloquy.

Ask about fever, chills, night sweats, and weight loss. The patient may be hypotensive because of a mediastinal deviation placing pressure on the heart. Palpate the point of maximal impulse (PMI) because it may be displaced.

A chest x-ray or CT scan is obtained, and a sample of the pleural fluid is obtained via thoracentesis for diagnosis. Empyema fluid is thick, opaque, exudative, and foul smelling. The pleural fluid is analyzed for color, RBC count, WBC count, glucose and protein levels, lactate dehydrogenase (LDH), and pH. Gram stains, acid-fast stains, and cytology studies are also performed. A protein level higher than 3 g/dL indicates an exudative process.

Therapy involves emptying the empyema cavity, re-expanding the lung, and controlling the infection. Intrapleural fibrinolytic therapy may be needed if adhesions have

developed, especially if they inhibit drainage (Dobbin, 2009). Appropriate antibiotics are prescribed. Closed-chest drainage is used to promote lung expansion. The health care provider places one or more chest tubes in the lower parts of the empyema sac. The tube is removed when the lung is fully expanded and the infection is under control. Open thoracotomy and removal of a portion of the pleura may be needed for thick pus or excessive pleural thickening. Nursing interventions are similar to those for patients with a pleural effusion, pneumothorax, or infection. Chapters 32 and 34 discuss these interventions in more detail.

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing inadequate oxygenation and tissue perfusion as a result of a respiratory infection?

- Respirations rapid and shallow
- Decreased oxygen saturation by pulse oximetry
- Skin cyanosis or pallor (in lighter-skinned patients)
- Cyanosis or pallor of the lips and oral mucous membranes (in patients of any skin color)
- Tachycardia
- Patient appears to work hard to inhale and exhale
- Patient is restless, anxious, or confused

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate oxygenation and tissue perfusion as a result of a respiratory infection?

Perform and interpret physical assessment, including:

- Taking vital signs
- Auscultating all lung fields
- Monitoring oxygen saturation by pulse oximetry
- Checking the accuracy of pulse oximetry readings
- Assessing cognition (Mini-Mental State Examination [MMSE])
- Assessing for the presence and characteristic of sputum production
- Assessing the patient's ability to cough and clear the airway

Interpret laboratory values:

- Elevated white blood cell count
- Arterial blood gas values: pH lower than 7.35, HCO_3^- at or below 24 mEq/L, Paco_2 at or below 45 mm Hg; Pao_2 below 90 mm Hg

Respond by:

- Administering oxygen
- Assisting the patient to an upright position, with arms resting on a table or armrests
- Prioritizing and pacing activities to prevent fatigue
- Administering prescribed IV, oral, or inhaled drugs
- Ensuring respiratory therapy treatments are administered
- Re-assessing respiratory status after respiratory therapy treatment
- Ensuring a fluid intake of at least 3 liters per day

On what should you REFLECT?

- Observe patient for evidence of improved oxygenation (see Chapter 29).
- Think about what patient teaching focus could help reduce the occurrence of a respiratory infection in the future.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Teach patients with respiratory infections to limit infection spread by washing hands after blowing the nose or using a tissue.
- Remind patients that colds are most easily spread to others during the first 2 to 3 days after symptoms begin.
- Ask any patient with a respiratory infection if he or she is from a foreign country or has recently visited a foreign country.

- Ask patients from other countries whether they have had BCG as a vaccination against TB. For patients who have had BCG, the PPD skin test is a less reliable indicator of TB.
- Use Airborne Precautions for any patient who has TB or SARS manifestations until proven otherwise.
- If possible, place the patient with a respiratory infection in a private room.
- Keep the door to the room of any patient with a respiratory infection closed until the cause of the infection is identified.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd**Health Promotion and Maintenance**

- Teach everyone the “etiquette” of sneezing or coughing into the upper sleeve rather than the hand when a tissue is not available.
- Receive a yearly influenza vaccination because you are more likely to care for infected people and because you could spread influenza to people who are immunocompromised.
- Urge all adults older than 50 years, anyone who has a chronic respiratory problem, anyone who is immunocompromised, and anyone who lives with a person who is older, immunocompromised, or has a chronic respiratory disease to receive the pneumonia vaccine and yearly influenza vaccinations.
- Urge patients to complete the anti-infective drug therapy course for any respiratory infection.
- Urge all people to quit smoking or using tobacco in any form.
- Teach people living with patients who have TB to ensure good ventilation of the home with open windows whenever possible.
- Teach all people to be prepared for an emergency or disaster by having sufficient food, water, and prescribed drugs for at least 2 weeks (see [Chapter 12](#)).
- Teach all people to follow community infection containment procedures if there is a possible outbreak of any pandemic influenza virus.
- Inform patients who have a positive TB test that far more people are infected with the bacillus than have active TB disease.
- Assess the likelihood of adherence to the drug regimen for patients with TB.
- Identify patients who may require a directly observed therapy (DOT) program in which they must be directly observed by a health care professional while swallowing the drug.

Physiological Integrity**Psychosocial Integrity**

- Administer humidified oxygen therapy to patients with hypoxemia.
- Assess the skin under and around a facemask or nasal cannula for evidence of skin breakdown at least every 8 hours.
- Teach all patients with a respiratory infection of bacterial origin to complete all anti-infective therapy as prescribed.
- Teach patients with allergic rhinitis to avoid contact with the offending allergen(s).
- Caution older adults using antihistamines that these drugs may make hypertension worse.
- Treat epiglottitis in an adult as an emergency because it can lead to complete respiratory obstruction.
- Assess the patient receiving first-line drug therapy for TB for any manifestation of liver impairment (dark urine, clay-colored stools, anorexia, jaundiced sclera or hard palate).
- Teach women taking rifampin or rifapentine as drug therapy for TB that these drugs reduce the effectiveness of oral contraceptives and that an additional form of birth control should be used while on this therapy.
- Assess older patients with acute confusion for pneumonia (cough and fever may not be present).
- Assure the family of an older adult patient with pneumonia who is confused that the new-onset confusion is temporary.
- Teach people who may be afraid of contracting inhalational anthrax that this disease is not transmitted by person-to-person contact.

CHAPTER

34

Care of Critically Ill Patients with Respiratory Problems

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Protect the patient receiving mechanical ventilation.
2. Ensure safe management of endotracheal tubes, tracheostomy tubes, and mechanical ventilators.
3. Modify the environment to protect patients receiving anticoagulating therapy (which includes anticoagulation, fibrinolytic, and antiplatelet therapies).

Health Promotion and Maintenance

4. Identify hospitalized patients at risk for a pulmonary embolism.
5. Teach people at risk for pulmonary embolism techniques to reduce the risk.
6. Teach patients and family members how to avoid injury during anticoagulating therapy.

Psychosocial Integrity

7. Support the patient and family in coping with changes in breathing status and the need for mechanical ventilation.

8. Use an appropriate nonverbal form of communication for a patient who is intubated.
9. Provide emotional support to patients experiencing acute respiratory difficulties.

Physiological Integrity

10. Assess the respiratory status of any patient who develops sudden-onset respiratory difficulty or acute confusion.
11. Use laboratory data and clinical manifestations to evaluate the adequacy of oxygenation and ventilatory interventions.
12. Coordinate nursing care for the patient being mechanically ventilated.
13. Maintain a patent airway on anyone who has experienced chest trauma.
14. Schedule essential patient care and diagnostic activities to promote rest and sleep.

Respiratory problems can progress to an emergency and death, even with prompt treatment. These problems interfere with *oxygenation and tissue perfusion* and may overwhelm the adaptive responses of the cardiac and blood oxygen delivery systems (Fig. 34-1). Thus *prompt recognition and interventions are needed to prevent serious complications and death*.

An acute injury or problem that results in severe respiratory impairment can occur at any age. Older adults, however, are more at risk for developing critical respiratory problems. The patient who is short of breath is also anxious and fearful. Be prepared to manage both the physical and emotional needs of the patient during any respiratory emergency.

FIG. 34-1 Rapid-onset acute respiratory problems overwhelm the ability of the cardiac oxygen delivery system to adapt and restore balance. The red blood cell (RBC) oxygen delivery system cannot begin to adapt to the acute respiratory problem.

PULMONARY EMBOLISM

Pathophysiology

A **pulmonary embolism (PE)** is a collection of particulate matter (solids, liquids, or air) that enters venous circulation and lodges in the pulmonary vessels. Large emboli obstruct pulmonary blood flow, leading to reduced oxygenation, pulmonary tissue hypoxia, and potential death. Any substance can cause an embolism, but a blood clot is the most common (McCance et al., 2010). PE is common, especially among hospitalized patients, and many die within 1 hour of the onset of symptoms or before the diagnosis has even been suspected (Farley et al., 2009).

Most often, a PE occurs when a blood clot from a venous thromboembolism (VTE), especially a deep vein thrombosis (DVT) in a vein in the legs or the pelvis, breaks off and travels through the vena cava into the right side of the heart. The clot then lodges in the pulmonary artery or within one or more of its branches. Platelets collect on the embolus, triggering the release of substances that cause blood vessel constriction. Widespread pulmonary vessel constriction and pulmonary hypertension impair gas exchange. Deoxygenated blood is moved into the arterial circulation, causing **hypoxemia** (low arterial blood oxygen level), although some patients with PE do *not* have hypoxemia.

Major risk factors for VTE leading to PE are:

- Prolonged immobility
- Central venous catheters
- Surgery
- Obesity
- Advancing age
- Conditions that increase blood clotting
- History of thromboembolism

CHART 34-1 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Prevention of Pulmonary Embolism

- Start passive and active range-of-motion exercises for the extremities of immobilized and postoperative patients.
- Ambulate patients soon after surgery.
- Use antiembolism and pneumatic compression stockings and devices after surgery.
- Avoid the use of tight garters, girdles, and constricting clothing.
- Prevent pressure under the popliteal space (e.g., do not place a pillow under the knee).
- Perform a comprehensive assessment of peripheral circulation.
- Elevate the affected limb 20 degrees or more above the level of the heart to improve venous return, as appropriate.
- Change patient position every 2 hours, or ambulate as tolerated.
- Prevent injury to the vessel lumen by preventing local pressure, trauma, infection, or sepsis.
- Refrain from massaging leg muscles.
- Instruct patient not to cross legs.
- Administer prescribed prophylactic low-dose anticoagulant and antiplatelet drugs.
- Teach the patient to avoid activities that result in the Valsalva maneuver (e.g., breath-holding, bearing down for bowel movements, coughing).
- Administer prescribed drugs, such as stool softeners, that will prevent episodes of the Valsalva maneuver.
- Teach the patient and family about precautions.
- Encourage smoking cessation.

In addition, smoking, pregnancy, estrogen therapy, heart failure, stroke, cancer (particularly lung or prostate), Trousseau's syndrome, and trauma increase the risk for VTE and PE (Gay, 2010).

Fat, oil, air, tumor cells, amniotic fluid, foreign objects (e.g., broken IV catheters), injected particles, and infected clots or pus can enter a vein and cause PE. Fat emboli from fracture of a long bone and oil emboli from diagnostic procedures do not impede blood flow in the lungs; instead, they cause blood vessel injury and acute respiratory distress syndrome (ARDS) (Powers & Talbot, 2011). Amniotic fluid embolus occurs in women as a rare complication of childbirth, abortion, or amniocentesis. Septic clots often arise from a pelvic abscess, an infected IV catheter, and injections of illegal drugs. The effects of sepsis are more serious than the venous blockage.

Health Promotion and Maintenance

Although pulmonary embolism (PE) can occur in healthy people and may give no warning, it occurs more often in some situations. Thus prevention of conditions that lead to PE is a major nursing concern. Preventive actions for PE are those that also prevent venous stasis and VTE. Best nursing practices for PE prevention are outlined in **Chart 34-1**. Also see **Chapter 16** for more information about core measures for VTE prevention.

Lifestyle changes can help reduce the risk for PE. Urge patients to stop smoking cigarettes, especially women who take oral contraceptives. Reducing weight and becoming more physically active, such as walking one or more miles each day, can reduce risk for PE. Teach patients who are traveling for long periods to drink plenty of water, change positions often, avoid crossing the legs, and get up from the sitting position at least 5 minutes out of every hour.

For patients known to be at risk for PE, small doses of heparin, low molecular weight heparin, or a similar drug may be prescribed every 8 to 12 hours. Heparin prevents excessive clotting in patients after trauma or surgery or when restricted to bedrest. Occasionally, an antiplatelet drug such as clopidogrel (Plavix) is used in place of heparin.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Assess any patient with sudden onset of breathing difficulty for the risk factors of PE, such as previous VTE, recent surgery, or immobility (Farley et al., 2009; Winkelman, 2009).

Physical Assessment/Clinical Manifestations

Respiratory manifestations are outlined in Chart 34-2. Assess the patient for difficulty breathing (dyspnea) occurring with a rapid heart rate and pleuritic chest pain (sharp, stabbing-type pain on inspiration). Other symptoms vary depending on the size and the type of embolism. Breath sounds may be normal, but crackles usually occur. Often a dry cough is present. **Hemoptysis** (bloody sputum) may result from pulmonary infarction.

Cardiac manifestations include tachycardiac, distended neck veins, **syncope** (fainting or loss of consciousness), cyanosis, and hypotension. Systemic hypotension results from acute pulmonary hypertension and reduced forward blood flow. Abnormal heart sounds, such as an S₃ or S₄, may occur. Electrocardiogram (ECG) findings are abnormal, nonspecific, and transient. T-wave and ST-segment changes occur in many patients; left-axis or right-axis deviations are also common.

! NURSING SAFETY PRIORITY

Critical Rescue

Assess patients at risk for PE for the symptom cluster of distended neck veins, syncope, cyanosis, and hypotension. If this cluster is present, notify the Rapid Response Team.

Miscellaneous manifestations include a low-grade fever and petechiae on the skin over the chest and in the axillae. *It is important to remember that many patients with PE do not have the “classic” manifestations but instead have vague symptoms resembling the flu, such as nausea, vomiting, and general malaise (Bahloul et al., 2010).*

CHART 34-2 KEY FEATURES

Pulmonary Embolism

Classic Symptoms

- Dyspnea, sudden onset
- Sharp, stabbing chest pain
- Apprehension, restlessness
- Feeling of impending doom
- Cough
- Hemoptysis

Signs

- Tachypnea
- Crackles
- Pleural friction rub
- Tachycardia
- S₃ or S₄ heart sound
- Diaphoresis
- Fever, low-grade
- Petechiae over chest and axillae
- Decreased arterial oxygen saturation (SaO₂)

Psychosocial Assessment

Symptom onset of PE often is abrupt, and the patient is anxious. Hypoxemia may stimulate a sense of impending doom and cause increased restlessness. The life-threatening nature of PE and admission to an intensive care unit increase the patient's anxiety and fear.

Laboratory Assessment

The hyperventilation triggered by hypoxia and pain first leads to respiratory alkalosis, indicated by low partial pressure of arterial carbon dioxide (Paco₂) values on arterial blood gas (ABG) analysis. The Pao₂-Fio₂ (fraction of inspired oxygen) ratio falls as a result of “shunting” of blood from the right side of the heart to the left without picking up oxygen from the lungs. Shunting causes the Paco₂ level to rise, resulting in respiratory acidosis (McCance et al., 2010). Later, metabolic acidosis results from buildup of lactic acid due to tissue hypoxia. (See Chapter 14 for a discussion.)

Even if ABG studies and pulse oximetry show hypoxemia, these results alone are not sufficient for the diagnosis of PE (Bahloul et al., 2010; McCance et al., 2010). A patient with a small embolus may not be hypoxemic, and PE is not the only cause of hypoxemia.

Imaging Assessment

A chest x-ray may show a PE if it is large. Some lung infiltration may be present around the embolism site. However, the chest x-ray may not show any acute changes. Computed tomography (CT) scans are most often used to diagnose PE. A newer diagnostic method is high-resolution multidetector computer tomographic angiography (MDCTA), which is very specific but is not available at all acute care settings.

The physician may perform a transesophageal echocardiography (TEE) (see Chapter 35) to help detect PE. Doppler ultrasound studies or impedance plethysmography (IPG) may be used to document the presence of VTE and to support a diagnosis of PE.

ANALYSIS

The priority problems for patients with PE are:

1. Hypoxemia related to mismatch of lung perfusion and alveolar oxygenation
2. Hypotension related to inadequate circulation to the left ventricle
3. Potential for bleeding related to anticoagulation or fibrinolytic therapy
4. Anxiety related to hypoxemia and fear of death

PLANNING AND IMPLEMENTATION

Managing Hypoxemia

When a patient has a sudden onset of dyspnea and chest pain, immediately notify the Rapid Response Team. Reassure the patient, and elevate the head of the bed. Prepare for oxygen therapy and blood gas analysis while continuing to monitor and assess for other changes.

Planning: Expected Outcomes. The patient with PE is expected to have adequate tissue perfusion in all major organs. Indicators of adequate perfusion are:

- ABGs within normal limits
- Pulse oximetry above 95% or the patient's baseline
- Cognitive status unimpaired compared with baseline
- Absence of pallor and cyanosis

Interventions. Nonsurgical management of PE is most common. In some cases, surgery also may be needed. Best nursing care practices for the patient with PE are listed in Chart 34-3.

Nonsurgical Management. Management activities for PE focus on increasing gas exchange, improving lung perfusion, reducing risk for further clot formation, and preventing complications. Priority nursing interventions include implementing oxygen therapy, administering anticoagulation or fibrinolytic therapy, monitoring the patient's responses to the interventions, and providing psychosocial support.

Oxygen therapy is critical for the patient with PE. The severely hypoxemic patient may need mechanical ventilation and close monitoring with ABG studies. In less severe cases, oxygen may be applied by nasal cannula or mask. Use pulse oximetry to monitor oxygen saturation and hypoxemia.

Monitor the patient continually for any changes in status. Check vital signs, lung sounds, and cardiac and respiratory status at least every 1 to 2 hours. Document increasing dyspnea, dysrhythmias, distended neck veins, and pedal or sacral edema. Assess for crackles and other abnormal lung sounds along with cyanosis of the lips, conjunctiva, oral mucosa, and nail beds.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Safety; Evidence-Based Practice

The patient is a 66-year-old truck driver who had a prostatectomy yesterday for prostate cancer. He had urinary dribbling for months and was not able to participate in his usual jogging program. He stopped smoking a year ago and uses nicotine gum daily to inhibit his ongoing urge to smoke. He drinks a can of beer per day but, overall, has reduced his fluid intake to prevent dribbling or incontinence. When you assess him this morning, he reports nausea and some chest pain.

1. What should be your first action?
2. What risk factors does he have for a pulmonary embolism?
3. For what other manifestations should you assess?
4. Is oxygen by mask or nasal cannula appropriate for this patient? Why or why not?
5. What other actions should you take?

Drug therapy with anticoagulants may be prescribed to prevent embolus enlargement and to prevent new clots from forming. Active bleeding, stroke, and recent trauma are reasons to avoid this therapy. Each patient is evaluated to determine the risk versus the benefit of anticoagulant therapy.

Heparin is usually used unless the PE is massive or occurs with hemodynamic instability. A fibrinolytic drug may then be used to break up the existing clot. Review the patient's partial thromboplastin time (PTT)—also called *activated partial thromboplastin time (aPTT)*—before therapy is started, every 4 hours when therapy begins, and daily thereafter. Therapeutic PTT values usually range between 1.5 and 2.5 times the control value for this health problem.

Fibrinolytic drugs, such as alteplase (Activase, tPA), are used for PE when specific criteria are met. These include massive PE (obstructing blood flow to a lobe or more than one segment) and hemodynamic instability in which blood pressure cannot be maintained without supportive measures.

Both heparin and fibrinolytic drugs are *high alert drugs*. These drugs have a high risk to cause harm if given at too high a dose, too low a dose, or to the wrong patient.

CHART 34-3 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Care of the Patient with a Pulmonary Embolism

- Reassure patient that the correct measures are being taken.
- Apply oxygen by nasal cannula or mask.
- Place patient in high-Fowler's position.
- Apply telemetry monitoring equipment.
- Obtain an adequate venous access.
- Assess oxygenation continuously with pulse oximetry.
- Assess respiratory status at least every 30 minutes by:
 - Listening with a stethoscope for presence or absence of breath sounds, crackles, or rales.
 - Measuring the rate, rhythm, and ease of respirations.
 - Checking skin color and capillary refill.
 - Checking position of trachea.
- Assess cardiac status by:
 - Comparing blood pressures in right and left arms.
 - Checking pulse for quality.
 - Checking cardiac monitor for dysrhythmias.
 - Checking for distention of neck veins.
- Ensure prescribed chest imaging and laboratory tests are obtained immediately (may include complete blood count with differential, platelet count, prothrombin time, partial thromboplastin time, D-dimer level, arterial blood gases).
- Examine the thorax for presence of petechiae.
- Administer prescribed anticoagulants.
- Assess for bleeding.
- Handle patient gently.
- Institute Bleeding Precautions.

NURSING SAFETY PRIORITY

Drug Alert

Heparin comes in a variety of concentrations. Check the prescribed dose carefully and ensure the correct concentration is being used to prevent overdosing or underdosing. Enoxaparin (Lovenox) can be given only subcutaneously or intravenously, NOT intramuscularly.

Heparin therapy usually continues for 5 to 10 days. Most patients are started on an oral anticoagulant, such as warfarin (Coumadin, Jantoven, Warfilone ) , on the third day of heparin use. Therapy with both heparin and warfarin continues until the international normalized ratio (INR) reaches 2.0 to 3.0. A low-molecular-weight heparin (e.g., dalteparin or enoxaparin) is often used with the warfarin. Monitor the INR daily. Warfarin use continues for 3 to 6 weeks, but some patients may take warfarin indefinitely. **Charts 34-4 and 34-5** list common drugs used and the laboratory tests to monitor.

GENETIC/GENOMIC CONSIDERATIONS

Many agencies are performing genetic tests before starting warfarin therapy. These tests check for variation in two specific genes. One gene, *VKORC1*, produces an enzyme that alters vitamin K so that it can help activate the vitamin K-dependent clotting factors. Warfarin interferes with the activity of this enzyme. Patients who have a variation in the enzyme are resistant to the effects of warfarin, and much higher doses are needed to achieve coagulation. On the other hand, the gene *CYP2C19* produces an enzyme that metabolizes warfarin and prepares it for elimination. Patients who have a variation in this gene do not metabolize warfarin well, so that higher blood levels remain and more severe side effects are possible. The dosage of warfarin needs to be much lower in patients with this gene variation.

CHART 34-4 COMMON EXAMPLES OF DRUG THERAPY

Pulmonary Embolism

DRUG AND USUAL DOSAGE	PURPOSE	NURSING INTERVENTIONS	RATIONALES
Heparin sodium (Hepalean ) 5000-10,000 units as a bolus by IV push initially; then dose adjustment is based on PTT, 1300 units/hr on continuous infusion or, less preferably, intermittent infusion	To begin anticoagulation to minimize growth of existing clots and to prevent the development of additional clots	Monitor PTT and know expected therapeutic PTT range for each patient. Report PTT results. Monitor patient for bleeding or bruising. Re-bolus every time infusion is increased. Do not use with salicylates. Monitor platelets daily for thrombocytopenia. Have the antidote <i>protamine sulfate</i> available. Avoid puncturing the skin, and apply pressure to venipuncture and IM injection sites. Avoid use of firm toothbrushes, razors, and rectal manipulation. Monitor antifactor Xa.	Ongoing assessment helps detect side effects and prevent complications. Reporting and monitoring enable early management of a prolonged PTT and excessive bleeding. To maintain anticoagulation within consistent therapeutic levels. An increased anticoagulation effect can occur with salicylates. Heparin-induced thrombocytopenia (HIT), a type of adverse reaction, can occur. Being prepared for an emergency helps prevent further complications. Pressure at puncture sites helps promote clotting. Safety measures help prevent bleeding.
Enoxaparin (Lovenox) usually 1 mg/kg subcutaneously every 12 hr	To allow for hospital discharge before complete switch to oral anticoagulants	Have the antidote <i>protamine sulfate</i> available. Safety precautions are the same as for heparin.	This test is used to determine therapy effectiveness. This drug is the only antidote for enoxaparin. Safety precautions are the same as for heparin.
Warfarin sodium (Coumadin, Jantoven, Warfilone sodium ) 10-15 mg orally once daily for 3 days initially; then dose adjustment is based on INR, usually 5-10 mg orally daily Now available as a parenteral drug for use in hospitalized patients. Dosage is the same as with the oral form of the drug.	To allow for long-term anticoagulation in at-risk patients to prevent the development of future clots	Monitor INR, and know expected therapeutic INR range for each patient. Report INR results. Monitor the patient for bleeding or bruising. Monitor for fever and skin rash. Consult the pharmacist about potential drug interactions. Have the antidote <i>vitamin K (phytonadione)</i> available. Avoid puncturing the skin, and apply pressure to venipuncture and IM injection sites. Apply pressure to venipuncture and IM injection sites. Avoid use of firm toothbrushes, razors, and rectal manipulation. Teach the patient which foods are high in vitamin K. Assess for internal and external bleeding. Reconstitute with sterile water without preservative immediately before use. Administer with caution to patients who have been receiving aspirin, dipyridamole, heparin, or other anticoagulants.	Ongoing assessment helps detect side effects and prevent complications. Reporting enables early management of a prolonged INR. Adverse drug reaction can occur. There are many drug interactions with warfarin. Being prepared for an emergency helps prevent further complications. Pressure at puncture sites helps promote clotting. Pressure at puncture sites helps promote clotting. Safety measures help prevent bleeding. Food sources of vitamin K will alter INR. Bleeding is the most common adverse effect. Recommended preparation ensures drug stability. Other drugs with anticoagulation effects increase the risk for bleeding.
Alteplase (tissue plasminogen activator, recombinant; tPA; Activase) 100 mg IV infusion over 2 hr	To promote lysis of large pulmonary emboli in those patients who are hemodynamically unstable		

INR, International normalized ratio; PTT, partial thromboplastin time.

CHART 34-5 LABORATORY PROFILE

Blood Tests Used to Monitor Anticoagulation Therapy

TEST	NORMAL RANGE	SIGNIFICANCE OF ABNORMAL FINDINGS
Partial thromboplastin time (PTT, aPTT [APTT])	Normal values for each local laboratory may vary. When activator reagents are used by the laboratory, the normal clotting time is shortened. Common normal ranges are 20-30 sec in some laboratories and 30-40 sec in others. Therapeutic range for PE is 1.5-2.5 times the normal value (e.g., if normal is 20-30 sec, then therapeutic range is 40-75 sec).	<i>Subtherapeutic times</i> may signify that the patient is not receiving enough heparin to prevent extension of the blood clot. An increase in the dosage or rate of infusion is usually indicated. <i>Therapeutic times</i> mean that the clotting time is increased from normal but this increase is indicated in the case of PE. <i>Prolonged times</i> in patients with PE (i.e., >75 sec) indicate that the patient is at risk for serious spontaneous bleeding. Heparin is usually held or decreased until the PTT drops back into the therapeutic range.
Prothrombin time (pro time, PT)	Common normal range is 11-12.5 sec. Therapeutic range for anticoagulant therapy in PE is 1.5-2 times the normal or control value in seconds. Control values can vary day to day because reagents used may vary. If INR values are reported with the PT, therapeutic range for PE is 2.5-3.0, or 3.0-4.5 for recurrent PE.	<i>Subtherapeutic values</i> may signify that the patient is not receiving enough warfarin. An increase in the dosage is usually indicated. <i>Therapeutic values</i> mean that the pro time is increased from normal but this increase is indicated in the case of PE. <i>Prolonged values</i> in the treatment of PE indicate that the patient is at risk for bleeding. The warfarin dose is usually decreased or held, the patient is instructed to eat foods high in vitamin K, or an injection of vitamin K may be given.

aPTT or APTT, Activated partial thromboplastin time; INR, international normalized ratio; PE, pulmonary embolism.

**NCLEX EXAMINATION CHALLENGE****Physiological Integrity**

A client who has been receiving heparin subcutaneously for 10 days has all of the following laboratory blood test values. Which value does the nurse report immediately to the prescriber?

- A. Activated partial thromboplastin time 1.5
- B. International normalized ratio 1.7
- C. Red blood cells 4.2 million/mm³
- D. Platelets 20,000/mm³

These drugs and the associated nursing care are discussed in Chapters 38, 40, and 41.

Anticoagulation and fibrinolytic therapy can lead to excessive bleeding. Also, even when clotting times are in the target ranges, other problems may develop that require invasive therapy and a return to normal coagulation responses. *The antidote for heparin is protamine sulfate; the antidote for warfarin is injectable phytonadione, vitamin K₁ (AquaMEPHYTON, Mephyton). Antidotes for fibrinolytic therapy include clotting factors, fresh frozen plasma, and aminocaproic acid (Amicar).*

**NURSING SAFETY PRIORITY****Drug Alert**

Keep antidotes to anticoagulant drugs and fibrinolytic drugs on the unit for patients undergoing these therapies.

Surgical Management. Two surgical procedures for the management of PE are embolectomy and inferior vena cava filtration.

Embolectomy is the surgical removal of the embolus from pulmonary blood vessels. It may be performed when fibrinolytic therapy cannot be used for a patient who has massive or multiple large pulmonary emboli with shock. Special thrombectomy catheters that mechanically break up clots, such as

the AngioJet, allow effective reduction of clots with or without the use of thrombolytic drugs. Earlier use of embolectomy for PE is being evaluated (Le & Dewan, 2009).

Inferior vena cava filtration with placement of a vena cava filter is a lifesaving measure by preventing further embolus formation for some patients. Some filters are removable, allowing filter placement before symptoms develop in patients who are at high risk for clots. These filters can be removed when the risk for clot formation decreases, or they can be left in place permanently. Patients for whom filter placement is considered less risky than drug therapy include those with recurrent or major bleeding while receiving anticoagulants, those with septic PE, and those undergoing pulmonary embolectomy. Placement of a vena cava filter is detailed in Chapter 38.

Managing Hypotension

Planning: Expected Outcomes. The patient with PE is expected to have adequate circulation. Indicators of adequate circulation are:

- Maintenance of pulse rate and blood pressure within the normal ranges
- Maintenance of a urine output of at least 30 mL/hr
- Absence of cyanosis

Interventions. In addition to the interventions used for hypoxemia, IV fluid therapy and drug therapy are used to increase cardiac output and maintain blood pressure.

IV fluid therapy involves giving crystalloid solutions to restore plasma volume and prevent shock (see Chapter 39). Continuously monitor the ECG and pulmonary artery and central venous/right atrial pressures of the patient receiving IV fluids because increased fluids can worsen pulmonary hypertension and lead to right-sided heart failure. Also monitor indicators of fluid adequacy, including urine output, skin turgor, and moisture of mucous membranes.

Drug therapy with agents that increase myocardial contractility (**positive inotropic agents**) may be prescribed when

IV therapy alone does not improve cardiac output. Common drugs include milrinone (Primacor) and dobutamine (Dobutrex). Assess the patient's cardiac status hourly during therapy with inotropic drugs. Vasodilators, such as nitroprusside (Nipride, Nitropress), may be used to decrease pulmonary artery pressure if it is impeding cardiac contractility.

Minimizing Bleeding

Planning: Expected Outcomes. The patient with PE is expected to remain free from bleeding. Indicators are:

- Absence of bruising or petechiae
- Maintenance of hematocrit and hemoglobin within the normal range

Interventions. As a result of drug therapy that disrupts clots or prevents their formation, the patient's ability to start and continue the blood-clotting cascade when injured is impaired, increasing the risk for bleeding. Priority nursing actions are ensuring that appropriate antidotes are present on the nursing unit, protecting the patient from situations that could lead to bleeding, and monitoring closely the amount of bleeding that is occurring.

Assess at least every 2 hours for evidence of bleeding (e.g., oozing, bruises that cluster, petechiae, or purpura). Examine all stools, urine, drainage, and vomitus for gross blood, and test for occult blood. Measure any blood loss as accurately as possible. Measure the patient's abdominal girth every 8 hours (increasing girth can indicate internal bleeding). Best practices to prevent bleeding are listed in [Chart 34-6](#).

Monitor laboratory values daily. Review the complete blood count (CBC) results to determine the risk for bleeding and whether actual blood loss has occurred. If the patient has severe blood loss, packed red blood cells may be prescribed (see Transfusion Therapy in [Chapter 42](#)). Monitor the platelet count. A decreasing count may indicate ongoing clotting or heparin-induced thrombocytopenia (HIT) caused by the formation of anti-heparin antibodies.

Minimizing Anxiety

Planning: Expected Outcomes. The patient with PE is expected to have anxiety reduced to an acceptable level. Indicators include that he or she consistently demonstrates these behaviors:

- States that anxiety is reduced
- Has no distress, irritability, or facial tension
- Uses coping strategies effectively

Interventions. The patient with PE is anxious and fearful for many reasons, including the presence of pain. Interventions for reducing anxiety in those with PE include oxygen therapy (see Interventions discussion on pp. 664-667 in the [Managing Hypoxemia](#) section), communication, and drug therapy.

Communication is critical in allaying anxiety. Acknowledge the anxiety and the patient's perception of a life-threatening situation. Stay with him or her, and speak calmly and clearly, providing assurance that appropriate measures are being taken. When giving drugs, changing position, taking vital signs, or assessing the patient, explain the rationale and share information.

Drug therapy with an antianxiety drug may be prescribed if the patient's anxiety increases or prevents adequate rest. Unless he or she is mechanically ventilated, sedating agents are avoided to reduce the risk for hypoventilation. When pain is present, pharmacologic therapy is used for pain

CHART 34-6 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Prevention of Injury for the Patient Receiving Anticoagulant, Fibrinolytic, or Antiplatelet Therapy

- Handle the patient gently.
- Use and teach UAP to use a lift sheet when moving and positioning the patient in bed.
- Avoid IM injections and venipunctures.
- When injections or venipunctures are necessary, use the smallest-gauge needle for the task.
- Apply firm pressure to the needle stick site for 10 minutes or until the site no longer oozes blood.
- Apply ice to areas of trauma.
- Test all urine, vomitus, and stool for occult blood.
- Observe IV sites every 4 hours for bleeding.
- Instruct alert patients to notify nursing personnel immediately if any trauma occurs and if bleeding or bruising is noticed.
- Avoid trauma to rectal tissues:
 - Do not administer enemas.
 - If suppositories are prescribed, lubricate liberally and administer with caution.
- Instruct the patient and UAP to use an electric shaver rather than a razor.
- When providing mouth care or supervising others in providing mouth care:
 - Use a soft-bristled toothbrush or tooth sponges
 - Do not use floss
 - Check to make certain that dentures fit and do not rub
- Instruct the patient not to blow the nose forcefully or insert objects into the nose.
- Ensure the patient wears shoes with firm soles whenever he or she is ambulating.
- Ensure that antidotes to anticoagulation therapy are on the unit.

UAP, Unlicensed assistive personnel.

management. Care is taken to avoid suppressing the respiratory response.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

A client who has a pulmonary embolism and a venous thromboembolism is to be started on oral warfarin (Coumadin) while still receiving intravenous heparin. What is the nurse's best action?

- Administer the medications as prescribed.
- Remind the prescriber that two anticoagulants should not be administered concurrently.
- Hold the dose of warfarin until the client's partial thromboplastin time is the same as the control value.
- Monitor the client for clinical manifestations of internal or external bleeding at least every 2 hours.

Community-Based Care

The patient with a PE is discharged when hypoxemia and hemodynamic instability are resolved and adequate anticoagulation has been achieved. Anticoagulation therapy usually continues after discharge.

Home Care Management

Some patients are discharged to home with minimal risk for recurrence and no permanent physiologic changes. Others have heart or lung damage that requires home and lifestyle modification.

CHART 34-7 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Preventing Injury and Bleeding

During the time you are taking anticoagulants:

- Use an electric shaver.
- Use a soft-bristled toothbrush, and do not floss.
- Do not have dental work performed without consulting your health care provider.
- Do not take aspirin or any aspirin-containing products. Read the label to be sure that the product does not contain aspirin or salicylates.
- Do not participate in contact sports or any activity likely to result in your being bumped, scratched, or scraped.
- If you are bumped, apply ice to the site for at least 1 hour.
- Avoid hard foods that would scrape the inside of your mouth.
- Eat warm, cool, or cold foods to avoid burning your mouth.
- Check your skin and mouth daily for bruises, swelling, or areas with small, reddish purple marks that may indicate bleeding.
- Notify your health care provider if you:
 - Are injured and persistent bleeding results
 - Have excessive menstrual bleeding
 - See blood in your urine or bowel movement
- Avoid anal intercourse.
- Take a stool softener to prevent straining during a bowel movement.
- Do not use enemas or rectal suppositories.
- Do not wear clothing or shoes that are tight or that rub.
- Avoid blowing your nose forcefully or placing objects in your nose. If you must blow your nose, do so gently without blocking either nasal passage.
- Avoid playing musical instruments that raise the pressure inside your head, such as brass wind instruments and woodwinds or reed instruments.
- Keep all appointments for laboratory tests.

Patients with extensive lung damage may have activity intolerance and become fatigued easily. The living arrangements may need to be modified so that patients can spend all or most of the time on one floor and avoid climbing stairs. Depending on the degree of impairment, patients may require some or much assistance with ADLs.

Teaching for Self-Management

The patient with a PE may continue anticoagulation therapy for weeks, months, or years after discharge, depending on the risks for PE. Teach him or her and the family about Bleeding Precautions, activities to reduce the risk for venous thromboembolism (VTE) and recurrence of PE, complications, and the need for follow-up care (Chart 34-7).

Health Care Resources

Patients using anticoagulation therapy are usually seen in a clinic or health care provider's office weekly for blood drawing and assessment. Those who are homebound may have a home care nurse perform these actions (see Chart 34-8 for a focused assessment guide). Patients with severe dyspnea may need home oxygen therapy. Respiratory therapy treatments can be performed in the home. The nurse or case manager coordinates arrangements for oxygen and other respiratory therapy equipment to be available if needed at home.

EVALUATION: OUTCOMES

Evaluate the care of the patient with PE on the basis of the identified priority patient problems. The expected outcomes are that he or she:

CHART 34-8 HOME CARE ASSESSMENT

The Patient After Pulmonary Embolism

Assess respiratory status:

- Observe rate and depth of ventilation.
- Auscultate lungs.
- Examine nail beds and mucous membranes for evidence of cyanosis.
- Take a pulse oximetry reading.
- Ask the patient if chest pain or shortness of breath is experienced in any position.
- Ask the patient about the presence of sputum and its color and character.

Assess cardiovascular status:

- Take vital signs, including apical pulse, pulse pressure; assess for presence or absence of orthostatic hypotension and quality and rhythm of peripheral pulses.
- Note presence or absence of peripheral edema.
- Examine hand vein filling in the dependent position.
- Examine neck vein filling in the recumbent and sitting positions.

Assess lower extremities for deep vein thrombosis:

- Examine lower legs and compare with each other for:
 - General edema
 - Calf swelling
 - Surface temperature
 - Presence of red streaks or cordlike, palpable structure

Measure calf circumference:

- Ask the patient to dorsiflex and plantarflex each foot. Note the ease with which the patient can do this, and ask whether pain is experienced in either position.
- Gently squeeze the calf of each leg laterally and from front to back. Ask the patient whether pain or tenderness is experienced with either maneuver.

Assess for evidence of bleeding:

- Examine the mouth and gums for oozing or frank bleeding.
- Examine all skin areas, especially old puncture sites and wounds, for bleeding, bruising, or petechiae.
- If the patient voids during the visit, test the urine for occult blood.

Assess cognition and mental status:

- Level of consciousness
- Orientation to time, place, and person
- Can the patient accurately read a seven-word sentence containing no words with more than three syllables?

Assess the patient's understanding of illness and adherence to treatment:

- Manifestations to report to health care provider
- Drug therapy plan (correct timing and dose)
- Bleeding Precautions
- Prevention of venous thromboembolism

- Attains and maintains adequate gas exchange and oxygenation
- Does not experience hypovolemia and shock
- Remains free from bleeding episodes
- States the level of anxiety is reduced
- Uses effective coping strategies

Specific indicators for these outcomes are listed for each patient problem under the Planning and Implementation section (see earlier).

ACUTE RESPIRATORY FAILURE

Pathophysiology

Acute respiratory failure is classified by blood gas abnormalities. The critical values are partial pressure of arterial oxygen (P_{aO_2}) less than 60 mm Hg, arterial oxygen saturation (S_{aO_2})

TABLE 34-1 COMMON CAUSES OF VENTILATORY FAILURE

Extrapulmonary Causes

- Neuromuscular disorders:
 - Myasthenia gravis
 - Guillain-Barré syndrome
 - Poliomyelitis
- Spinal cord injuries affecting nerves to intercostal muscles
- Central nervous system dysfunction:
 - Stroke
 - Increased intracranial pressure
 - Meningitis
- Chemical depression:
 - Opioid analgesics, sedatives, anesthetics
- Kyphoscoliosis
- Massive obesity
- Sleep apnea
- External obstruction/constriction

Intrapulmonary Causes

- Airway disease:
 - Chronic obstructive pulmonary disease (COPD), asthma
- Ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch:
 - Pulmonary embolism
 - Pneumothorax
 - Acute respiratory distress syndrome (ARDS)
 - Amyloidosis
 - Pulmonary edema
 - Interstitial fibrosis

TABLE 34-2 COMMON CAUSES OF OXYGENATION FAILURE

- Low atmospheric oxygen concentration:
 - High altitudes, closed spaces, smoke inhalation, carbon monoxide poisoning
- Pneumonia
- Congestive heart failure with pulmonary edema
- Pulmonary embolism (PE)
- Acute respiratory distress syndrome (ARDS)
- Interstitial pneumonitis-fibrosis
- Abnormal hemoglobin
- Hypovolemic shock
- Hypoventilation
- Complications of nitroprusside therapy:
 - Thiocyanate toxicity, methemoglobinemia

less than 90%, or partial pressure of arterial carbon dioxide (P_{aCO_2}) more than 50 mm Hg occurring with acidemia (pH <7.30). Respiratory failure is further defined as *ventilatory failure*, *oxygenation failure*, or a *combination of both ventilatory and oxygenation failure*. Whatever the underlying problem, the patient in acute respiratory failure is always **hypoxemic** (has low arterial blood oxygen levels).

Ventilatory Failure

Ventilatory failure is a problem in oxygen intake (ventilation) and blood delivery (perfusion) that causes a ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch in which perfusion is normal but ventilation is inadequate. It occurs when the chest pressure does not change enough to permit air movement into and out of the lungs. As a result, too little oxygen reaches the alveoli and carbon dioxide is retained. Either inadequate oxygen intake or carbon dioxide retention leads to hypoxemia.

Ventilatory failure usually results from any of these problems: a physical problem of the lungs or chest wall; a defect in the respiratory control center in the brain; or poor function of the respiratory muscles, especially the diaphragm. The problem is defined by a P_{aCO_2} level above 45 mm Hg in patients who have otherwise healthy lungs.

Causes of ventilatory failure are either **extrapulmonary** (involving nonpulmonary tissues but affecting respiratory function) or **intrapulmonary** (disorders of the respiratory tract). Table 34-1 lists causes of ventilatory failure.

Oxygenation Failure

In oxygenation failure, chest pressure changes are normal and air moves in and out without difficulty but does not oxygenate the blood sufficiently. It occurs in the type of $\dot{V}/\dot{Q}$ mismatch in which air movement and oxygen intake (ventilation) are normal but lung blood flow (perfusion) is decreased.

Many lung disorders can cause oxygenation failure. Problems include impaired diffusion of oxygen at the alveolar level, right-to-left shunting of blood in the pulmonary vessels, $\dot{V}/\dot{Q}$ mismatch, breathing air with a low oxygen level, and

abnormal hemoglobin that fails to bind oxygen. In one type of $\dot{V}/\dot{Q}$ mismatch, areas of the lungs are still being perfused but gas exchange does not occur, which leads to hypoxemia. An extreme example of $\dot{V}/\dot{Q}$ mismatch is when systemic venous blood (oxygen-poor) passes through the lungs without being oxygenated and is shunted to the left side of the heart and into the systemic circulation. Normally, less than 5% of cardiac output contains venous blood that has bypassed oxygenation. With poor oxygenation in the lungs or a shunt that allows venous blood to bypass the lungs, even more arterial blood is not oxygenated, and applying 100% oxygen does not correct the problem. A classic cause of this $\dot{V}/\dot{Q}$ mismatch is acute respiratory distress syndrome (ARDS). Table 34-2 lists specific causes of oxygenation failure.

Combined Ventilatory and Oxygenation Failure

Combined ventilatory and oxygenation failure involves **hypoventilation** (poor respiratory movements). Impaired gas exchange at the alveolar-capillary membrane results in poor diffusion of oxygen into arterial blood and carbon dioxide retention. The condition may or may not include poor lung perfusion. When lung perfusion is not adequate, $\dot{V}/\dot{Q}$ mismatch occurs and both ventilation and perfusion are inadequate. This type of respiratory failure leads to a more profound hypoxemia than either ventilatory failure or oxygenation failure alone.

A combination of ventilatory failure and oxygenation failure occurs in patients who have abnormal lungs, such as those who have any form of chronic bronchitis, have emphysema, or are having an asthma attack. The bronchioles and alveoli are diseased (causing oxygenation failure), and the work of breathing increases until the respiratory muscles cannot function effectively (causing ventilatory failure). Acute respiratory failure results. This process can also occur in patients who have cardiac failure along with respiratory failure. This problem is serious because the cardiac system cannot adapt to the hypoxia by increasing the cardiac output.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Assess for **dyspnea** (perceived difficulty breathing), the hallmark of respiratory failure. Evaluate dyspnea with a dyspnea assessment guide (Fig. 34-2). Depending on the underlying

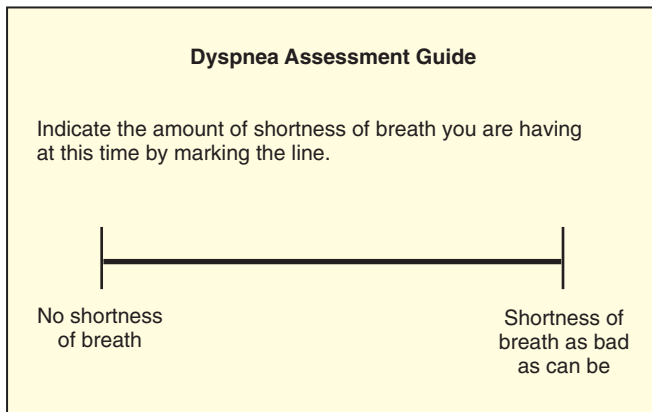

FIG. 34-2 A dyspnea assessment tool.

problem, the patient might not be aware of changes in the work of breathing. In addition, he or she needs to be alert to perceive the sensation of breathlessness.

Dyspnea is more intense when it develops rapidly. Slowly progressive respiratory failure may first be noticed as dyspnea on exertion (DOE) or when lying down. The patient may have **orthopnea**, finding it is easier to breathe in an upright position. With chronic respiratory problems, a minor increase in dyspnea may represent severe gas exchange problems.

Assess for a change in the patient's respiratory rate or pattern, a change in lung sounds, and manifestations of hypoxemia (pallor, cyanosis, increased heart rate, restlessness, confusion) and **hypercarbia** (high arterial blood levels of carbon dioxide). Pulse oximetry may show decreased oxygen saturation, but an arterial blood gas (ABG) analysis is needed for the most accurate assessment of oxygenation. The health care provider reviews the ABG studies to identify the degree of hypercarbia and hypoxemia.

INTERVENTIONS

Oxygen therapy is appropriate for any patient with acute hypoxemia. It is used in acute respiratory failure to keep the arterial oxygen (PaO_2) level above 60 mm Hg while treating the cause of the respiratory failure. Oxygen therapy is discussed in Chapter 30. If oxygen therapy does not maintain acceptable PaO_2 levels, mechanical ventilation may be used.

Help the patient find a position of comfort that allows easier breathing—usually a more upright position. To decrease the anxiety occurring with dyspnea, assist him or her to use relaxation, diversion, and guided imagery. Start energy-conserving measures, such as minimal self-care and no unnecessary procedures. Drugs given systemically or by metered dose inhaler (MDI) may be prescribed to widen the bronchioles and decrease inflammation to promote gas exchange. Teach the patient how to use the inhaler (see Chart 32-8 in Chapter 32) and about the drugs. Encourage deep breathing and other breathing exercises.

ACUTE RESPIRATORY DISTRESS SYNDROME

Pathophysiology

Acute respiratory distress syndrome (ARDS) is acute respiratory failure with these features:

- Hypoxemia that persists even with 100% oxygen
- Decreased pulmonary compliance

- Dyspnea
- Noncardiac-associated bilateral pulmonary edema
- Dense pulmonary infiltrates on x-ray (ground-glass appearance)

Often ARDS occurs after an *acute lung injury* (ALI) as a traumatic event in people who have no pulmonary disease. The mortality rate is high even when intensive interventions are used. Other terms for ARDS include *adult respiratory distress syndrome* and *shock lung*.

Despite different causes of ALI in ARDS, the trigger is a systemic inflammatory response (Winkelman, 2008). As a result, ARDS manifestations are similar regardless of the cause. The main site of injury in the lung is the alveolar-capillary membrane, which normally is permeable only to small molecules. It can be injured during sepsis, pulmonary embolism, shock, aspiration, or inhalation injury. When injured, this membrane becomes more permeable to large molecules, which allows debris, proteins, and fluid into the alveoli. Lung tissue normally remains relatively dry, but in patients with ARDS, lung fluid increases and contains more proteins (McCance et al., 2010).

Other changes occur in the alveoli and respiratory bronchioles. The type II pneumocytes produce surfactant, a substance that increases lung **compliance** (elasticity) and prevents alveolar collapse. Surfactant activity is reduced in ARDS because type II pneumocytes are damaged and because the surfactant is diluted by excess lung fluids. As a result, the alveoli become unstable and tend to collapse unless they are filled with fluid. These fluid-filled or collapsed alveoli cannot exchange gases. As a result, edema forms around terminal airways, which are compressed and closed and can be destroyed. Lung volume and compliance are further reduced. As fluid continues to leak in more lung areas, fluid, protein, and blood cells collect in the alveoli and in the spaces between the alveoli. Lymph channels are compressed, and more fluid collects. Poorly inflated alveoli receive blood but cannot oxygenate it, increasing the shunt. Hypoxemia and ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch result.

Transfusion-related acute lung injury (TRALI) is a non-cardiogenic pulmonary edema associated with the activation of the inflammatory response due to a recent transfusion of plasma-containing products (McAdams-Jones, 2009). These products include whole blood, packed red blood cells (PRBCs), platelets, and fresh frozen plasma, all of which are associated with TRALI in critically ill adults (Kleinman et al., 2007).

Etiology and Genetic Risk

Acute lung injury (ALI) leading to ARDS has many causes (Table 34-3). Some causes result in direct injury to lung tissue; other causes do not directly involve the lungs. Nervous system injury, such as head or spinal trauma, strokes, tumors, and sudden increases in intracranial pressure, may cause massive sympathetic discharge. Systemic blood vessel constriction results and moves large volumes of blood into lung circulation. Lung pressure increases and injures the lung. Any problems that cause cerebral hypoxia can lead to ALI (McCance et al., 2010).

TRALI is mediated by inflammation. During transfusion, patients are exposed to plasma that contains foreign proteins and antibodies. This exposure activates white blood cells (WBCs) and causes them to clump with these proteins, which

TABLE 34-3 COMMON CAUSES OF ACUTE LUNG INJURY

- Shock
- Trauma
- Serious nervous system injury
- Pancreatitis
- Fat and amniotic fluid emboli
- Pulmonary infections
- Sepsis
- Inhalation of toxic gases (smoke, oxygen)
- Pulmonary aspiration (especially of stomach contents)
- Drug ingestion (e.g., heroin, opioids, aspirin)
- Hemolytic disorders
- Multiple blood transfusions
- Cardiopulmonary bypass
- Submersion in water with water aspiration (especially in fresh water)

then go to the lungs. The clumped material injures lung capillaries, causing capillary leak and inflammation.

Other factors produce ARDS by direct injury to the lung. For example, aspiration of acidic gastric contents may obstruct or burn the airway. This type of direct injury destroys type I pneumocytes. Injured capillaries allow protein and cells to escape from the blood vessels into lung tissues. Lung radiation, submersion in water with aspiration, and inhalation of toxic gases all injure the alveolar and capillary tissue layers. Trauma, sepsis, drowning, and burns also cause the release of proteins (thromboplastins) that form fibrin clots in the blood. These clots, together with platelets and leukocytes, are filtered out in the lung. In many cases of ARDS, especially after trauma, clot production is increased and **fibrinolysis** (clot breakdown) is reduced. As a result, small emboli remain in the lung. Disseminated intravascular coagulation (DIC) plays a role in some patients.

GENETIC/GENOMIC CONSIDERATIONS

An increased genetic risk is suspected in the development and progression of ARDS. The inflammatory response clearly allows progression of an acute lung injury (ALI) to ARDS; however, not all patients with ALI progress to ARDS. It appears that patients who have hyperinflammatory responses to injury are more likely to develop ARDS (Workman & Winkelman, 2008) and their inflammatory response is genetically mediated. Ask about the patient's previous responses to infection or injury. If the patient has consistently had greater-than-expected inflammatory responses, he or she may be at increased risk for ARDS after ALI and should be closely monitored for manifestations of the disorder.

Incidence/Prevalence

The actual incidence of ARDS is unknown because it is part of other health problems and is not systematically reported as a separate disorder. A 2010 estimate suggested that 150,000 to 200,000 cases of ARDS occur yearly in North America (ARDS Foundation, 2010) although many health care professionals believe this estimate to be low.

Health Promotion and Maintenance

The nursing priority in the prevention of ARDS is early recognition of patients at high risk for the syndrome. Because patients who aspirate gastric contents are at great risk, closely assess

and monitor those receiving tube feeding and those with problems that impair swallowing and gag reflexes. Follow meticulous infection control guidelines, including hand-washing, invasive catheter and wound care, and Contact Precautions. Teach unlicensed assistive personnel (UAP) the importance of always adhering to infection control guidelines. Carefully observe patients who are being treated for any health problem associated with ARDS.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Physical Assessment/Clinical Manifestations

Assess the breathing of any patient at increased risk for ARDS. Determine whether increased work of breathing is present, as indicated by hyperpnea, noisy respiration, cyanosis, pallor, and retraction **intercostally** (between the ribs) or **substernally** (below the ribs). Document sweating, respiratory effort, and any change in mental status. *Abnormal lung sounds are not heard on auscultation because the edema occurs first in the interstitial spaces and not in the airways.* Assess vital signs at least hourly for hypotension, tachycardia, and dysrhythmias.

Diagnostic Assessment

The diagnosis of ARDS is established by a lowered partial pressure of arterial oxygen (Pao₂) value, determined by arterial blood gas (ABG) measurements. Because a widening alveolar oxygen gradient (increased fraction of inspired oxygen [Fio₂] does not lead to increased Pao₂ levels) develops with increased shunting of blood, the patient has a progressive need for higher levels of oxygen. He or she does not respond to high concentrations of oxygen (*refractory hypoxemia*) and often needs intubation and mechanical ventilation. A large difference between the predicted and actual alveolar oxygen tension indicates shunting. Sputum cultures obtained by bronchoscopy and by transtracheal aspiration are used to determine if a lung infection also is present.

The chest x-ray may show diffuse haziness or a “whited-out” (ground-glass) appearance of the lung. An ECG rules out cardiac problems and usually shows no specific changes. Hemodynamic monitoring with a pulmonary artery catheter helps diagnose ARDS. In ARDS, the pulmonary capillary wedge pressure (PCWP) is low to normal, whereas in cardiac-induced pulmonary edema the PCWP is above 18 mm Hg. **Chapter 40** explains hemodynamic monitoring in detail.

INTERVENTIONS

The patient with ARDS often needs intubation and conventional mechanical ventilation with positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP). Airway pressure-release ventilation (APRV) and high-frequency oscillatory ventilation are alternative modes of mechanical ventilation that improve oxygenation and ventilation in patients with moderate to severe ARDS (Rose, 2008). Sedation and paralysis may be needed for adequate ventilation and to reduce tissue oxygen needs. Because one of the side effects of PEEP is tension pneumothorax, assess lung sounds hourly and suction as often as needed to maintain a patent airway. Positioning may be important in promoting gas exchange, but the exact position is controversial. Some patients do better in the prone position, especially if it is started early

in the disease course. Prone positioning may be achieved using a mechanical turning device, although the turning equipment is awkward and care in the prone position is more difficult. Manually turning the patient every 2 hours had been shown to improve perfusion; however, this intervention often is not performed as frequently as needed (Winkelman & Chiang, 2010) (see the Evidence-Based Practice box at right).

Drug and Fluid Therapy

Corticosteroids are used to manage ARDS because they decrease white blood cell movement, reduce inflammation, and stabilize capillary membranes. Their effectiveness, however, has not been determined. It is thought that they help reduce the fibrosis that occurs in late ARDS. Antibiotics are used to treat infections when organisms are identified.

Many interventions are under investigation, but none has been effective in improving survival. Such interventions include agents that modify the inflammatory responses and reduce oxidative stress (vitamins C and E, *N*-acetylcysteine), nitric oxide, and surfactant replacement.

Research shows that patients with ARDS who receive conservative fluid therapy have better lung function and a shorter duration of mechanical ventilation and ICU length of stay compared with those who receive more liberal fluid therapy. Conservative fluid therapy uses smaller amounts of IV fluid along with diuretics to maintain fluid balance, whereas liberal fluid therapy often results in greater positive fluid balance and more systemic edema.

Nutrition Therapy

The patient with ARDS is at risk for malnutrition, which further reduces respiratory muscle function and the immune response. Consultation with a dietitian is needed, and enteral nutrition (tube feeding) or parenteral nutrition is started as soon as possible.

Case Management

Case management of the patient with ARDS focuses on the phases of ARDS rather than on day-to-day care. The course of ARDS and its management are divided into four phases:

- **Phase 1.** This phase includes early changes of dyspnea and tachypnea. Early interventions focus on supporting the patient and providing oxygen.
- **Phase 2.** Patchy infiltrates form from increasing pulmonary edema. Interventions include mechanical ventilation and prevention of complications.
- **Phase 3.** This phase occurs over days 2 through 10, and the patient has increasing hypoxemia that responds poorly to high levels of oxygen. Interventions focus on delivering adequate oxygen, preventing complications, and supporting the lungs.
- **Phase 4.** Pulmonary fibrosis with progression occurs after 10 days. This phase is irreversible and is often called “late” or “chronic” ARDS. Patients who develop this stage and survive it will have some permanent lung damage. Interventions focus on preventing sepsis, pneumonia, and multiple organ dysfunction syndrome (MODS), as well as weaning the patient from the ventilator. The patient in this phase may be ventilator dependent for weeks to months. Care may occur in specialized units or facilities that focus on rehabilitation and long-term weaning. Some patients

EVIDENCE-BASED PRACTICE

To Turn or Not to Turn

Winkelman, C., & Chiang, L. (2010). Manual turns in patients receiving mechanical ventilation. *Critical Care Nurse*, 30(4), 36-43.

Turning bedfast patients in any setting every 2 hours has been shown to reduce skin problems and other complications and is recommended as a best practice. However, in acute care settings, especially among patients being mechanically ventilated, performance of this practice is not consistent. Concern also has been raised about possible patient harm as a result of manual or automated turn/tilt practices in mechanically ventilated patients.

The authors reviewed the evidence and performed a meta-analysis related to frequency of turning (manual and automated) and turning positions in patients receiving mechanical ventilation. After a thorough search of electronic databases, reports from four clinical trials (including one with a quasi-experimental design), two additional systematic reviews, and two older meta-analyses were analyzed. Common outcome measures included presence of fever, length of stay, and occurrence of pressure ulcers.

Although some results indicated that incidence of pneumonia (as evidenced by the presence of fever) and lengths of stay were lower among patients who were turned, the data regarding decreased pressure ulcer formation and other complications were inconclusive. In addition, issues regarding the patient environment, including bedding surfaces, were not factored into determining best turning schedules or turning techniques. The majority of studies in this analysis were completed more than 20 years ago, had small sample sizes, and were not experimental in design. Evaluation methods varied by study and issues related to other common complications of prolonged bedrest during mechanical ventilation, such as urinary tract infections and adverse effects on hemodynamic stability.

Level of Evidence: 1

The results are based on a systematic review and meta-analysis of previous studies related to the outcomes among patients receiving mechanical ventilation who were turned compared with those who were not turned or who were turned less frequently. Results of this analysis do not demonstrate clear positive outcomes or harmful outcomes from turning bedfast patients receiving mechanical ventilation in intensive care settings every 2 hours.

Commentary: Implications for Practice and Research

This article typifies the problem of generalizing known positive practices to all situations. Rather than relying on the “turn-every-2-hours regimens” that have demonstrated benefits for bedfast patients in the general population, the best turning schedules and techniques among bedfast patients being mechanically ventilated have yet to be determined. More frequent or less frequent turning may be needed. Manually turning patients who cannot help themselves is time-consuming and has resulted in staff injury. Automated turning devices are costly and not available in all settings.

At the present time, no evidence supports any specific schedule or position for turning bedfast patients requiring mechanical ventilation. One randomized controlled clinical trial is comparing the outcomes of 2-hour and 4-hour turning schedules. Another is comparing outcomes of manual turning versus automated turning. It is hoped that the results of these studies can clearly indicate which turning practices are best for populations of bedfast patients receiving mechanical ventilation. Until this evidence is known, the use of pressure-reducing/relieving devices, along with meticulous and continuous nursing assessment of individual patient responses to bedrest and turning/tilting, may be the safest practices.

may not be “weanable” and may go home or to a long-term care facility dependent on mechanical ventilation.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Teamwork and Collaboration

The patient is a 21-year-old college student who went swimming in his apartment complex swimming pool after drinking 10 cans of beer. He hit his head on the side of the pool and was under water for about 2 minutes before his friends pulled him out. During CPR, he vomited a large amount before the emergency squad came to the scene. In the emergency department, he is unconscious and breathing on his own. Oral, nasal, and tracheal suctioning have produced stomach contents and fluid that smells strongly of chlorine. On auscultation, wheezes and mild crackles are present. The chest x-ray is normal, and these are the ABG values: pH = 7.28; PaO_2 = 88 mm Hg; Paco_2 = 58 mm Hg.

1. What factors could contribute to an acute lung injury in this patient?
2. Is this patient at risk for TRALI? Why or why not?
3. What is your interpretation of the ABG results?
4. Why does the current chest x-ray show no abnormalities?
5. Should this patient be intubated and mechanically ventilated at this time? Why or why not?
6. What are your care priorities for this patient at this time?

THE PATIENT REQUIRING INTUBATION AND VENTILATION

Pathophysiology

With mechanical ventilation, the patient who has severe problems of gas exchange may be supported until the underlying problem improves or resolves. Usually mechanical ventilation is a temporary life-support technique. The need for this support may be lifelong for those with severe restrictive lung disease or chronic progressive neuromuscular disease that reduces ventilation.

Mechanical ventilation is most often used for patients with hypoxemia and progressive alveolar hypoventilation with respiratory acidosis. The hypoxemia is usually due to pulmonary shunting of blood when other methods of oxygen delivery do not provide a sufficiently high fraction of inspired oxygen (FiO_2). Mechanical ventilation may be used for patients who need ventilatory support after surgery, those

who expend too much energy with breathing and barely maintain adequate gas exchange, or those who have general anesthesia or heavy sedation.

PATIENT-CENTERED COLLABORATIVE CARE

Assess the patient to be intubated in the same way as for other breathing problems. Once mechanical ventilation has been started, assess the respiratory system on an ongoing basis. Monitor and assess for problems related to the artificial airway or ventilator.

Endotracheal Intubation

The patient who needs mechanical ventilation must have an artificial airway. The most common type of airway for a short-term basis is the endotracheal (ET) tube. A tracheostomy is considered if an artificial airway is needed for longer than 10 to 14 days (see Chapter 30) to reduce tracheal and vocal cord damage. The purposes of intubation are to maintain a patent airway, provide a means to remove secretions, and provide ventilation and oxygen.

Endotracheal Tube. An ET tube is a long polyvinyl chloride tube that is passed through the mouth or nose and into the trachea (Fig. 34-3). When properly positioned, the tip of the ET tube rests about 2 cm above the **carina** (the point at which the trachea divides into the right and left bronchi). Oral intubation is a fast and easy way to establish an airway and is often performed as an emergency procedure. The nasal route is used for facial or oral traumas/surgeries and when oral intubation is not possible. This route is not used if the patient has a blood clotting problem. An anesthesiologist, nurse anesthetist, or pulmonologist usually performs the intubation.

The shaft of the ET tube has a radiopaque line running the length of the tube. This line shows on x-ray and is used to determine correct tube placement. Short horizontal lines (depth markings) are used to place the tube correctly at the naris or mouth (at the incisor tooth) and to identify how far the tube has been inserted.

The cuff at the distal end of the tube is inflated after placement and can create a seal between the trachea and the cuff. The seal ensures delivery of a set tidal volume when mechanical ventilation is used. When the cuff is inflated to an adequate sealing volume, a minimal amount of air can pass around the cuff to the vocal cords, nose, or mouth. The

FIG. 34-3 A, Endotracheal tubes. B, Correct placement of an oral endotracheal tube.

patient cannot talk when the cuff is inflated. The cuff should be inflated using a minimal-leak technique.

The pilot balloon with a one-way valve permits air to be inserted into the cuff and prevents air from escaping. This balloon is a guide for determining when air is present in the cuff but not how much or how little air is present.

The adaptor connects the ET tube to ventilator tubing or to an oxygen delivery system. The ET tube size is listed on the shaft of the tube. Adult tube sizes range from 7 to 9 mm. Tube size selected is based on the size of the patient.

Preparing for Intubation. Know the proper procedure for summoning intubation personnel in the facility to the bedside in an emergency situation. Explain the procedure to the patient as clearly as possible. *Basic life support measures, such as obtaining a patent airway and delivering 100% oxygen by a manual resuscitation bag with a facemask, are crucial to survival until help arrives.*

! NURSING SAFETY PRIORITY

Critical Rescue

For the patient requiring emergency intubation and ventilation, bring the code (or “crash”) cart, airway equipment box, and suction equipment (often already on the code cart) to the bedside. Maintain a patent airway through positioning and the insertion of an oral or nasopharyngeal airway until the patient is intubated.

During intubation, the nurse coordinates the response and continuously monitors for changes in vital signs, signs of hypoxia or hypoxemia, dysrhythmias, and aspiration. Ensure that each intubation attempt lasts no longer than 30 seconds, preferably less than 15 seconds. After 30 seconds, provide oxygen by means of a mask and manual resuscitation bag to prevent hypoxia and cardiac arrest. Suction as necessary.

Verifying Tube Placement. Immediately after an ET tube is inserted, placement should be verified. The most accurate ways to verify placement are by checking end-tidal carbon dioxide levels and by chest x-ray. Assess for breath sounds bilaterally, symmetric chest movement, and air emerging from the ET tube. If breath sounds and chest wall movement are absent on the left side, the tube may be in the right main-stem bronchus. The person intubating the patient should be able to reposition the tube without repeating the entire intubation procedure.

If the tube is in the stomach, the abdomen may be distended and must be decompressed with the insertion of a nasogastric (NG) tube. Monitor chest wall movement and breath sounds until tube placement is verified by x-ray.

Stabilizing the Tube. The nurse, respiratory therapist, or anesthesia provider stabilizes the ET tube at the mouth or nose. The tube is marked at the level where it touches the incisor tooth or naris. Two people working together use a head halter technique to secure the tube. [Chart 34-9](#) outlines best practices for securing an oral or nasal ET tube.

An oral airway also may be inserted or a commercial bite block placed to keep the patient from biting an oral endotracheal tube. One person stabilizes the tube at the correct position and prevents head movement while a second person applies the tape. After the procedure is completed, verify and document the presence of bilateral and equal breath sounds and the level of the tube.

Nursing Care. Assess tube placement, cuff leak, breath sounds, and chest wall movement regularly. Prevent pulling or tugging on the tube by the patient to prevent dislodgment or “slipping” of the tube, and check the pilot balloon to ensure that the cuff is inflated. Suctioning, coughing, and speaking can cause dislodgment. Neck flexion moves the tube away from the carina; neck extension moves the tube closer to the carina. Rotation of the head also causes the tube to move. Mouth secretions and tongue movement can loosen the tape and change the tube’s position. When other measures fail, obtain a prescription for soft wrist restraints and apply these for the patient who is pulling on the tube. *Restraints are used as a last resort to prevent accidental extubation.* Adequate sedation (chemical restraint) may be needed to decrease agitation or prevent extubation. Obtain permission for restraints from the patient or family. More information on airway management is found in [Chapter 30](#).

Complications of an ET or nasotracheal tube can occur during placement, while in place, during extubation, or after extubation (either early or late). Trauma and other problems can occur to the face; eye; nasal and paranasal areas; oral, pharyngeal, bronchial, tracheal, and pulmonary areas; esophageal and gastric areas; and cardiovascular, musculoskeletal, and neurologic systems.

? NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

Which assessment finding in a client with an endotracheal tube most strongly indicates to the nurse that the tube remains correctly in the trachea and is not in the esophagus?

- A. Stomach contents cannot be aspirated.
- B. Oxygen saturation is greater than 50%.
- C. End-tidal carbon dioxide level is 38 mm Hg.
- D. No air is heard in the stomach when auscultated with a stethoscope.

Mechanical Ventilation

Mechanical ventilation to support and maintain gas exchange is widely used in many settings, not just in critical care units. The nurse plays a pivotal role in the coordination of care and the prevention of problems. [Chart 34-10](#) lists best practices for patient care during mechanical ventilation.

The purposes of mechanical ventilation are to improve gas exchange and to decrease the work needed for effective breathing. It is used to support the patient until lung function is adequate or until the acute episode has passed. *A ventilator does not cure diseased lungs; it provides ventilation until the patient can resume the process of breathing.* Remember *why* the patient is using the ventilator so that management efforts also focus on correcting the causes of the respiratory failure. If normal oxygenation, ventilation, and respiratory muscle strength are achieved, mechanical ventilation can be discontinued.

Types of Ventilators. Many types of ventilators are available. The ventilator selected depends on the severity of the breathing problem and the length of time ventilator support is needed. Most ventilators are positive-pressure ventilators. During inspiration, pressure is generated that pushes air into the lungs and expands the chest. Usually, an endotracheal (ET) tube or tracheostomy is needed. Positive-pressure ventilators are classified by the mechanism that ends inspiration

CHART 34-9 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Securing an Oral and Nasal Endotracheal Tube

Adhesive tape is the easiest, least expensive, and most commonly used method to secure endotracheal (ET) and nasotracheal tubes.

However, adhesive tape may be irritating to the skin, and frequent tape changes may tear the skin. Another reported complication is a fungal infection occurring around the surgical tape securing the ET tube.

Protecting the skin, especially on the face, is a high priority for patients and nurses. This must be balanced against making sure the ET tube is not dislodged. A simple yet effective method of securing oral and nasotracheal tubes is demonstrated here:

1. Prepare the skin by shaving the cheeks and upper lip, if possible.
2. Protect the skin by applying tincture of benzoin to the skin and to the exposed part of the ET tube and allow to dry (Mastisol may also be used, but Detachol must be used before removing the tape); then apply a 1 × 3-inch piece of thin DuoDerm or other protective or hydrocolloid membrane to the skin on the cheeks (A).
3. Lay a 30-inch (about 2½-foot) piece of adhesive tape on a flat surface, sticky side up. Cover the middle portion of the tape with another piece of tape (about 10 inches long) (sticky side to sticky side) to protect the back of the patient's neck. A tongue blade on each end folded over can keep it from getting tangled or sticking prematurely.
4. Place the tape behind the patient's neck. Remove the tongue blades, and place the tape on the protective membrane up to the end of the mouth on each side. Trim the tape as needed, and split each end of the tape. On the ends of the tape that will be wrapped around the tube, fold the tape so that the sticky sides meet to form a small tab that will make tape removal easier.
5. Place the upper part of one end of the tape on the upper lip. Wrap the lower part of the tape securely around the tube (B, C). Place the upper part of the other end of the tape on the upper lip, and wrap the lower part securely around the tube (D, E). Do not have the tube too far to either side of the mouth, or it can cause skin breakdown in the corner of the mouth or lips.
6. The same method can be used for nasal tubes, but do not tape the tube too tightly to the nose or skin breakdown will occur on the naris (F).

7. *Always tape the tube to the upper lip; never the lower.* The lower jaw moves too much, which moves the tube and causes irritation and discomfort for the patient. Inspect the tape at least every shift for signs of loosening or skin irritation or breakdown, especially with increased oral secretions. Check tightness of the tape each shift if swelling in the face and neck occurs or if there is an increase in fluid retention (as in anasarca, sepsis, or ARDS).

An additional technique for securing tubing that can decrease ET tube movement and provide a fulcrum for pulling on ventilator tubing is to attach a 6-inch (50-mL) piece of flexible ventilator tubing between the ET tube adaptor and the Y-connector of the ventilator tubing. The procedure for this technique is:

1. Shave the chest or clean with alcohol a portion of the chest at right angles to the angle of Louis. Apply tincture of benzoin, and allow to dry.
2. Prepare Montgomery straps by taking two 6-inch pieces of 2-inch-wide adhesive tape. Double-back one end of each piece of tape, and cut a small hole in the ends that are doubled over.
3. Apply the tape to the prepared chest with the ends with the hole over each other. Thread a 12-inch piece of twill (trach) tape through both holes. Position the tubing with the Y-connector over the holes, and tie into place. This procedure allows all pulling on the tubing to place strain on the tape (straps) and not on the face or the tube.

and starts expiration. Inspiration is cycled in three major ways: pressure-cycled, time-cycled, or volume-cycled.

Pressure-cycled ventilators push air into the lungs until a preset airway pressure is reached. Tidal volumes and inspiratory time vary. These ventilators are used for short periods, such as just after surgery and for respiratory therapy. Bi-level positive airway pressure (Bi-PAP) ventilators are a modern form of pressure-cycled ventilator in which the ventilator provides a preset inspiratory pressure and an expiratory pressure similar to positive end-expiratory pressure (PEEP).

Time-cycled ventilators push air into the lungs until a preset time has elapsed. Tidal volume and pressure vary, depending on the needs of the patient and the type of ventilator.

Volume-cycled ventilators push air into the lungs until a preset volume is delivered. A constant tidal volume is delivered regardless of the pressure needed to deliver the tidal volume. A set pressure limit, however, prevents excessive pressure from being exerted on the lungs. The advantage of this type of ventilator is that a constant tidal volume is delivered regardless of changes in lung or chest wall compliance or in airway resistance.

Microprocessor ventilators are computer-managed positive-pressure ventilators. A computer is built into the ventilator to allow ongoing monitoring of ventilatory functions, alarms, and patient conditions. It often has components of volume-, time-, and pressure-cycled ventilators. These ventilators are more responsive to patients who have severe lung disease and

those who need prolonged weaning trials. Examples are the Draeger Evita XL (Fig. 34-4) and Puritan-Bennett 840.

Modes of Ventilation. The mode of ventilation is the way in which the patient receives breaths from the ventilator.

Assist-control (AC) ventilation is used often as a resting mode. The ventilator takes over the work of breathing for the patient. The tidal volume and ventilatory rate are

FIG. 34-4 Display signals, alarms, and control panel of a typical volume-cycled ventilator.

CHART 34-10 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Care of the Patient Receiving Mechanical Ventilation

- Assess the patient's respiratory status at least every 4 hours for the first 24 hours and then as needed:
 - Take vital signs at least every 4 hours.
 - Assess the patient's color (especially lips and nail beds).
 - Observe the patient's chest for bilateral expansion.
 - Assess the placement of the nasotracheal or endotracheal tube.
 - Obtain pulse oximetry reading.
 - Evaluate ABGs as available.
 - Maintain head of the bed more than 30 degrees when patient is supine to prevent aspiration and ventilator-associated pneumonia.
- Document pertinent observations in the patient's medical record.
- Check at least every 8 hours to be sure the ventilator setting is as prescribed.
- Check to be sure alarms are set (especially low-pressure and low-exhaled volume).
- If the patient is on PEEP, observe the peak airway pressure dial to determine the proper level of PEEP.
- Check the exhaled volume digital display to be sure the patient is receiving the prescribed tidal volume.
- Empty ventilator tubings when moisture collects. *Never empty fluid in the tubing back into the cascade.*
- Ensure humidity by keeping delivered air temperature maintained at body temperature.
- Be sure the tracheostomy cuff (or endotracheal cuff) is adequately inflated to ensure tidal volume.
- Auscultate the lungs for crackles, wheezes, equal breath sounds, and decreased or absent breath sounds.
- Check the patient's need for tracheal, oral, or nasal suctioning every 2 hours, and suction as needed.
- Assess the patient's mouth around the ET tube for pressure ulcers.
- Perform mouth care every 2 hours.
- Change tracheostomy tape or endotracheal tube tape as needed:
 - Carefully move the oral endotracheal tube to the opposite side of the mouth once daily to prevent ulcers.
 - Provide tracheostomy care every 8 hours.
- Assess ventilated patients for GI distress (diarrhea, constipation, tarry stools).
- Maintain accurate intake and output records to monitor fluid balance.
- Turn the patient at least every 2 hours, and get the patient out of bed as prescribed to promote pulmonary hygiene and prevent complications of immobility.
- Schedule treatments and nursing care at intervals for rest.
- Monitor the patient's progress on current ventilator settings, and make appropriate changes, as indicated.
- Monitor the patient for the effectiveness of mechanical ventilation in terms of his or her physiologic and psychological status.
- Monitor for adverse effects of mechanical ventilation: infection, barotrauma, reduced cardiac output.
- Position the patient to facilitate ventilation-perfusion ($\dot{V}/\dot{Q}$ matching ("good lung down")), as appropriate.
- Monitor the effects of ventilator changes on oxygenation and the patient's subjective response.
- Monitor readiness to wean.
- Explain all procedures and treatments; provide access to a call light; visit the patient frequently.
- Provide a method of communication. Request consultation with a speech-language pathologist for assistance, if necessary.
- Initiate relaxation techniques, as appropriate.
- Administer muscle-paralyzing agents, sedatives, and narcotic analgesics, as prescribed.
- Include the patient and family whenever possible (especially during suctioning and tracheostomy care).

preset. If the patient does not have spontaneous breaths, a ventilatory pattern is established by the ventilator. It is programmed to respond to the patient's inspiratory effort if he or she begins a breath. In this case, the ventilator delivers the preset tidal volume while allowing the patient to control the breathing rate.

A disadvantage of the AC mode is that the ventilator continues to deliver a preset tidal volume even when the patient's spontaneous breathing rate increases. This can cause hyperventilation and respiratory alkalosis. Investigate and correct causes of hyperventilation, such as pain, anxiety, or acid-base imbalances.

Synchronized intermittent mandatory ventilation (SIMV) is similar to AC ventilation in that tidal volume and ventilatory rate are preset. If the patient does not breathe, a ventilatory pattern is established by the ventilator. Unlike the AC mode, SIMV allows spontaneous breathing at the patient's own rate and tidal volume between the ventilator breaths. It can be used as a main ventilatory mode or as a weaning mode. When used for weaning, the number of mechanical breaths (SIMV breaths) is gradually decreased (e.g., from 12 to 2) and the patient gradually resumes spontaneous breathing. The mandatory ventilator breaths are delivered when the patient is ready to inspire. This action coordinates breathing between the ventilator and the patient.

Bi-level positive airway pressure (BiPAP) provides noninvasive pressure support ventilation by nasal mask or face-mask. It is most often used for patients with sleep apnea but also may be used for patients with respiratory muscle fatigue to avoid more invasive ventilation methods.

Other modes of ventilation, such as pressure support and continuous flow (flow-by), are part of most microprocessor ventilators. Both types decrease the work of breathing and are used for weaning patients from mechanical ventilation. Other modes are maximum mandatory ventilation (MMV), inverse inspiration-expiration (I/E) ratio, permissive hypercarbia, airway pressure-release ventilation (APRV), proportional assist ventilation, and high-frequency oscillation. Most modes use special ventilators, tubing, or airways.

Ventilator Controls and Settings. The volume-cycled ventilator is the most widely used type in the acute care setting. Regardless of the type of volume-cycled ventilator used, the controls and types of settings are universal (see Fig. 34-4). The physician prescribes the ventilator settings, and usually the ventilator is readied or set up by the respiratory department. The nurse assists in connecting the patient to the ventilator and monitors the ventilator settings.

Tidal volume (V_T) is the volume of air the patient receives with each breath, as measured on either inspiration or expiration. The average prescribed V_T ranges between 7 and 10 mL/kg of body weight. Adding a zero to a patient's weight in kilograms gives an estimate of tidal volume.

Rate, or breaths/min, is the number of ventilator breaths delivered per minute. The rate is usually set between 10 and 14 breaths/min.

Fraction of inspired oxygen (F_{IO_2}) is the oxygen level delivered to the patient. The prescribed F_{IO_2} is based on the ABG values and the patient's condition. The range is 21% to 100% oxygen.

The oxygen delivered to the patient is warmed to body temperature (98.6° F [37° C]) and humidified to 100%. This is needed because upper air passages of the respiratory tree,

which normally warm and humidify air, are bypassed. Humidifying and warming prevent mucosal damage.

Peak airway (inspiratory) pressure (PIP) is the pressure used by the ventilator to deliver a set tidal volume at a given lung compliance. The PIP value appears on the display of the ventilator. It is the highest pressure reached during inspiration. Monitoring trends in PIP reflect changes in resistance of the lungs and resistance in the ventilator. An increased PIP reading means increased airway resistance in the patient or in the ventilator tubing (bronchospasm or pinched tubing), increased secretions, pulmonary edema, or decreased pulmonary compliance (the lungs or chest wall is "stiffer" or harder to inflate). An upper pressure limit is set to prevent barotrauma. When the limit is reached, the high-pressure alarm sounds and the remaining volume is not given.

Continuous positive airway pressure (CPAP) applies positive airway pressure throughout the entire respiratory cycle for spontaneously breathing patients. Sedating drugs are given lightly if at all when the patient is receiving CPAP so that respiratory effort is not suppressed. CPAP keeps the alveoli open during inspiration and prevents alveolar collapse during expiration. This process increases functional residual capacity (FRC) and improves oxygenation.

CPAP is commonly used to help in the weaning process. During CPAP, no ventilator breaths are delivered. The ventilator just delivers oxygen and provides monitoring and an alarm system. The respiratory pattern is determined by the patient's efforts. Normal levels of CPAP are 5 to 15 cm H₂O to promote adequate oxygenation. If no pressure is set, the patient receives no positive pressure. Thus the patient is then using the ventilator as a T-piece with alarms. Modifications of CPAP include nasal CPAP and BiPAP, which are used on a very temporary basis for select problems.

Positive end-expiratory pressure (PEEP) is positive pressure exerted during expiration. PEEP improves oxygenation by enhancing gas exchange and preventing atelectasis. It is used to treat persistent hypoxemia that does not improve with an acceptable oxygen delivery level. It may be added when the arterial oxygen pressure (P_{aO_2}) remains low with an F_{IO_2} of 50% to 70% or greater.

The need for PEEP indicates a severe gas-exchange problem. *It is important to lower the F_{IO_2} delivered whenever possible because prolonged use of a high F_{IO_2} can damage lungs from the toxic effects of oxygen.* PEEP prevents alveoli from collapsing because the lungs are kept partially inflated so that alveolar-capillary gas exchange is promoted throughout the ventilatory cycle. The effect should be an increase in arterial blood oxygenation so that the F_{IO_2} can be decreased.

PEEP is "dialed in" on the control panel. The amount of PEEP is usually 5 to 15 cm H₂O and is monitored on the peak airway pressure dial, the same dial used to read the PIP. When PEEP is added, the dial does not return to zero at the end of exhalation; rather, it returns to a baseline that is increased from zero by the amount of PEEP applied.

Flow rate is how fast each breath is delivered and is usually set at 40 L/min. *If a patient is agitated or restless, has a widely fluctuating inspiratory pressure reading, or has other signs of air hunger, the flow may be set too low. Increasing the flow should be tried before using chemical restraints.*

Other settings may be used, depending on the type of ventilator and mode of ventilation. Examples include inspiratory

and expiratory cycle, waveform, expiratory resistance, and plateau.

Nursing Management. The use of mechanical ventilation involves a collaborative and complex decision-making process for the patient and family and the health care team. Address the physical and psychological concerns of the patient and family because the mechanical ventilator often causes them anxiety. Explain the purpose of the ventilator, and acknowledge that the patient might feel some different sensations. Encourage the patient and family to express their concerns. Act as the coach to help and support them through this experience. Patients undergoing mechanical ventilation in ICUs often experience delirium, or “ICU psychosis.” These patients need frequent, repeated explanations and reassurance.

When caring for a ventilated patient, be concerned with the patient first and the ventilator second. It is vital to understand why mechanical ventilation is needed. Causes such as excessive amounts of secretions, sepsis, and trauma require different interventions for ventilator independence. In addition, understand the patient’s chronic health problems, especially chronic obstructive pulmonary disease (COPD), left-sided heart failure, anemia, and malnutrition. These problems may slow weaning from mechanical ventilation and require close monitoring and intervention.

! NURSING SAFETY PRIORITY

Action Alert

The nursing priorities in caring for the patient during mechanical ventilation are monitoring and evaluating patient responses, managing the ventilator system safely, and preventing complications.

Monitoring the Patient’s Response. Monitor, evaluate, and document the patient’s response to the ventilator. Assess vital signs and listen to breath sounds every 30 to 60 minutes at first. Monitor respiratory parameters (e.g., capnography, pulse oximetry), and check ABG values.

Assess the breathing pattern in relation to the ventilatory cycle to determine whether the patient is tolerating or fighting the ventilator. Assess and record breath sounds, including bilateral equal breath sounds to ensure proper endotracheal (ET) tube placement. Determine the need for suctioning by observing secretions for type, color, and amount.

Assess the area around the ET tube or tracheostomy site at least every 4 hours for color, tenderness, skin irritation, and drainage, and document the findings. Monitoring provides information to guide the patient’s activities, such as weaning, physical or occupational therapy, and self-care. Pace activities to ensure adequate oxygenation and effective ventilation. Interpret ABG values to evaluate ventilation, and suggest ventilator settings that help the patient.

The nurse spends the most time with the patient and is often the first person to recognize changes in vital signs or

ABG values, fatigue, or distress. Promptly coordinate with the physician and implement the appropriate interventions.

Serve as a resource for the psychological needs of the patient and family. Anxiety can reduce tolerance for mechanical ventilation. Skilled and sensitive nursing care promotes emotional well-being and synchrony with the ventilator. The patient cannot speak, and communication can be frustrating and anxiety producing. The patient may panic for fear that the voice has been lost. Reassure them that the ET tube prevents speech only temporarily.

Plan methods of communication to meet the patient’s needs, such as a slate, picture board, pen and paper, alphabet board, or programmable speech-generating device (Rodriguez & Rowe, 2010). Finding a successful means for communication is important because the patient often feels isolated as a result of the inability to speak. (See Chart 31-2 in Chapter 31.) Try to anticipate his or her needs and provide easy access to frequently used belongings. Visits from family, friends, and pets and keeping a call light within reach are some ways of giving patients a sense of control over the environment. Urge them to participate in self-care.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

A 6-foot, 6-inch tall 38-year-old man is being mechanically ventilated at a tidal volume of 500 mL and a respiratory rate of 16 breaths per minute. His most recent arterial blood gas (ABG) results are: pH = 7.33; PaO₂ = 85 mm Hg; PaCO₂ = 55 mm Hg. What is the nurse’s interpretation of these results?

- A. Ventilation is adequate to maintain oxygenation.
- B. Ventilation is excessive; respiratory alkalosis is present.
- C. Ventilation is inadequate; respiratory acidosis is present.
- D. Ventilation status cannot be determined from the information presented.

Managing the Ventilator System. Ventilator settings are prescribed by the physician in conjunction with the respiratory therapist. Settings include tidal volume, respiratory rate, fraction of inspired oxygen (Fio₂), and mode of ventilation (assist-control [AC] ventilation, synchronized intermittent mandatory ventilation [SIMV], and adjunctive modes, such as positive end-expiratory pressure [PEEP], pressure support, or continuous flow).

Perform and document ventilator checks according to the standards of the unit or facility. Respond promptly to alarms. During a ventilator check, compare the prescribed ventilator settings with the actual settings. Check the level of water in the humidifier and the temperature of the humidifying system to ensure that they are not too high. Temperature extremes damage the airway mucosa. Remove any condensation in the ventilator tubing by draining water into drainage collection receptacles, and empty them every shift.

! NURSING SAFETY PRIORITY

Critical Rescue

If the patient develops respiratory distress during mechanical ventilation, immediately remove the ventilator and provide ventilation with a bag-valve mask device. This action allows quick determination of whether the problem is with the ventilator or with the patient.

NCLEX EXAMINATION CHALLENGE

Action Alert

To prevent bacterial contamination, do not allow moisture and water in the ventilator tubing to enter the humidifier.

Mechanical ventilators have alarm systems that warn of a problem with either the patient or the ventilator. *Alarm systems must be activated and functional at all times. If the cause*

of the alarm cannot be determined, ventilate the patient manually with a resuscitation bag until the problem is corrected by another health care professional. The major alarms on a ventilator indicate either a high pressure or a low exhaled volume. Table 34-4 lists interventions for causes of ventilator alarms.

Assess and care for the ET or tracheostomy tube. Maintain a patent airway by suctioning when these are present:

- Secretions
- Increased peak airway (inspiratory) pressure (PIP)
- Rhonchi (wheezes)
- Decreased breath sounds

Proper care of the ET or tracheostomy tube also ensures a patent airway. Assess tube position at least every 2 hours, especially when the airway is attached to heavy ventilator tubing that may pull on the tube. Position the ventilator tubing in such a way that the patient can move without pulling on the ET or tracheostomy tube. If the ET moves, it could slip into the right mainstem bronchus. To detect changes in tube position, mark it where the tube touches the patient's teeth or nose. Give mouth care at least every 8 hours for hygiene and to prevent loosening of the tape that holds the tube.

Special attention is needed for the patient being transported while receiving mechanical ventilation. Monitor Spo₂

during transport to assess ET tube placement and adequacy of ventilation.

Preventing Complications. Most problems are caused by the positive pressure from the ventilator. Nearly every body system is affected.

Cardiac problems from mechanical ventilation include hypotension and fluid retention. Hypotension is caused by positive pressure that increases chest pressure and inhibits blood return to the heart. The decreased blood return reduces cardiac output, causing hypotension. Hypotension is most often seen in patients who are dehydrated or need high PIP for ventilation. Teach the patient to avoid a **Valsalva maneuver** (bearing down while holding the breath).

Fluid is retained because of decreased cardiac output. The kidneys receive less blood flow, which stimulates the renin-angiotensin-aldosterone system to retain fluid. Humidified air in the ventilator system contributes to fluid retention. Monitor the patient's fluid intake and output, weight, hydration, and signs of hypovolemia.

Lung problems from mechanical ventilation include **barotrauma** (damage to the lungs by positive pressure), **volutrauma** (damage to the lung by excess volume delivered to one lung over the other), and acid-base imbalance.

TABLE 34-4 NURSING INTERVENTIONS FOR VARIOUS CAUSES OF VENTILATOR ALARMS

CAUSE	NURSING INTERVENTIONS
High-Pressure Alarm (sounds when peak inspiratory pressure reaches the set alarm limit [usually set 10-20 mm Hg above the patient's baseline PIP])	
An increased amount of secretions or a mucus plug is in the airways.	Suction as needed.
The patient coughs, gags, or bites on the oral ET tube.	Insert oral airway to prevent biting on the ET tube.
The patient is anxious or fights the ventilator.	Provide emotional support to decrease anxiety. Increase the flow rate. Explain all procedures to the patient. Provide sedation or paralyzing agent per the physician's prescription.
Airway size decreases related to wheezing or bronchospasm.	Auscultate breath sounds.
Pneumothorax occurs.	Alert the physician or Rapid Response Team for management of bronchospasm. Auscultate breath sounds. Alert the physician or Rapid Response Team about a new onset of decreased breath sounds or unequal chest excursion, which may be due to pneumothorax.
The artificial airway is displaced; the ET tube may have slipped into the right mainstem bronchus.	Assess the chest for unequal breath sounds and chest excursion. Obtain a chest x-ray as ordered to evaluate the position of the ET tube. After the proper position is verified, tape the tube securely in place.
Obstruction in tubing occurs because the patient is lying on the tubing or there is water or a kink in the tubing.	Assess the system, moving from the artificial airway toward the ventilator.
There is increased PIP associated with deliverance of a sigh.	Empty water from the ventilator tubing, and remove any kinks. Coordinate with respiratory therapist or physician to adjust the pressure alarm.
Decreased compliance of the lung is noted; a trend of gradually increasing PIP is noted over several hours or a day.	Evaluate the reasons for the decreased compliance of the lungs. Increased PIP occurs in ARDS, pneumonia, or any worsening of pulmonary disease.
Low Exhaled Volume (or Low-Pressure) Alarm (sounds when there is a disconnection or leak in the ventilator circuit or a leak in the patient's artificial airway cuff)	
A leak in the ventilator circuit prevents breath from being delivered.	Assess all connections and all ventilator tubings for disconnection.
The patient stops spontaneous breathing in the SIMV or CPAP mode or on pressure support ventilation.	Evaluate the patient's tolerance of the mode.
A cuff leak occurs in the ET or tracheostomy tube.	Evaluate the patient for a cuff leak. A cuff leak is suspected when the patient can talk (air escapes from the mouth) or when the pilot balloon on the artificial airway is flat (see Tracheostomy Tubes section in Chapter 30).

ARDS, Acute respiratory distress syndrome; CPAP, continuous positive airway pressure; ET, endotracheal; PIP, peak inspiratory pressure; SIMV, synchronized intermittent mandatory ventilation.

Barotrauma includes pneumothorax, subcutaneous emphysema, and pneumomediastinum. Patients at highest risk for barotrauma have chronic airflow limitation (CAL), have blebs or bullae, are on PEEP, have dynamic hyperinflation, or require high pressures to ventilate the lungs (because of “stiff” lungs, as seen in acute respiratory distress syndrome [ARDS]). Blood gas problems can be corrected by ventilator changes and adjustment of fluid and electrolyte imbalances.

GI and nutritional problems result from the stress of mechanical ventilation. Stress ulcers occur in many patients receiving mechanical ventilation. These ulcers complicate the nutritional status and, because the mucosa is not intact, increase the risk for systemic infection. Antacids, sucralfate (Carafate, Sulcrate ) , and histamine blockers such as ranitidine (Zantac) or proton-pump inhibitors such as esomeprazole (Nexium) may be prescribed as soon as the patient is intubated. Changes in chest and abdominal cavity pressure can lead to a paralytic ileus. This problem reduces nutrient absorption through the GI system, requiring short-term parenteral nutritional support.

Because many other acute or life-threatening events occur at the same time, nutrition is often neglected. Malnutrition is an extreme problem for these patients and is a main reason for failure to wean from the ventilator. In malnutrition, the respiratory muscles lose mass and strength. The diaphragm, the major muscle of inspiration, is affected early. When it and other respiratory muscles are weak, ineffective breathing results, fatigue occurs, and the patient cannot be weaned.

Balanced nutrition, whether by diet, enteral feedings, or parenteral feeding, is essential during ventilation (Racco, 2009). Also, nutrition for the patient with chronic obstructive pulmonary disease (COPD) requires a reduction in the percentage of carbohydrates in the diet. During metabolism, carbohydrates are broken down to glucose, which then produces energy, carbon dioxide, and water. Excessive carbohydrate loads increase carbon dioxide production, which the patient with COPD may be unable to exhale. Hypercarbic respiratory failure results. Nutritional formulas with a higher fat content (e.g., Pulmocare, Nutri-Vent, intralipids) are calorie sources to combat this problem.

Electrolyte replacement is also important because electrolytes influence muscle function. Monitor potassium, calcium, magnesium, and phosphate levels, and replace them as prescribed.

Infections are a threat for the patient using a ventilator, especially ventilator-associated pneumonia (VAP). The ET or tracheostomy tube bypasses the body’s filtering process and provides a direct access for bacteria to enter the lower respiratory system. The artificial airway is colonized with bacteria within 48 hours, which promotes pneumonia development and increases morbidity. Aspiration of colonized fluid from the mouth or the stomach can be a source of infection. *Infection prevention through strict adherence to infection control, especially handwashing during suctioning and care of the tracheostomy or ET tube, is essential.* To prevent pneumonia, perform oral care every 2 hours and implement pulmonary hygiene, including chest physiotherapy, postural drainage, and turning and positioning (Halm & Armola, 2009). Information on VAP can be found in [Chapter 33](#).

Muscle deconditioning and weakness can occur because of immobility. Getting the patient out of bed and having him or

her ambulate with help and perform exercises not only improve muscle strength but also boost morale, enhance gas exchange, and promote oxygen delivery to all muscles (Winkelman, 2009).

Ventilator dependence is the inability to wean off the ventilator. This problem usually has a physiologic basis but can be psychological. The longer a patient uses a ventilator, the more difficult is the weaning process because the respiratory muscles fatigue and cannot assume breathing. The health care team uses every method of weaning before a patient is declared “unweanable.”

Collaborate with the physician, social worker or psychologist, and a member of the clergy to discuss with the patient and family the patient’s quality of life, goals, and values. As a result of this discussion, arrange for home ventilation, nursing home placement, or withdrawal of life support (in terminal cases). Special units and facilities can maximize the rehabilitation and weaning of ventilator-dependent patients.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

At the hourly assessment of an intubated client after positive end-expiratory pressure (PEEP) has been discontinued, the nurse notes all of the following changes. For which one does the nurse notify the physician?

- A. The client is now talking around the endotracheal tube.
- B. Breath sounds are reduced over the left lung compared with the right.
- C. Oxygen saturation has increased from 90% to 95% at an FiO_2 of 40%.
- D. The PIP dial now drops to zero at the end of exhalation instead of to only 10 cm H_2O .

Weaning. Weaning is the process of going from ventilatory dependence to spontaneous breathing. The process is prolonged by complications. Many problems can be reduced with good nursing care. For example, turning and positioning the patient not only promote comfort and prevent skin breakdown but also improve gas exchange and prevent pneumonia and atelectasis. [Table 34-5](#) lists various weaning techniques.

CONSIDERATIONS FOR OLDER ADULTS

The older patient, especially one who has smoked or who has a chronic lung problem such as COPD, is at risk for ventilator dependence and failure to wean. Age-related changes, such as increased chest wall stiffness, reduced ventilatory muscle strength, and decreased lung elasticity, reduce the likelihood of weaning. The usual manifestations of ventilatory failure—hypoxemia and hypercarbia—may be less obvious in the older adult, and other clinical measures of oxygenation, such as a change in mental status, should be used to determine breathing effectiveness.

Extubation. Extubation is the removal of the endotracheal (ET) tube. The tube is removed when the need for intubation has been resolved. Before removal, explain the procedure. Set up the prescribed oxygen delivery system at the bedside, and bring in the equipment for emergency reintubation. Hyperoxygenate the patient, and thoroughly suction both the ET tube and the oral cavity. Then rapidly deflate the cuff of the ET tube and remove the tube at peak inspiration. Immediately instruct the patient to cough. It is normal for

TABLE 34-5 WEANING METHODS

Synchronous Intermittent Mandatory Ventilation

- The patient breathes between the machine's preset breaths/min rate.
- The machine is initially set on an SIMV rate of 12, meaning the patient receives a minimum of 12 breaths/min by the ventilator.
- The patient's respiratory rate will be a combination of ventilator breaths and spontaneous breaths.
- As the weaning process ensues, the physician prescribes gradual decreases in the SIMV rate, usually at a decrease of 1 to 2 breaths/min.

T-Piece Technique

- The patient is taken off the ventilator for short periods (initially 5 to 10 minutes) and allowed to breathe spontaneously.
- The ventilator is replaced with a T-piece (see Chapter 30) or CPAP, which delivers humidified oxygen.
- The prescribed FiO_2 may be higher for the patient on the T-piece than on the ventilator.
- Weaning progresses as the patient can tolerate progressively longer periods off the ventilator.
- Nighttime weaning is not usually attempted until the patient can maintain spontaneous respirations most of the day.

Pressure Support Ventilation

- PSV allows the patient's respiratory effort to be augmented by a predetermined pressure assist from the ventilator.
- As the weaning process ensues, the amount of pressure applied to inspiration is gradually decreased.
- Another method of weaning with PSV is to maintain the pressure but gradually decrease the ventilator's preset breaths/min rate.

CPAP, Continuous positive airway pressure; FiO_2 , fraction of inspired oxygen; PSV, pressure support ventilation; SIMV, synchronized intermittent mandatory ventilation.

large amounts of oral secretions to collect. Give oxygen by facemask or nasal cannula. The fraction of inspired oxygen (FiO_2) is usually prescribed at 10% higher than the level used while the ET tube was in place.

Monitor vital signs after extubation every 5 minutes at first, and assess the ventilatory pattern for manifestations of respiratory distress. It is common for patients to be hoarse and have a sore throat for a few days after extubation. Teach the patient to sit in a semi-Fowler's position, take deep breaths every half-hour, use an incentive spirometer every 2 hours, and limit speaking. These measures help gas exchange, decrease laryngeal edema, and reduce vocal cord irritation. Observe closely for respiratory fatigue and airway obstruction.

Early manifestations of obstruction are mild dyspnea, coughing, and the inability to clear secretions. **Stridor** is a high-pitched, crowing noise during inspiration caused by laryngospasm or edema above or below the glottis. This sound is a late manifestation of a narrowed airway and requires prompt attention. Racemic epinephrine, a topical aerosol vasoconstrictor, is given, and reintubation may be needed.

! NURSING SAFETY PRIORITY**Critical Rescue**

When stridor or other manifestations of obstruction occur after extubation, immediately call the Rapid Response Team before the airway becomes completely obstructed.

CHEST TRAUMA

Chest injuries are responsible for about 25% of traumatic deaths in the United States each year. Many of the injured die before arriving at the hospital. A few types of chest injury require thoracotomy. Most can be treated with basic resuscitation, intubation, or chest tube placement. *The first emergency approach to all chest injuries is ABC (airway, breathing, circulation) followed by rapid assessment and treatment of life-threatening conditions.*

Pulmonary Contusion

Pulmonary contusion, a potentially lethal injury, is a common chest injury and occurs most often with injuries caused by rapid deceleration during car crashes. After a contusion, respiratory failure develops over time rather than immediately. Hemorrhage and edema occur in and between the alveoli, reducing both lung movement and the area available for gas exchange. The patient becomes hypoxemic and dyspneic. The bronchial mucosa is irritated, and secretions increase.

Patients may be asymptomatic at first and can later develop respiratory failure. These patients often have bloody sputum, decreased breath sounds, crackles, and wheezes. At first, the chest x-ray may show no abnormalities. A hazy opacity in the lobes or parenchyma may develop over several days. If there is no disruption of the parenchyma, bruise resorption often occurs without treatment.

Management includes maintenance of ventilation and oxygenation. Monitor central venous pressure (CVP) closely, and restrict fluid intake as needed. The patient in obvious respiratory distress may need mechanical ventilation with positive end-expiratory pressure (PEEP) to inflate the lungs.

A vicious cycle occurs in which more muscle effort is needed for ventilating a lung with a contusion and the patient becomes progressively hypoxemic. This situation causes him or her to tire easily, have reduced gas exchange, and become more fatigued and hypoxemic. Flail chest may also occur when pulmonary contusion occurs with parenchymal damage. This condition often leads to acute respiratory distress syndrome (ARDS).

Rib Fracture

Rib fractures are a common injury to the chest wall, often resulting from direct blunt trauma to the chest. The force applied to the ribs fractures them and drives the bone ends into the chest. Thus there is a risk for deep chest injury, such as pulmonary contusion, pneumothorax, and hemothorax.

The patient has pain on movement and splints the chest defensively. Splinting reduces breathing depth and clearance of secretions. If the patient has pre-existing lung disease, the risk for atelectasis and pneumonia increases. Those with injuries to the first or second ribs, flail chest, seven or more fractured ribs, or expired volumes of less than 15 mL/kg often have a deep chest injury and a poor prognosis.

Management of uncomplicated rib fractures is simple because the fractured ribs reunite spontaneously. The chest is usually not splinted by tape or other materials. The main focus is to decrease pain so that adequate ventilation is maintained. An intercostal nerve block may be used if pain is severe. Analgesics that cause respiratory depression are avoided.

Flail Chest

Flail chest is the inward movement of the thorax during inspiration, with outward movement during expiration. It often involves one side of the chest and results from multiple rib fractures caused by blunt chest trauma leaving a segment of the chest wall loose, often as a result of high-speed car crashes. It is more common in older patients and has a high mortality rate (Qasim & Gwinnutt, 2009).

The movement of this loose segment becomes opposite of the expansion and contraction movement of the rest of the chest wall. Flail chest can also occur from bilateral separations of the ribs from their cartilage connections to each other anteriorly, without an actual rib fracture. This condition can occur during cardiopulmonary resuscitation on an older adult. Other injuries to the lung tissue under the flail segment may be present. Gas exchange, coughing, and clearance of secretions are impaired. Splinting further reduces the patient's ability to exert the extra effort to breathe and may contribute later to failure to wean.

Assess the patient with a flail chest for paradoxical chest movement, dyspnea, cyanosis, tachycardia, and hypotension. **Paradoxical chest movement** is the “sucking inward” of the loose chest area during inspiration and a “puffing out” of the same area during expiration (Fig. 34-5). The patient is often anxious, short of breath, and in pain (McCance et al., 2010).

Interventions include humidified oxygen, pain management, promotion of lung expansion through deep breathing and positioning, and secretion clearance by coughing and tracheal aspiration.

The patient with a flail chest may be managed with vigilant respiratory care. Mechanical ventilation is needed if respiratory failure or shock occurs. Monitor ABG values and vital capacity closely. With severe hypoxemia and hypercarbia, the patient is intubated and mechanically ventilated with PEEP. With lung contusion or an underlying pulmonary disease, the

risk for respiratory failure increases. Usually, flail chest is stabilized by positive-pressure ventilation. Surgical stabilization is used only in extreme cases of flail chest.

Monitor the patient's vital signs and fluid and electrolyte balance closely so that hypovolemia or shock can be managed immediately. If he or she has a lung contusion, monitor central venous pressure (CVP) and give IV fluids as prescribed. Assess for and relieve pain with prescribed analgesic drugs by IV, epidural, or nerve block route. Give psychosocial support to the anxious patient by explaining all procedures, talking slowly, and allowing time for expression of feelings and concerns.

Pneumothorax

Any chest injury that allows air to enter the pleural space results in a rise in chest pressure and a reduction in vital capacity. Severity depends on the amount of lung collapse produced. Pneumothorax is often caused by blunt chest trauma and may occur with some degree of hemothorax. It can also occur as a complication of medical procedures (Day, 2011; Ruiz, 2011). The pneumothorax can be open (pleural cavity is exposed to outside air, as through an open wound in the chest wall) or closed (such as when a patient with chronic obstructive pulmonary disease [COPD] has a spontaneous pneumothorax). Assessment findings commonly include:

- Reduced breath sounds on auscultation
- Hyperresonance on percussion
- Prominence of the involved side of the chest, which moves poorly with respirations
- Deviation of the trachea away from (closed) or toward (open) the affected side

In addition, the patient may have pleuritic pain, tachypnea, and **subcutaneous emphysema** (air under the skin in the subcutaneous tissues) (Roman, 2010).

An ultrasound examination or a chest x-ray is used for diagnosis. Chest tubes may be needed to allow the air to escape and the lung to re-inflate.

Tension Pneumothorax

Tension pneumothorax, a rapidly developing and life-threatening complication of blunt chest trauma, results from an air leak in the lung or chest wall. Air forced into the chest cavity causes complete collapse of the affected lung. Air that enters the pleural space during inspiration does not exit during expiration. As a result, air collects under pressure, compressing blood vessels and limiting blood return. This process leads to decreased filling of the heart and reduced cardiac output. *If not promptly detected and treated, tension pneumothorax is quickly fatal.* Causes include blunt chest trauma, mechanical ventilation with positive end-expiratory pressure (PEEP), closed-chest drainage (chest tubes), and insertion of central venous access catheters.

Assessment findings with tension pneumothorax include:

- Asymmetry of the thorax
- Tracheal movement *away* from midline toward the *unaffected* side
- Respiratory distress
- Absence of breath sounds on one side
- Distended neck veins
- Cyanosis
- Hypertympanic sound on percussion over the affected side

FIG. 34-5 Flail chest. Normal respiration: **A**, Inspiration; **B**, Expiration. Paradoxical motion: **C**, Inspiration—area of the lung underlying unstable chest wall sucks in on inspiration; **D**, Expiration—unstable area balloons out. Note movement of mediastinum toward opposite lung during inspiration.

Pneumothorax is detectable on a chest x-ray. ABG assays show hypoxia and respiratory alkalosis.

A large-bore needle is inserted by the health care provider into the second intercostal space in the midclavicular line of the affected side as initial treatment for tension pneumothorax. Then, a chest tube is placed into the fourth intercostal space and the other end is attached to a water seal drainage system until the lung re-inflates. Chest tubes are discussed in detail in [Chapter 32](#).

Hemothorax

Hemothorax is a common problem occurring after blunt chest trauma or penetrating injuries. A *simple* hemothorax is a blood loss of less than 1500 mL into the chest cavity; a *massive* hemothorax is a blood loss of more than 1500 mL.

Bleeding is caused by injury to the lung tissue, such as lung contusions or lacerations, that can occur with rib and sternal fractures. Massive internal bleeding in blunt chest trauma may stem from the heart, great vessels, or the intercostal arteries.

Assessment findings vary with the size of the hemothorax. If it is small, the patient may not have symptoms. With a large hemothorax, the patient may have respiratory distress. In addition, breath sounds are reduced on auscultation. Percussion on the involved side produces a dull sound. Blood in the pleural space is visible on a chest x-ray and confirmed by thoracentesis.

Interventions focus on removing the blood in the pleural space to normalize breathing and to prevent infection. Anterior and posterior chest tubes are inserted to empty the pleural space. Closely monitor the chest tube drainage. Serial chest x-rays are used to determine treatment effectiveness.

An open thoracotomy is needed when there is initial blood loss of 1500 to 2000 mL from the chest or persistent bleeding at the rate of 200 mL/hr over 3 hours. Monitor the vital signs, blood loss, and intake and output. Assess the patient's response to the chest tubes, and infuse IV fluids and blood as prescribed. The blood lost through chest drainage can be infused back into the patient if needed.

Tracheobronchial Trauma

Most tears of the tracheobronchial tree result from severe blunt trauma or rapid deceleration and often involve the mainstem bronchi. Injuries to the trachea usually occur at the junction of the trachea and cricoid cartilage, often by striking the neck against the dashboard or steering wheel during a car crash. Patients with tracheal lacerations develop massive air leaks, which cause air to enter the mediastinum and leads to extensive subcutaneous emphysema. Upper airway obstruction may occur, causing severe respiratory distress and stridor. Large tracheal tears require cricothyroidotomy or tracheotomy below the level of injury. A patient with a torn mainstem bronchus may develop a tension pneumothorax rapidly when intubated and ventilated with positive pressure.

Assess for hypoxemia by ABG assays. Apply oxygen as needed. Depending on the degree of injury, the patient may need mechanical ventilation or surgical repair. Assess vital signs every 15 minutes because hypotension and shock are likely. Assess for subcutaneous emphysema and listen to the lungs every 1 to 2 hours. Decreased breath sounds or wheezing may indicate further obstruction, atelectasis, or pneumothorax. Care of the patient with a tracheostomy is discussed in [Chapter 30](#).

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing inadequate oxygenation and tissue perfusion as a result of an acute critical respiratory problem?

- Respirations rapid and shallow
- Change in cognition, acute confusion (especially in older adults)
- Decreased oxygen saturation by pulse oximetry
- Cyanosis or pallor of the lips and oral mucous membranes
- Tachycardia
- Patient appears to strain to catch breath
- Patient is restless or anxious

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate oxygenation and tissue perfusion as a result of an acute critical respiratory problem?

Perform and interpret physical assessment, including:

- Taking vital signs
- Auscultating all lung fields
- Monitoring oxygen saturation by pulse oximetry
- Checking the accuracy of pulse oximetry readings
- Checking most recent laboratory values for ABG levels

- Assessing chest symmetry
- Assessing for accessory muscle use
- Assessing cognition (Mini-Mental State Examination [MMSE])
- Assessing for the presence of hemoptysis
- Assessing the patient's ability to cough and clear the airway
- Asking the patient if he or she has chest pain
- Checking for petechiae, especially over the chest

Respond by:

- Applying oxygen with a non-rebreather mask, and assessing the patient's responses
- Keeping the patient's head elevated to about 30 degrees
- Suctioning (oral, pharyngeal, endotracheal, tracheostomy), if needed
- Notifying the physician or Rapid Response Team
- Staying with the patient
- Calling for the emergency cart to be brought to the patient's bedside
- Reassuring the patient that appropriate interventions are being instituted
- Preparing for intubation

NURSING CONCEPT REVIEW—cont'd

- Using a manual resuscitation bag if the patient's Sao_2 falls below 60% while receiving oxygen by mask
- Starting an IV

On what should you REFLECT?

- Observe patient for evidence of restored oxygenation (see Chapter 29).
- Think about what may have precipitated this episode and what steps could be taken to either prevent a similar episode or identify it earlier.
- Think about what additional resources could improve the nursing response to this situation.

Safe and Effective Care Environment

- Use aseptic technique when caring for a patient requiring pulmonary suctioning.
- Identify patients in your setting who are at risk for developing a pulmonary embolism.
- Use Bleeding Precautions for patients receiving anticoagulating therapy (see Chart 34-6).
- Keep antidotes available when patients are receiving heparin (antidote is protamine) or warfarin (antidote is phytonadione).
- Inspect the mouth and perform oral care every 2 hours for anyone who has an endotracheal tube or is being mechanically ventilated.
- Check and document ventilator settings hourly.
- Ensure that alarm systems on mechanical ventilators are activated and functional at all times.
- Ensure that bag-valve mask device and suction equipment are at the bedside at all times.
- Evaluate the need for chemical restraint or soft wrist restraints.

Health Promotion and Maintenance

- Teach patients ways to promote venous return and avoid venous thromboembolism (VTE), especially when traveling long distances (see Chart 34-1).
- Use Aspiration Precautions for any patient with an altered level of consciousness, poor gag reflex, or neurologic impairment or who has an endotracheal tube.
- Check the patient with ARDS hourly for oxygen saturation, vital sign changes, or indications of increased work of breathing such as cyanosis, pallor, and retractions.
- Assess all patients with blunt chest trauma for tracheal position and bilateral breath sounds.

Psychosocial Integrity

- Allow the patient and family members the opportunity to express feelings and concerns about a change in breathing status or the possibility of intubation and mechanical ventilation.
- Teach family members ways to communicate with a patient who is intubated or being mechanically ventilated.
- Reassure intubated patients that speech loss is temporary.
- Remember that patients who are receiving mechanical ventilation and are being chemically paralyzed usually can hear and can feel pain.
- Provide appropriate pain management.

Physiological Integrity

- Notify the physician immediately for any patient who develops sudden-onset respiratory difficulty.
- Check oxygen saturation by pulse oximetry for any patient who has trouble breathing or who develops acute confusion.
- Evaluate ABG values to assess the severity of hypoxia and the patient's response to therapy.
- Apply oxygen to anyone who is hypoxemic.
- Ensure that oxygen therapy delivered to the patient is humidified.
- Assess lung sounds bilaterally each hour for patients who are receiving PEEP.
- Check all ventilator settings against the prescription at least once per shift.
- Administer drugs for pain to patients who have rib fractures, and encourage deep breaths.
- Evaluate nutritional status and collaborate with the dietitian to meet the patient's nutritional needs.
- If a patient experiences respiratory distress during mechanical ventilation, remove him or her from the ventilator and provide ventilation by bag-valve mask device.

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Prioritize care for patients having invasive cardiac diagnostic tests.

Health Promotion and Maintenance

2. Identify patients at risk for cardiovascular (CV) problems.
3. Differentiate modifiable and nonmodifiable risk factors for CV disease.
4. Teach patients about ways to decrease their risk for CV health problems.

5. Explain nursing implications related to CV changes associated with aging.

Psychosocial Integrity

6. Explain psychological responses to CV disease.

Physiological Integrity

7. Review the anatomy and physiology of the CV system.
8. Describe the unique characteristics of heart disease in women.

LEARNING OUTCOMES—cont'd

9. Perform focused physical assessment for patients with CV problems.
10. Interpret laboratory test findings for patients with suspected or actual CV disease.
11. Differentiate invasive hemodynamic pressures and their significance.

As the name implies, the cardiovascular (CV) system is made up of the heart and blood vessels (both arteries and veins). It is responsible for supplying oxygen to body organs and other tissues (*perfusion*). The heart muscle, called the **myocardium**, must receive sufficient oxygen to pump blood to other parts of the body. The arteries must be patent so that the pumped blood can reach the rest of the body. *Oxygen in the blood* is needed for cells to live and function properly. When diseases or other problems of the CV systems occur, *oxygenation and perfusion* decrease, often resulting in life-threatening events or a risk for these events.

The CV system works with the respiratory and hematologic systems to meet the human need for oxygenation and tissue perfusion (see Fig. 1 of the Concept Overview). Any problem in these systems requires the CV system to work harder to meet oxygenation and tissue perfusion needs.

In almost every year since 1900, cardiovascular disease (CVD) has been the number-one cause of death in the United States. Nearly 2300 Americans die of CVD each day, an average of one death every 38 seconds (**American Heart Association [AHA], 2010b**). The disease kills more people than the next four causes of death combined, including cancer, chronic lower respiratory diseases, accidents, and diabetes. *Of particular concern is that CVD is the leading cause of death for*

women. In addition, the American Heart Association (AHA) estimates that more than one in three adults is living with some form of the disease. About 20% of people who experience a myocardial infarction will die within 1 year from the initial cardiac event (**AHA, 2010b**).

ANATOMY AND PHYSIOLOGY REVIEW**Heart****Structure**

The human heart is a fist-sized, muscular organ located in the mediastinum between the lungs (**Fig. 35-1**). Each beat of the heart pumps about 60 mL of blood, or 5 L/min. During strenuous physical activity, it can double the amount of blood pumped to meet the body's increased oxygenation needs. The heart is protected by a covering called the *pericardium*. A muscular wall (septum) separates the heart into two halves: right and left. Each half has an atrium and a ventricle (**Fig. 35-2**).

The *right atrium (RA)* receives *deoxygenated* venous blood, which is returned from the body through the superior and inferior venae cavae. It also receives blood from the heart muscle through the coronary sinus. Most of this venous

FIG. 35-1 Surface anatomy of the heart.

FIG. 35-2 Blood flow through the heart.

return flows passively from the RA, through the opened tricuspid valve, and to the right ventricle during ventricular diastole, or filling. The remaining venous return is actively propelled by the RA into the right ventricle during atrial systole, or contraction.

The *right ventricle (RV)* is a muscular pump located behind the sternum. It generates enough pressure to close the tricuspid valve, open the pulmonic valve, and propel blood into the pulmonary artery and the lungs.

After blood is *reoxygenated* in the lungs, it flows freely from the four pulmonary veins into the left atrium. Blood then flows through an opened mitral valve into the left ventricle during ventricular diastole. When the left ventricle is almost full, the *left atrium (LA)* contracts, pumping the remaining blood volume into the left ventricle. With systolic contraction, the *left ventricle (LV)* generates enough pressure to close the mitral valve and open the aortic valve. Blood is propelled into the aorta and into the systemic arterial circulation. Blood flow through the heart is shown in Fig. 35-2.

Blood moves from the aorta throughout the systemic circulation to the various tissues of the body. The pressure of blood in the aorta of a young adult averages about 100 to 120 mm Hg, whereas the pressure of blood in the RA averages about 0 to 5 mm Hg. These differences in pressure produce a pressure gradient, with blood flowing from an area of higher pressure to an area of lower pressure. The heart and

vascular structures are responsible for maintaining these pressures.

The four *cardiac valves* are responsible for maintaining the forward flow of blood through the chambers of the heart (see Fig. 35-2). These valves open and close when pressure and volume change within the heart's chambers. The cardiac valves are classified into two types: atrioventricular (AV) valves and semilunar valves.

The *AV valves* separate the atria from the ventricles. The **tricuspid valve** separates the RA from the RV. The **mitral (bicuspid) valve** separates the LA from the LV. During ventricular diastole, these valves act as funnels and help move the flow of blood from the atria to the ventricles. During systole, the valves close to prevent the backflow (**regurgitation**) of blood into the atria.

The *semilunar valves* are the pulmonic valve and the aortic valve that prevent blood from flowing back into the ventricles during diastole. The **pulmonic valve** separates the right ventricle from the pulmonary artery. The **aortic valve** separates the left ventricle from the aorta.

The heart muscle receives blood to meet its metabolic needs through the coronary arterial system (Fig. 35-3). The coronary arteries originate from an area on the aorta just beyond the aortic valve. All of the coronary arteries feeding the left heart originate from the left main coronary artery (LMCA). The right coronary artery (RCA) branches from the

FIG. 35-3 Coronary arterial system.

aorta to perfuse the right heart and inferior wall of the left heart.

Coronary artery blood flow to the myocardium occurs primarily during diastole, when coronary vascular resistance is minimized. *To maintain adequate blood flow through the coronary arteries, mean arterial pressure (MAP) must be at least 60 mm Hg. A MAP of between 60 and 70 mm Hg is necessary to maintain perfusion of major body organs, such as the kidneys and brain.*

The *left main artery* divides into two branches: the left anterior descending (LAD) branch and the left circumflex (LCX) branch. The LAD branch descends toward the anterior wall and the apex of the left ventricle. It supplies blood to portions of the left ventricle, ventricular septum, chordae tendineae, papillary muscle, and, to a lesser extent, the right ventricle.

The LCX branch descends toward the lateral wall of the left ventricle and apex. It supplies blood to the left atrium, the lateral and posterior surfaces of the left ventricle, and sometimes portions of the interventricular septum. In about half of people, the LCX branch supplies the sinoatrial (SA) node. In a very small number of people, it supplies the AV node. Peripheral branches arise from the LAD and LCX branches and form an abundant network of vessels throughout the entire myocardium.

The *right coronary artery (RCA)* originates from the right sinus of Valsalva, encircles the heart, and descends toward the apex of the right ventricle. The RCA supplies the RA, RV, and inferior portion of the LV. In about half of people, the RCA supplies the SA node, and in almost everyone, it supplies the AV node.

Function

The *electrophysiologic properties* of heart muscle are responsible for regulating heart rate (HR) and rhythm. Cardiac muscle cells possess the characteristics of automaticity, excitability, conductivity, contractility, and refractoriness. [Chapter 36](#) describes these properties and cardiac conduction in detail.

Sequence of Events During the Cardiac Cycle. The phases of the cardiac cycle are generally described in relation to changes in pressure and volume in the left ventricle during filling (diastole) and ventricular contraction (systole) ([Fig. 35-4](#)). **Diastole**, normally about two thirds of the cardiac cycle, consists of relaxation and filling of the atria and ventricles. **Systole** consists of the contraction and emptying of the atria and ventricles.

Myocardial contraction results from the release of large numbers of calcium ions from the sarcoplasmic reticulum and from the blood. These ions diffuse into the **myofibril sarcomere** (the basic contractile unit of the myocardial cell). Calcium ions promote the interaction of actin and myosin protein filaments, causing these filaments to link and overlap. Cross-bridges, or linkages, are formed as the protein filaments slide over or overlap each other. These cross-bridges act as force-generating sites. The sliding of these protein filaments shortens the sarcomeres, producing myocardial contraction.

Cardiac muscle relaxes when calcium ions are pumped back into the sarcoplasmic reticulum, causing a decrease in the number of calcium ions around the myofibrils. This reduced number of ions causes the protein filaments to disengage, the sarcomere to lengthen, and the muscle to relax.

Mechanical Properties of the Heart. The electrical and mechanical properties of cardiac muscle determine the function of the cardiovascular system. The healthy heart can adapt to various pathophysiologic conditions (e.g., stress, infections, hemorrhage) to maintain adequate blood flow to the various body tissues. Blood flow from the heart into the systemic arterial circulation is measured clinically as **cardiac output (CO)**, the amount of blood pumped from the left ventricle each minute. *CO depends on the relationship between heart rate (HR) and stroke volume (SV); it is the product of these two variables:*

$$\text{Cardiac output} = \text{Heart rate} \times \text{Stroke volume}$$

In adults, the CO ranges from 4 to 7 L/min. Because CO requirements vary according to body size, the cardiac index is calculated to adjust for differences in body size. The **cardiac index** can be determined by dividing the CO by the body surface area. The normal range is 2.7 to 3.2 L/min/m² of body surface area.

Heart rate (HR) refers to the number of times the ventricles contract each minute. The normal resting HR for an adult is between 60 and 100 beats/min. Increases in rate increase myocardial oxygen demand. The HR is extrinsically controlled by the autonomic nervous system (ANS), which adjusts rapidly when necessary to regulate cardiac output. *The parasympathetic (vagus nerve) system slows the HR, whereas sympathetic stimulation increases the heart rate.* An increase in circulating catecholamines (e.g., epinephrine and norepinephrine) usually causes an increase in HR and contractility. Many cardiovascular drugs, particularly beta blockers, block this sympathetic (fight or flight) pattern by decreasing the HR.

Stroke volume (SV) is the amount of blood ejected by the left ventricle during each contraction. Several variables influence SV and, ultimately, CO. These variables include HR, preload, afterload, and contractility.

Preload refers to the degree of myocardial fiber stretch at the end of diastole and just before contraction. The stretch

FIG. 35-4 Events of the cardiac cycle.

imposed on the muscle fibers results from the volume contained within the ventricle at the end of diastole. *Preload is determined by the amount of blood returning to the heart from both the venous system (right heart) and the pulmonary system (left heart) (left ventricular end-diastolic [LVED] volume).*

An increase in ventricular volume increases muscle-fiber length and tension, thereby enhancing contraction and improving stroke volume. This statement is derived from Starling's law of the heart: The more the heart is filled during diastole (within limits), the more forcefully it contracts. Excessive filling of the ventricles results in excessive LVED volume and pressure, however, and may result in decreased cardiac output.

Another factor affecting stroke volume, **afterload**, is the pressure or resistance that the ventricles must overcome to eject blood through the semilunar valves and into the peripheral blood vessels. The amount of resistance is directly related to arterial blood pressure and the diameter of the blood vessels.

Impedance, the peripheral component of afterload, is the pressure that the heart must overcome to open the aortic valve. The amount of impedance depends on aortic compliance and total **systemic vascular resistance**, a combination of blood viscosity (thickness) and arteriolar constriction. A

decrease in stroke volume can result from an increase in afterload without the benefit of compensatory mechanisms, thus leading to a decrease in cardiac output.

Myocardial contractility affects stroke volume and CO and is the force of cardiac contraction independent of preload. Contractility is increased by factors such as sympathetic stimulation, calcium release, and positive inotropic drugs. It is decreased by factors such as hypoxia and acidemia.

Vascular System

The vascular system serves several purposes:

- Provides a route for blood to travel from the heart to nourish the various tissues of the body
- Carries cellular wastes to the excretory organs
- Allows lymphatic flow to drain tissue fluid back into the circulation
- Returns blood to the heart for recirculation

The vascular system is divided into the arterial system and the venous system. In the arterial system, blood moves from the larger arteries to a network of smaller blood vessels, called *arterioles*, which meet the capillary bed. In the venous system, blood travels from the capillaries to the venules and to the larger system of veins, eventually returning in the vena cava to the heart for recirculation.

Arterial System

The primary function of the arterial system is to deliver oxygen and nutrients to various tissues in the body. Nutrients are carried through arteries to arterioles, then branch into smaller terminal arterioles and finally join with capillaries and venules to form a capillary network. Within this network, nutrients are exchanged across capillary membranes by three primary processes: osmosis, filtration, and diffusion. (See Chapter 13 for detailed discussions of these processes.)

The arterial system delivers blood to various tissues for oxygen and nourishment. At the tissue level, nutrients, chemicals, and body defense substances are distributed and exchanged for cellular waste products, depending on the needs of the particular tissue. The arteries transport the cellular wastes to the excretory organs (e.g., kidneys and lungs) to be reprocessed or removed. These vessels also contribute to temperature regulation in the tissues. Blood can be either directed toward the skin to promote heat loss or diverted away from the skin to conserve heat.

Blood pressure (BP) is the force of blood exerted against the vessel walls. Pressure in the larger arterial blood vessels is greater (about 80 to 100 mm Hg) and decreases as blood flow reaches the capillaries (about 25 mm Hg). By the time blood enters the right atrium, the BP is about 0 to 5 mm Hg. Volume, ventricular contraction, and vascular tone are necessary to maintain blood pressure.

BP is determined primarily by the quantity of blood flow or cardiac output (CO), as well as by the resistance in the arterioles:

$$\text{Blood pressure} = \text{Cardiac output} \times \text{Peripheral vascular resistance}$$

Any factor that increases CO or total peripheral vascular resistance increases the BP. In general, BP is maintained at a relatively constant level. Therefore an increase or decrease in total peripheral vascular resistance is associated with a decrease or an increase in CO, respectively. Three mechanisms mediate and regulate BP:

- The autonomic nervous system (ANS), which excites or inhibits sympathetic nervous system activity in response to impulses from chemoreceptors and baroreceptors
- The kidneys, which sense a change in blood flow and activate the renin-angiotensin-aldosterone mechanism
- The endocrine system, which releases various hormones (e.g., catecholamine, kinins, serotonin, histamine) to stimulate the sympathetic nervous system at the tissue level

Systolic BP is the amount of pressure/force generated by the left ventricle to distribute blood into the aorta with each contraction of the heart. It is a measure of how effectively the heart pumps and is an indicator of vascular tone. **Diastolic BP** is the amount of pressure/force against the arterial walls during the relaxation phase of the heart.

BP is regulated by balancing the sympathetic and parasympathetic nervous systems of the autonomic nervous system. Changes in autonomic activity are responses to messages sent by the sensory receptors in the various tissues of the body. These receptors, including the baroreceptors, chemoreceptors, and stretch receptors, respond differently to the biochemical and physiologic changes of the body.

Baroreceptors in the arch of the aorta and at the origin of the internal carotid arteries are stimulated when the arterial walls are stretched by an increased BP. Impulses from these baroreceptors inhibit the vasomotor center, which is located in the pons and the medulla. Inhibition of this center results in a drop in BP.

Several 1- to 2-mm collections of tissue have been identified in the carotid arteries and along the aortic arch known as **peripheral chemoreceptors**. These receptors are sensitive primarily to hypoxemia (a decrease in the partial pressure of arterial oxygen [PaO_2]). When stimulated, these chemoreceptors send impulses along the vagus nerves to activate a vasoconstrictor response and raise BP.

The central chemoreceptors in the respiratory center of the brain are also stimulated by **hypercapnia** (an increase in partial pressure of arterial carbon dioxide [PaCO_2]) and acidosis. The direct effect of carbon dioxide on the central nervous system (CNS), however, is 10 times stronger than the effect of hypoxia on the peripheral chemoreceptors.

Stretch receptors in the vena cava and the right atrium are sensitive to pressure or volume changes. When a patient is hypovolemic, stretch receptors in the blood vessels sense a reduced volume or pressure and send fewer impulses to the CNS. This reaction stimulates the sympathetic nervous system to increase the heart rate (HR) and constrict the peripheral blood vessels.

The *kidneys* also help regulate cardiovascular activity. When renal blood flow or pressure decreases, the kidneys retain sodium and water. BP tends to rise because of fluid retention and activation of the renin-angiotensin-aldosterone mechanism (see Fig. 13-6 in Chapter 13). This mechanism results in vasoconstriction and sodium retention (and thus fluid retention). Vascular volume is also regulated by the release of antidiuretic hormone (vasopressin) from the posterior pituitary gland (see Chapter 13).

Other factors can also influence the activity of the cardiovascular system. Emotional behaviors (e.g., excitement, pain, anger) stimulate the sympathetic nervous system to increase blood pressure (BP) and heart rate (HR). Increased physical activity such as exercise also increases BP and HR during the activity. Body temperature can affect the metabolic needs of the tissues, thereby influencing the delivery of blood. In hypothermia, tissues require fewer nutrients and blood pressure falls. In hyperthermia, the metabolic requirement of the tissues is greater and BP and pulse rate rise.

Venous System

The primary function of the venous system is to complete the circulation of blood by returning blood from the capillaries to the right side of the heart. It is composed of a series of veins that are located next to the arterial system. A second superficial venous circulation runs parallel to the subcutaneous tissue of the extremity. These two venous systems are connected by communicating veins that provide a means for blood to travel from the superficial veins to the deep veins. Blood flow is directed toward the deep venous circulation.

Veins have the ability to accommodate large shifts in volume with minimal changes in venous pressure. This flexibility allows the venous system to accommodate the administration of IV fluids and blood transfusions, as well as to

CHART 35-1 NURSING FOCUS ON THE OLDER ADULT

Changes in the Cardiovascular System Related to Aging

CHANGE	NURSING INTERVENTIONS	RATIONALES
Cardiac Valves Calcification and mucoid degeneration occur, especially in mitral and aortic valves.	Assess heart rate and rhythm and heart sounds for murmurs. Question patients about dyspnea.	Murmurs may be detected before other symptoms. Valvular abnormalities may result in rhythm changes.
Conduction System Pacemaker cells decrease in number. Fibrous tissue and fat in the sinoatrial node increase. Few muscle fibers remain in the atrial myocardium and bundle of His. Conduction time increases.	Assess the electrocardiogram (ECG) and heart rhythm for dysrhythmias or a heart rate less than 60 beats/min.	The sinoatrial (SA) node may lose its inherent rhythm. Atrial dysrhythmias occur in many older adults; 80% of older adults experience premature ventricular contractions (PVCs).
Left Ventricle The size of the left ventricle increases. The left ventricle becomes stiff and less distensible. Fibrotic changes in the left ventricle decrease the speed of early diastolic filling by about 50%.	Assess the ECG for a widening QRS complex and a longer QT interval. Assess the heart rate at rest and with activity. Assess for activity intolerance.	Ventricular changes result in decreased stroke volume, ejection fraction, and cardiac output during exercise; the heart is less able to meet increased oxygen demands. Maximum heart rate with exercise is decreased. The heart is less able to meet increased oxygen demands.
Aorta and Other Large Arteries The aorta and other large arteries thicken and become stiffer and less distensible. Systolic blood pressure increases to compensate for the stiff arteries. Systemic vascular resistance increases as a result of less distensible arteries; therefore the left ventricle pumps against greater resistance, contributing to left ventricular hypertrophy.	Assess blood pressure. Note increases in systolic, diastolic, and pulse pressures. Assess for activity intolerance and shortness of breath. Assess the peripheral pulses.	Hypertension may occur and must be treated to avoid target organ damage.
Baroreceptors Baroreceptors become less sensitive.	Assess the patient's blood pressure with the patient lying and then sitting or standing. Assess for dizziness when the patient changes from a lying to a sitting or standing position. Teach the patient to change positions slowly.	Orthostatic (postural) and postprandial changes occur because of ineffective baroreceptors. Changes may include blood pressure decreases of 10 mm Hg or more, dizziness, and fainting.

maintain pressure during blood loss and dehydration. Veins in the superficial and deep venous systems (except the smallest and the largest veins) have valves that direct blood flow back to the heart and prevent backflow. Skeletal muscles in the extremities provide a force that helps push the venous blood forward. The superior vena cava and inferior vena cava are valveless and large enough to allow blood flow to return easily to the heart.

Gravity exerts an increase in **hydrostatic pressure** in the capillaries when the patient is in an upright position, delaying venous return. Hydrostatic pressure is decreased in dependent areas such as the legs when the patient is lying down, and thus there is less hindrance of venous return to the heart.

Cardiovascular Changes Associated with Aging

A number of physiologic changes in the cardiovascular system occur with advancing age (Chart 35-1). Many of these changes result in a loss of cardiac reserve. Thus these changes are usually not evident when the older adult is resting. They

become apparent only when the person is physically or emotionally stressed and the heart cannot meet the increased metabolic demands of the body.

ASSESSMENT METHODS

Patient History

The focus of the patient history is on obtaining information about risk factors and symptoms of cardiovascular disease (Chart 35-2). Assess *nonmodifiable* (uncontrollable) risk factors including the patient's age, gender, ethnic origin, and family history of cardiovascular disease. Ask about any chronic disease or illness that the patient may have. The incidence of conditions such as coronary artery disease (CAD) and valvular disease increases with age. The incidence of CAD also varies with the patient's gender. Men have a higher risk for CAD than women of all ages except in the oldest age-group of 80 years and older (AHA, 2010b).

Heart disease is the leading cause of diabetes-related death for both men and women. Adults with diabetes have heart

CHART 35-2 CARDIOVASCULAR ASSESSMENT

Using Gordon's Functional Health Patterns

Health Perception–Health Management Pattern

- What advice has your health care provider offered you about exercise, diet, or smoking?
- Can you follow that advice?
- What medications (both over-the-counter and prescription) are you supposed to be taking?
- Are you taking them as suggested or prescribed?
- What problems have you had with the medications?

Nutrition–Metabolic Pattern

- What is your usual daily diet? (Analyze the diet for saturated fat, cholesterol, total calorie, and sodium content.)
- How much fluid do you drink daily? Are you thirsty?
- What do you weigh? When did you last weigh yourself?
- How often do you weigh yourself?
- What is your height?
- Do you know your cholesterol level? What is it?
- How often do you feel nauseated or not interested in eating?
- Do your feet/ankles swell during the day? At night, too?

Elimination Pattern

- How often do you urinate in the daytime?
- How often do you wake up at night to urinate?

Activity/Exercise Pattern

- What is the most strenuous exercise you did last week?
- How active are you compared with 6 months ago? 1 year ago?
- How often do you feel fatigued or tired?
- Can you climb a flight of stairs and walk a block without feeling short of breath or experiencing chest pain?
- Do you experience leg cramps when you walk or climb stairs?

Sleep/Rest Pattern

- Where do you sleep? (In bed? In a lounge chair?)
- How many pillows do you sleep on?

- Do you ever wake up at night short of breath?
- What happens when you wake up short of breath?
- Do you ever wake up at night with pain or cramps in your legs? How do you relieve that sensation?

Cognitive/Perceptual Pattern

- How is your memory? What does your family say about your memory?
- How often do you feel dizzy, disoriented, or faint?
- Do you ever have chest discomfort? How often? What precipitates it? What is it like? How do you relieve it? What is its level on a scale of 0 to 10?
- Do you ever have leg or buttock pain? What are its characteristics?
- How do you learn best?

Role/Relationship Pattern

- What is your job?
- What does a day's work entail?
- What are your family responsibilities?
- With whom do you live?
- Who is available to help you?

Sexuality/Reproductive Pattern

- Has your ability to engage in sexual activity changed in the past year? If so, how?
- Do you take any medications that affect your sexual response? If so, what?

Coping/Stress Tolerance Pattern

- What do you think has been happening to you?
- How do you respond to being caught in a traffic jam or meeting a deadline?
- What do you do to relax?
- What do you do when you feel stressed?

Based on Gordon, M. (2011). *Manual of nursing diagnosis* (12th ed.). Boston: Jones & Bartlett.

WOMEN'S HEALTH CONSIDERATIONS

Postmenopausal women are two to three times more likely than premenopausal women to have CAD. The incidence for the disease in women is about 10 years later than in men and 20 years later for myocardial infarction (MI) and death to occur. After an acute MI, women tend to have a higher mortality rate and suffer more complications when compared with men (AHA, 2010b).

Women with waist and abdominal obesity (greater waist-hip ratio) are more likely to experience cardiovascular disease (CVD) than are women with excess fat in their buttocks, hips, and thighs.

disease death rates 2 to 4 times higher than those without diabetes. The risk for stroke is also 2 to 4 times higher among people with diabetes. The number of premature deaths (younger than 65 years) from heart disease is greatest among American Indians and Alaska Natives and lowest among Asians (AHA, 2010b).

Modifiable (controllable) risk factors should also be assessed. *Modifiable* risk factors are personal lifestyle habits, including cigarette use, physical inactivity, obesity, and psychological variables. Ask the patient about each of these common risk factors.

Cigarette smoking is a major risk factor for CVD, specifically coronary artery disease (CAD) and peripheral vascular disease (PVD). Three compounds in cigarette smoke have

been implicated in the development of CAD: tar, nicotine, and carbon monoxide. The smoking history should include the number of cigarettes smoked daily, the duration of the smoking habit, and the age of the patient when smoking started. Record the smoking history in **pack-years**, which is the number of packs per day multiplied by the number of years the patient has smoked.

Ask about the patient's desire to quit, past attempts to quit, and the methods used. Determine nicotine dependence by asking questions such as:

- How soon after you wake up in the morning do you smoke?
- Do you wake up in the middle of your sleep time to smoke?
- Do you find it difficult not to smoke in places where smoking is prohibited?
- Do you smoke when you are ill?

Three to four years after a patient has stopped smoking, his or her CVD risk appears to be similar to that of a person who has never smoked. Be sure to ask those who do not currently smoke whether they have ever smoked and when they quit. Passive smoke significantly reduces blood flow in healthy young adults' coronary arteries, and the risk for dying increases among those who are exposed to secondhand smoke (AHA, 2010a).

A *sedentary lifestyle* is also a major risk factor for heart disease. Regular physical activity promotes cardiovascular fitness and produces beneficial changes in blood pressure and levels of blood lipids and clotting factors. Unfortunately, few people in the United States follow the recommended exercise guidelines: 30 minutes daily of light to moderate exercise, which is equivalent to a 30-minute brisk walk. According to the [American Heart Association \(AHA\) \(2010a\)](#), fewer than two thirds of people in the United States engage in this much exercise five times a week and fewer engage in more vigorous physical activity to promote cardiopulmonary fitness. Encourage increased physical exercise as part of a lifestyle change to reduce the risk for CAD. Ask patients about the type of exercise they perform, how long a period they have participated in the exercise, and the frequency and intensity of the exercise.

About two thirds of American adults are **overweight** when defined as a body mass index (BMI) of 25 to 30. **Obesity**, defined as a BMI greater than 30, is particularly a problem for African-American women, Mexican Americans, and native Hawaiians, but the exact cause of this cultural difference is unknown ([AHA, 2010a](#)). Obesity is also associated with hypertension, hyperlipidemia, and diabetes; all are known contributors to CVD.

The American Heart Association provides guidelines to combat obesity and improve cardiac health, including ingesting more nutrient-rich foods that have vitamins, minerals, fiber, and other nutrients but are low in calories. To get the necessary nutrients, teach patients to choose foods like vegetables, fruits, whole-grain products, and fat-free dairy products most often. Also teach patients to not eat more calories than they can burn every day ([AHA, 2010a](#)).

A variety of *psychological factors* make people more vulnerable to the development of heart disease. Those who are highly competitive, overly concerned about meeting deadlines, and often hostile or angry are at higher risk for heart disease. Psychological stress, anger, depression, and hostility are all closely associated with risk for developing heart disease.

You might ask the patient, “How do you respond when you have to wait for an appointment?” Chronic anger and hostility appear to be closely associated with CVD. The constant arousal of the sympathetic nervous system as a result of anger may influence blood pressure, serum fatty acids and lipids, and clotting mechanisms. Observe the patient, and assess his or her response to stressful situations.

Review the patient’s medical history, noting any major illnesses such as diabetes mellitus, renal disease, anemia, high BP, stroke, bleeding disorders, connective tissue diseases, chronic pulmonary diseases, heart disease, and thrombophlebitis. These conditions can influence the patient’s cardiovascular status.

Ask about previous treatment for CVD, identify previous diagnostic procedures (e.g., electrocardiography [ECG], cardiac catheterization), and request information about any medical or invasive treatment of CVD. Ask specifically about recurrent tonsillitis, streptococcal infections, and rheumatic fever because these conditions may lead to valvular abnormalities of the heart. In addition, inquire about any known congenital heart defects. Many patients with congenital heart problems live into adulthood because of improved treatment and surgeries.

Ask patients about their drug history, beginning with any current or recent use of prescription or over-the-counter (OTC) medications or herbal/natural products. Inquire about known sensitivities to any drug and the nature of the reaction (e.g., nausea, rash). Patients should be asked whether they have recently used cocaine or any IV “street” drugs, because these substances are often associated with heart disease.

Ask women whether they are taking oral contraceptives or an estrogen replacement. The incidence of myocardial infarction (MI) and stroke in women older than 35 years who take oral contraceptives is increased if they smoke, have diabetes, or have hypertension.

The *social history* includes information about the patient’s living situation, including having a domestic partner, other household members, environment, and occupation. Identification of support systems is especially important in exploring the possibility that the patient might have difficulty paying for medications or treatment. People who report an annual household income less than \$30,000 have a greater risk for CVD than people who have an income over \$50,000 (Metcalf et al., 2008; Wright et al., 2009).

Ask about occupation, including the type of work performed and the requirements of the specific job. For instance, does the job involve physical exertion such as lifting heavy objects? Is the job emotionally stressful? What does a day’s work entail? Does the patient’s job require him or her to be outside in extreme weather conditions?

Nutrition History

A nutrition history includes the patient’s recall of food and fluid intake during a 24-hour period, self-imposed or medically prescribed dietary restrictions or supplementations, and the amount and type of alcohol consumption. If needed, the dietitian reviews the type of foods selected by the patient for the amount of sodium, sugar, cholesterol, fiber, and fat. Cultural beliefs and economic status can influence the choice of food items and therefore are seriously considered. Family members or significant others who are responsible for shopping and cooking should be included in this screening.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

The nurse is providing education to help reduce cardiovascular risks for adults at a community health fair. Which statement made by a participant indicates understanding of the health education?

- A. “I can’t do anything about my disease risk because it is in my genes.”
- B. “I will take my blood pressure medication only when I have symptoms.”
- C. “I will start walking on the treadmill each day when I watch my favorite TV show.”
- D. “I don’t need to stop smoking because damage to my blood vessels is irreversible.”

Family History and Genetic Risk

Review the family history, and obtain information about the age, health status, and cause of death of immediate family members. A positive family history for CAD in a first-degree relative (parent, sibling, or child) is a major risk factor. It is *more* important than other factors such as hypertension, obesity, diabetes, or sudden cardiac death ([AHA, 2010b](#)).

GENETIC/GENOMIC CONSIDERATIONS

Cardiovascular disease has many contributory factors, including a genetic tendency. A significant association between familial cardiac history and cardiovascular disease is consistently demonstrated in the evidence of multiple large-scale prospective epidemiology studies (Lloyd-Jones et al., 2009). Although several genes have been reported to be associated with heart disease, stroke, and hypertension, the impact of each individual gene is not fully understood. Numerous genetic association studies are underway to determine more specific genetic variants that may underlie the family history (Lloyd-Jones et al., 2009). Additional discussions about genetic factors related to specific CV diseases are found in other chapters in this unit.

Current Health Problems

Ask the patient to describe his or her health concerns. Expand on the description of these concerns by obtaining information about their onset, duration, sequence, frequency, location, quality, intensity, associated symptoms, and precipitating, aggravating, and relieving factors. Major symptoms usually identified by patients with CVD include chest pain or discomfort, dyspnea, fatigue, palpitations, weight gain, syncope, and extremity pain.

Pain or discomfort, considered a traditional symptom of heart disease, can result from ischemic heart disease, pericarditis, and aortic dissection. Chest pain can also be due to noncardiac conditions such as pleurisy, pulmonary embolus, hiatal hernia, gastroesophageal reflux disease, neuromuscular abnormalities, and anxiety.

! NURSING SAFETY PRIORITY

Action Alert

Thoroughly evaluate the nature and characteristics of the chest pain. Because pain resulting from myocardial ischemia is life threatening and can lead to serious complications, its cause should be considered ischemic (reduced or obstructed blood flow to the myocardium) until proven otherwise. When assessing for symptoms, ask the patient if he or she has “discomfort,” “heaviness,” “pressure,” and “indigestion.”

WOMEN'S HEALTH CONSIDERATIONS

Some patients, especially women, do not experience pain in the chest but instead feel discomfort or indigestion. Women often present with a “triad” of symptoms. In addition to indigestion or feeling of abdominal fullness, chronic fatigue despite adequate rest and feelings of an “inability to catch my breath” are also common in heart disease. The patient may also describe the sensation as aching, choking, strangling, tingling, squeezing, constricting, or viselike. Others with severe neuropathy may experience few or no traditional symptoms except shortness of breath, despite major ischemia.

Ask the patient to identify when the symptoms were first noticed (onset):

- Did the symptoms begin suddenly or develop gradually (manner of onset)?
- How long did the symptoms last (duration)?

If he or she has repeated painful episodes, assess how often the symptoms occur (frequency). If pain is present, ask whether it is different from any other episodes of pain. Ask the patient to describe what activities he or she was doing when it first occurred, such as sleeping, arguing, or running

(precipitating factors). If possible, the patient should point to the area where the chest pain occurred (location) and describe if and how the pain radiated (spread).

In addition, ask how the pain feels and whether it is sharp, dull, or crushing (quality of pain). To understand the severity of the pain, ask the patient to grade it from 1 to 10, with 10 indicating severe pain (intensity). He or she may also report other signs and symptoms that occur at the same time (associated symptoms), such as dyspnea, diaphoresis (excessive sweating), nausea, and vomiting. Other factors that need to be addressed are those that may have made the chest pain worse (aggravating factors) or less intense (relieving factors). Chest pain can arise from a variety of sources (Table 35-1). By obtaining the appropriate information, you can help identify the source of the chest discomfort.

Dyspnea (difficult or labored breathing) can occur as a result of both cardiac and pulmonary disease. It is experienced by the patient as uncomfortable breathing or shortness of breath. When obtaining the history, ask what factors precipitate and relieve dyspnea, what level of activity produces dyspnea, and what the patient's body position was when dyspnea occurred.

*Dyspnea that is associated with activity, such as climbing stairs, is referred to as **dyspnea on exertion (DOE)**. This is usually an early symptom of heart failure and may be the only symptom experienced by women.*

The patient with advanced heart disease may experience **orthopnea** (dyspnea that appears when he or she lies flat). Several pillows may be needed to elevate the head and chest, or a recliner to prevent breathlessness may be used. *The severity of orthopnea is measured by the number of pillows or the amount of head elevation needed to provide restful sleep.* This symptom is usually relieved within a matter of minutes by sitting up or standing.

Paroxysmal nocturnal dyspnea (PND) develops after the patient has been lying down for several hours. In this position, blood from the lower extremities is redistributed to the venous system, which increases venous return to the heart. A diseased heart cannot compensate for the increased volume and is ineffective in pumping the additional fluid into the circulatory system. Pulmonary congestion results. The patient awakens abruptly, often with a feeling of suffocation and panic. He or she sits upright and dangles the legs over the side of the bed to relieve the dyspnea. This sensation may last for 20 minutes.

Fatigue may be described as a feeling of tiredness or weariness resulting from activity. The patient may report that an activity takes longer to complete or that he or she tires easily after activity. Although fatigue in itself is not diagnostic of heart disease, many people with heart failure are limited by leg fatigue during exercise. Fatigue that occurs after mild activity and exertion usually indicates inadequate cardiac output (due to low stroke volume) and anaerobic metabolism in skeletal muscle. *It can also accompany other symptoms or may be an early indication of heart disease in women.*

Ask about the time of day the patient experiences fatigue and the activities that he or she can perform. Fatigue resulting from decreased cardiac output is often worse in the evening. Ask whether the patient can perform the same activities as he or she could perform a year ago or the same activities as others of the same age. Often he or she limits activities in response to fatigue and, unless questioned, is unaware how much less active he or she has become.

TABLE 35-1 ASSESSMENT OF CHEST DISCOMFORT: HOW VARIOUS TYPES OF CHEST PAIN DIFFER

ONSET	QUALITY AND SEVERITY	LOCATION AND RADIATION	DURATION AND RELIEVING FACTORS
Angina			
Sudden, usually in response to exertion, emotion, or extremes in temperature	Squeezing, viselike pain	Substernal; may spread across the chest and the back and/or down the arms	Usually the left side of chest without radiation Usually lasts less than 15 min; relieved with rest, nitrate administration, or oxygen therapy
Myocardial Infarction			
Sudden, without precipitating factors, often in early morning	Intense stabbing, viselike pain or pressure, severe	Substernal; may spread throughout the anterior chest and to the arms, jaw, back, or neck	Continuous or no chest discomfort; relieved with morphine, cardiac drugs, and oxygen therapy
Pericarditis			
Sudden	Sharp, stabbing, moderate to severe	Substernal; usually spreads to the left side or the back	Intermittent; relieved with sitting upright, analgesia, or administration of anti-inflammatory agents
Pleuropulmonary			
Variable	Moderate ache, worse on inspiration	Lung fields	Continuous until the underlying condition is treated or the patient has rested
Esophageal-Gastric			
Variable	Squeezing, heartburn, variable severity	Substernal; may spread to the shoulders or the abdomen	Variable; may be relieved with antacid administration, food intake, or taking a sitting position
Anxiety			
Variable, may be in response to stress or fatigue	Dull ache to sharp stabbing; may be associated with numbness in fingers	Not well located and usually does not radiate to other parts of the body as pain	Usually lasts a few minutes

A feeling of fluttering or unpleasant feeling in the chest caused by an irregular heartbeat is referred to as **palpitations**. They may result from a change in heart rate or rhythm or from an increase in the force of heart contractions. Rhythm disturbances that may cause palpitations include paroxysmal supraventricular tachycardia, premature contractions, and sinus tachycardia. Those that occur during or after strenuous physical activity, such as running and swimming, may indicate overexertion or possibly heart disease. Noncardiac factors that may precipitate palpitations include anxiety, stress, fatigue, insomnia, hyperthyroidism, and the ingestion of caffeine, nicotine, or alcohol. Ask the patient about specific factors that cause his or her palpitations.

A sudden weight increase of 2.2 pounds (1 kg) can result from excess fluid (1 L) in the interstitial spaces. The best indicator of fluid balance is weight. Excess fluid accumulation is commonly known as **edema**. It is possible for weight gains of up to 10 to 15 pounds (4.5 to 6.8 kg, or 4 to 7 L of fluid) to occur before edema is apparent. Ask whether the patient has noticed a tightness of shoes, indentations from socks, or tightness of rings.

Syncope refers to a brief loss of consciousness. The most common cause is decreased perfusion to the brain. Any condition that suddenly reduces cardiac output, resulting in decreased cerebral blood flow, can lead to a syncopal episode. Conditions such as cardiac rhythm disturbances, especially ventricular dysrhythmias, and valvular disorders, such as aortic stenosis, may trigger this symptom. **Near-syncope** refers to dizziness with an inability to remain in an upright position. Explore the circumstances that lead to dizziness or syncope.

CONSIDERATIONS FOR OLDER ADULTS

Syncope in the aging person may result from hypersensitivity of the carotid sinus bodies in the carotid arteries. Pressure applied to these arteries while turning the head, shrugging the shoulders, or performing a Valsalva maneuver (bearing down during defecation) may stimulate a vagal response. A decrease in blood pressure and heart rate can result, which can produce syncope. This type of syncopal episode may also result from postural (orthostatic) or postprandial (after eating) hypotension.

Extremity pain may be caused by two conditions: ischemia from atherosclerosis and venous insufficiency of the peripheral blood vessels. Patients who report a moderate to severe cramping sensation in their legs or buttocks associated with an activity such as walking have **intermittent claudication** related to decreased arterial tissue perfusion. *Claudication pain is usually relieved by resting or lowering the affected extremity to decrease tissue demands or to enhance arterial blood flow.* Leg pain that results from prolonged standing or sitting is related to venous insufficiency from either incompetent valves or venous obstruction. This pain may be relieved by elevating the extremity.

Functional History

After the history of the patient's cardiovascular status is obtained, he or she may be classified according to the New York Heart Association Functional Classification (Table 35-2) or other system. The four classifications (I, II, III, and IV) depend on the degree to which ordinary physical activities (routine ADLs) are affected by heart disease. The Killip Classification provides a more objective description of the hemodynamics of heart failure and is described in Chapter 40.

TABLE 35-2 NEW YORK HEART ASSOCIATION FUNCTIONAL CLASSIFICATION OF CARDIOVASCULAR DISABILITY

Class I

- Patients with cardiac disease but without resulting limitations of physical activity
- Ordinary physical activity does not cause undue fatigue, palpitation, dyspnea, or anginal pain

Class II

- Patients with cardiac disease resulting in slight limitation of physical activity
- They are comfortable at rest
- Ordinary physical activity results in fatigue, palpitation, dyspnea, or anginal pain

Class III

- Patients with cardiac disease resulting in marked limitation of physical activity
- They are comfortable at rest
- Less than ordinary physical activity causes fatigue, palpitation, dyspnea, or anginal pain

Class IV

- Patients with cardiac disease resulting in inability to carry on any physical activity without discomfort
- Symptoms of cardiac insufficiency or of the anginal syndrome may be present, even at rest
- If any physical activity is undertaken, discomfort is increased

Excerpted from *The New York Heart Association. (1964). Diseases of the heart and blood vessels: Nomenclature and criteria for diagnosis* (6th ed.). Boston: Little, Brown.

Physical Assessment

A thorough physical assessment is the foundation for the nursing database and the patient's priority problems. Any changes noted during the course of illness can be compared with this initial database. Evaluate the patient's vital signs on admission to the hospital or during the initial visit to the clinic or health care provider's office.

General Appearance

Physical assessment begins with the patient's general appearance. Assess general build and appearance, skin color, distress level, level of consciousness, shortness of breath, position, and verbal responses.

Patients can have left- or right-sided heart failure, or both. They can also be diagnosed with systolic and/or diastolic heart failure. *As a result, poor cardiac output and decreased cerebral perfusion may cause confusion, memory loss, and slowed verbal responses, especially in older adults.* Patients with chronic heart failure may also appear malnourished, thin, and cachectic. Late signs of severe right-sided heart failure are ascites, jaundice, and **anasarca** (generalized edema) as a result of prolonged congestion of the liver. Heart failure may also cause fluid retention and may be manifested by obvious generalized dependent edema. **Chapter 37** differentiates right and left failure and systolic from diastolic heart failure in detail.

Skin

Skin assessment includes color and temperature. The best areas in which to assess circulation include the nail beds, mucous membranes, and conjunctival mucosa, because small

blood vessels are located near the surface of the skin in those areas.

If there is normal blood flow or adequate perfusion to a given area in *light-colored skin*, it appears pink, perhaps rosy, and is warm. *Decreased perfusion is manifested as cool, pale, and moist skin. Pallor is characteristic of anemia and can be seen in areas such as the nail beds, palms, and conjunctival mucous membranes in any patient.*

A bluish or darkened discoloration of the skin and mucous membranes in *light-skinned* people is referred to as **cyanosis**. This condition results from an increased amount of deoxygenated hemoglobin. It is not an early sign of decreased perfusion but occurs later with other symptoms. *Dark-skinned patients may experience cyanosis as a graying of the same tissues.*

Central cyanosis involves decreased oxygenation of the arterial blood in the lungs and appears as a bluish tinge of the conjunctivae and the mucous membranes of the mouth and tongue. Central cyanosis may indicate impaired lung function or a right-to-left shunt found in congenital heart conditions. Because of impaired circulation, there is marked desaturation of hemoglobin in the peripheral tissues, which produces a bluish or darkened discoloration of the nail beds, earlobes, lips, and toes.

Peripheral cyanosis occurs when blood flow to the peripheral vessels is decreased by peripheral vasoconstriction. Constriction results from a low cardiac output or an increased extraction of oxygen from the peripheral tissues. Peripheral cyanosis localized in an extremity is usually a result of arterial or venous insufficiency. **Rubor** (dusky redness) that replaces pallor in a dependent foot suggests arterial insufficiency.

Skin temperature can be assessed for symmetry by touching different areas of the body with the dorsal (back) surface of the hand or fingers. Decreased blood flow results in decreased skin temperature. It is lowered in several clinical conditions, including heart failure, peripheral vascular disease, and shock.

Extremities

Assess the patient's hands, arms, feet, and legs for skin changes, vascular changes, clubbing, and edema. Skin mobility and turgor are affected by fluid status. Dehydration and aging reduce skin turgor, and edema decreases skin elasticity. Vascular changes in an affected extremity may include paresthesia, muscle fatigue and discomfort, numbness, pain, coolness, and loss of hair distribution from a reduced blood supply.

Clubbing of the fingers and toes is caused by *chronic* oxygen deprivation in body tissues. It is common in patients with advanced chronic pulmonary disease, congenital heart defects, and cor pulmonale (right-sided heart failure). The angle of the normal nail bed is 160 degrees. With **clubbing**, the nail straightens out to an angle of 180 degrees and the base of the nail becomes spongy. **Fig. 35-5** describes assessment of clubbing. **Fig. 32-12** in **Chapter 32** shows late clubbing.

Peripheral edema is a common finding in patients with cardiovascular problems. The location of edema helps determine its potential cause. Bilateral edema of the legs may be seen in those with heart failure or chronic venous insufficiency. Abdominal and leg edema can be seen in patients with heart disease and cirrhosis of the liver. Localized edema in one extremity may be the result of venous obstruction

FIG. 35-5 Assessment of clubbing. The patient places the fingernails of the ring fingers together and holds them up to a light. If the examiner can see a diamond shape between the nails, there is no clubbing. Clubbing is identified by the absence of the diamond shape.

(thrombosis) or lymphatic blockage of the extremity (lymphedema). Edema may also be noted in dependent areas, such as the sacrum, when a patient is confined to bed. In other patients, edema results from third spacing when plasma proteins decrease. Dependent foot and ankle edema is also a common side effect of certain antihypertensive drugs, such as amlodipine (Norvasc).

Document the location of edema as precisely as possible (e.g., midtibial or sacral) and the number of centimeters from an anatomic landmark. The extent of edema can be assessed as mild, moderate, or severe (or 1+, 2+, 3+, or 4+). However, these values are not precise and are very unreliable. Determine whether the edema is **pitting** (the skin can be indented) or nonpitting.

Blood Pressure

Arterial blood pressure is measured *indirectly* by sphygmomanometry. This technique of measurement is described in detail in nursing skills textbooks.

The **National High Blood Pressure Education Program Joint National Committee (JNC) on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (2003)** defines **hypertension** as a systolic pressure of 140 mm Hg or higher or a diastolic pressure of 90 mm Hg or higher, or taking drugs to control blood pressure. A blood pressure that exceeds 135/85 mm Hg increases the workload of the left ventricle and oxygen consumption of the myocardium. About one of every five Americans has hypertension (**AHA, 2010b**). **Chapter 38** describes hypertension in detail.

A BP less than 90/60 mm Hg (hypotension) may not be adequate for providing enough oxygen and sufficient nutrition to body cells. In certain circumstances, such as shock, the Korotkoff sounds are less audible or are absent. In these cases, palpate the BP, use an ultrasonic device (Doppler device), or obtain a direct measurement by arterial catheter in the critical care setting. When BP is palpated, only the systolic pressure can be determined. More information on *direct* measurement of arterial pressure is available in the Hemodynamic Monitoring section on p. 708.

Patients may report dizziness or light-headedness when they move from a flat, supine position to a sitting or a standing position at the edge of the bed. Normally these symptoms

are transient and pass quickly; pronounced symptoms may be due to postural hypotension. **Postural (orthostatic) hypotension** occurs when the BP is not adequately maintained while moving from a lying to a sitting or standing position. It is defined as a decrease of more than 20 mm Hg of the systolic pressure or more than 10 mm Hg of the diastolic pressure, as well as a 10% to 20% increase in heart rate. The causes of postural hypotension include cardiovascular drugs, blood volume decrease, prolonged bedrest, age-related changes, or disorders of the ANS.

To detect orthostatic changes in BP, first measure the BP when the patient is supine. After remaining supine for at least 3 minutes, the patient changes position to sitting or standing. Normally systolic pressure drops slightly or remains unchanged as the patient rises, whereas diastolic pressure rises slightly. After the position change, wait for at least 1 minute before auscultating BP and counting the radial pulse. The cuff should remain in the proper position on the patient's arm. Observe and record any signs or symptoms of dizziness. If the patient cannot tolerate the position change, return him or her to the previous position of comfort.

Paradoxical blood pressure is an exaggerated decrease in systolic pressure by more than 10 mm Hg during the inspiratory phase of the respiratory cycle (normal is 3 to 10 mm Hg). Certain clinical conditions that potentially alter the filling pressures in the right and left ventricles may produce a paradoxical BP. Such conditions include pericardial tamponade, constrictive pericarditis, and pulmonary hypertension. During inspiration, the filling pressures normally decrease slightly. However, decreased fluid volume in the ventricles resulting from these pathologic conditions produces a marked reduction in cardiac output. The procedure for assessing a paradoxical BP is found in **Chart 37-9** in **Chapter 37**.

The difference between the systolic and diastolic values is referred to as **pulse pressure**. This value can be used as an indirect measure of cardiac output. Narrowed pulse pressure is rarely normal and results from increased peripheral vascular resistance or decreased stroke volume in patients with heart failure, hypovolemia, or shock. It can also be seen in those with mitral stenosis or regurgitation. An increased pulse pressure may occur in patients with slow heart rates, aortic regurgitation, atherosclerosis, hypertension, and aging.

The **ankle-brachial index (ABI)** can be used to assess the vascular status of the lower extremities. A BP cuff is applied to the lower extremity just above the malleolus. The systolic pressure is measured by Doppler ultrasound at both the dorsalis pedis and posterior tibial pulses. The higher of these two pressures is then divided by the higher of the two brachial pulses to obtain the ABI.

Normal values for the ABI are 1.00 or higher because BP in the legs is usually higher than BP in the arms. ABI values less than 0.80 usually indicate moderate vascular disease, whereas values less than 0.50 indicate severe vascular compromise. Although used primarily to help identify peripheral vascular disease, the ABI may be effective as a risk factor in predicting other CV disease in women, especially coronary artery disease (Pearson, 2010).

A **toe brachial pressure index (TBPI)** may be performed instead of or in addition to the ABI to determine arterial perfusion in the feet and toes. TBPI is the toe systolic pressure divided by the brachial (arm) systolic pressure.

Venous and Arterial Pulses

Observe the *venous pulsations* in the neck to assess the adequacy of blood volume and central venous pressure (CVP). Specially educated or critical care nurses can assess jugular venous pressure (JVP) to estimate the filling volume and pressure on the right side of the heart. An increase in JVP causes **jugular venous distention (JVD)**.

Normally the JVP is 3 to 10 cm H₂O. Increases are usually caused by right ventricular failure. Other causes include tricuspid regurgitation or stenosis, pulmonary hypertension, cardiac tamponade, constrictive pericarditis, hypervolemia, and superior vena cava obstruction.

Assessment of *arterial pulses* provides information about vascular integrity and circulation. For patients with suspected or actual vascular disease, all major peripheral pulses should be assessed for presence or absence, amplitude, contour, rhythm, rate, and equality. Palpate the peripheral arteries in a head-to-toe approach with a side-to-side comparison (Fig. 35-6).

A **hypokinetic** pulse is a weak pulse indicative of a narrow pulse pressure. It is seen in patients with hypovolemia, aortic stenosis, and decreased cardiac output. A **hyperkinetic** pulse is a large, “bounding” pulse caused by an increased ejection of blood. It occurs in patients with a high cardiac output (with exercise, sepsis, or thyrotoxicosis) and in those with increased sympathetic system activity (with pain, fever, or anxiety).

Auscultation of the major arteries (e.g., carotid and aorta) is necessary to assess for bruits. **Bruits** are swishing sounds that may occur from turbulent blood flow in narrowed or atherosclerotic arteries. Assess for the absence or presence of bruits by placing the bell of the stethoscope on the neck over the carotid artery while the patient holds his or her breath. Normally there are no sounds if the artery has uninterrupted blood flow. A bruit may develop when the internal diameter of the vessel is narrowed by 50% or more, but this does not indicate the severity of disease in the arteries. Once the vessel is blocked 90% or greater, the bruit often cannot be heard.

Precordium

Assessment of the precordium (the area over the heart) involves inspection, palpation, percussion, and auscultation. In most settings, the medical-surgical nurse seldom performs

FIG. 35-6 Pulse points for assessment of arterial pulses.

precordial palpation and percussion. Critical care nurses and advanced practice nurses are qualified to perform the complete assessment. Therefore only inspection and auscultation are described here. Begin by placing the patient in a supine position, with the head of the bed slightly elevated for comfort. Some patients may require elevation of the head of the bed to 45 degrees for ease and comfort in breathing.

Inspection. A cardiac examination is usually performed in a systematic order, beginning with inspection. Inspect the chest from the side, at a right angle, and downward over areas of the precordium where vibrations are visible. Cardiac motion is of low amplitude, and sometimes the inward movements are more easily detected by the naked eye.

Examine the entire precordium (Fig. 35-7), and note any prominent pulses. Movement over the aortic, pulmonic, and tricuspid areas is abnormal. Pulses in the mitral area (the apex of the heart) are considered normal and are referred to as the **apical impulse**, or the **point of maximal impulse (PMI)**. The PMI should be located at the left fifth intercostal space (ICS) in the midclavicular line. If it appears in more than one ICS and has shifted lateral to the midclavicular line, the patient may have left ventricular hypertrophy.

Auscultation. Auscultation evaluates heart rate and rhythm, cardiac cycle (systole and diastole), and valvular function. The technique of auscultation requires a good-quality stethoscope and extensive clinical practice. Identifying specific abnormal heart sounds is most important in critical care beds and telemetry. Some hospitals are equipped with monitored beds in every unit, but telemetry is used only when needed.

Listen to heart sounds in a systematic order. Examination usually begins at the aortic area and progresses slowly to the

FIG. 35-7 Areas for myocardial inspection and auscultation.

apex of the heart. The diaphragm of the stethoscope is pressed tightly against the chest to listen for high-frequency sounds and is useful in listening to the first and second heart sounds and high-frequency murmurs. Repeat the progression from the base to the apex of the heart using the bell of the stethoscope, which is held lightly against the chest. The bell can screen out high-frequency sounds and is useful in listening for low-frequency gallops (diastolic filling sounds) and murmurs.

Normal Heart Sounds. The **first heart sound (S_1)** is created by the closure of the mitral and tricuspid valves (atrioventricular valves) (see Fig. 35-4). When auscultated, S_1 is softer and longer; it is of a low pitch and is best heard at the lower left sternal border or the apex of the heart. It may be identified by palpating the carotid pulse while listening. S_1 marks the beginning of ventricular systole and occurs right after the QRS complex on the ECG.

S_1 can be accentuated or intensified in conditions such as exercise, hyperthyroidism, and mitral stenosis. A decrease in sound intensity occurs in patients with mitral regurgitation and heart failure. If you have difficulty hearing heart sounds, have the patient lean forward or roll to his or her left side.

The **second heart sound (S_2)** is caused mainly by the closing of the aortic and pulmonic valves (semilunar valves) (see Fig. 35-4). S_2 is characteristically shorter. It is higher pitched and is heard best at the base of the heart at the end of ventricular systole.

The splitting of heart sounds is often difficult to differentiate from diastolic filling sounds (gallops). A splitting of S_1 (closure of the mitral valve followed by closure of the tricuspid valve) occurs physiologically because left ventricular contraction occurs slightly before right ventricular contraction. Closure of the mitral valve is louder than closure of the tricuspid valve, however, so splitting is often not heard. Normal splitting of S_2 occurs because of the longer systolic phase of the right ventricle. Splitting of S_1 and S_2 can be accentuated by inspiration (increased venous return), and it narrows during expiration.

Abnormal Heart Sounds. Abnormal splitting of S_2 is referred to as **paradoxical splitting** and has a wider split heard on expiration. Paradoxical splitting of S_2 is heard in

patients with severe myocardial depression that causes early closure of the pulmonic valve or a delay in aortic valve closure. Such conditions include myocardial infarction (MI), left bundle-branch block, aortic stenosis, aortic regurgitation, and right ventricular pacing.

Gallops and murmurs are common abnormal heart sounds that may occur with heart disease, but they can occur in some healthy people. Diastolic filling sounds (S_3 and S_4) are produced when blood enters a noncompliant chamber during rapid ventricular filling. The third heart sound (S_3) is produced during the rapid passive filling phase of ventricular diastole when blood flows from the atrium to a noncompliant ventricle. The sound arises from vibrations of the valves and supporting structures. The fourth heart sound (S_4) occurs as blood enters the ventricles during the active filling phase at the end of ventricular diastole.

S_3 is called a **ventricular gallop**, and S_4 is referred to as **atrial gallop**. These sounds can be caused by decreased compliance of either or both ventricles. Left ventricular diastolic filling sounds are best heard with the patient on his or her left side. The bell of the stethoscope is placed at the apex and at the left lower sternal border during expiration.

An S_3 heart sound is most likely to be a normal finding in those younger than 30 years. An S_3 gallop in patients older than 35 years is considered abnormal and represents a decrease in left ventricular compliance. It can be detected as an early sign of heart failure or as a ventricular septal defect.

An atrial gallop (S_4) may be heard in patients with hypertension, anemia, ventricular hypertrophy, MI, aortic or pulmonic stenosis, and pulmonary emboli. *It may be heard also with advancing age because of a stiffened ventricle.*

The presence of both S_3 and S_4 , called a **summation** or a **quadruple gallop**, is an indication of severe heart failure. If the quadruple rhythm is present and the patient has tachycardia, the two sounds may fuse to produce a rhythm that sounds like a horse galloping.

Murmurs reflect turbulent blood flow through normal or abnormal valves. They are classified according to their timing in the cardiac cycle: **systolic** murmurs (e.g., aortic stenosis and mitral regurgitation) occur between S_1 and S_2 , whereas **diastolic** murmurs (e.g., mitral stenosis and aortic regurgitation)

TABLE 35-3 GRADING OF HEART MURMURS

Grade I	Very faint
Grade II	Faint but recognizable
Grade III	Loud but moderate in intensity
Grade IV	Loud and accompanied by a palpable thrill
Grade V	Very loud, accompanied by a palpable thrill, and audible with the stethoscope partially off the patient's chest
Grade VI	Extremely loud, may be heard with the stethoscope slightly above the patient's chest, accompanied by a palpable thrill

occur between S_2 and S_1 . Murmurs can occur during presystole, midsystole, or late systole or diastole or can last throughout both phases of the cardiac cycle. They are also graded according to their intensity, depending on their level of loudness (Table 35-3).

Although you are not expected to grade murmurs as a medical-surgical nurse, describe their location based on where they are best heard. Some murmurs transmit or radiate from their loudest point to other areas, including the neck, the back, and the axilla. The configuration is described as *crescendo* (increases in intensity) or *decrescendo* (decreases in intensity). The quality of murmurs can be further characterized as harsh, blowing, whistling, rumbling, or squeaking. They are also described by pitch—usually *high* or *low*.

A **pericardial friction rub** originates from the pericardial sac and occurs with the movements of the heart during the cardiac cycle. Rubs are usually transient and are a sign of inflammation, infection, or infiltration. They may be heard in patients with pericarditis resulting from MI, cardiac tamponade, or post-thoracotomy.

Psychosocial Assessment

To most people, the heart is a symbol of their ability to exist, survive, and love. A patient with a heart-related illness, whether acute or chronic, usually perceives it as a major life crisis. The patient and family confront not only the possibility of death but also fears about pain, disability, lack of self-esteem, physical dependence, and changes in family dynamics. Assess the meaning of the illness to the patient and family by asking “What do you understand about what happened to you (or the patient)?” and “What does that mean to you?” When they perceive the stressor as overwhelming, formerly adequate support systems may no longer be effective. In these circumstances, the patient and family members attempt to cope to regain a sense or feeling of control.

Coping behaviors vary among patients and their families. Those who feel helpless to meet the demands of the situation may exhibit behaviors such as disorganization, fear, and anxiety. Ask them, “Have you ever encountered such a situation before?” “How did you manage that situation?” and “To whom can you turn for help?” The answers to these questions often reassure the patient and family that they have encountered difficult situations in the past and have the ability and resources to cope with them.

A common and normal response is denial, which is a defense mechanism that enables the patient to cope with threatening circumstances. He or she may deny the current cardiovascular

condition, may state that it was present but is now absent, or may be excessively cheerful. Denial becomes maladaptive when the patient is noncompliant or does not adhere to the interdisciplinary plan of care.

Family members and significant others may be more anxious than the patient. Often they recall all events of the illness, are unprotected by denial, and are afraid of recurrence. Disagreements may occur between the patient and family members over adherence to appropriate follow-up care.

DECISION-MAKING CHALLENGE

Safety; Teamwork and Collaboration

An older adult patient is admitted to the telemetry unit after falling at home. She states she fell after getting up from her recliner in the late afternoon. The patient is alert and oriented; BP = 96/55 and HR = 88. You are the RN assigned to her care. There is an unlicensed nursing technician working with you.

1. What assessment data will you perform upon her arrival to the unit? Why?
2. What could be the cause of this patient's fall? Think of all the possibilities.
3. The internist orders IV fluids, orthostatic pressure checks, and oxygen at 2 liters per nasal cannula. What part of the patient's care will you delegate to the unlicensed nursing technician? What information will you communicate upon delegation?
4. What interventions will you implement to ensure this patient's safety?
5. The patient's daughter is at the bedside and expresses concerns about her mother's safety upon discharge. What education will you provide the patient and her daughter at this time? With what health care team members will you collaborate to ensure positive patient outcomes?

Diagnostic Assessment

Laboratory Assessment

Assessment of the patient with cardiovascular dysfunction includes examination of the blood for abnormalities. The examination is performed to help establish a diagnosis, detect concurrent disease, assess risk factors, and monitor response to treatment. Normal values for serum cardiac enzymes and serum lipids are listed in Chart 35-3.

Serum Markers of Myocardial Damage. Events leading to cellular injury cause a release of enzymes from intracellular storage, and circulating levels of these enzymes are dramatically elevated. Acute myocardial infarction (MI), also known as **acute coronary syndrome**, can be confirmed by abnormally high levels of certain proteins or isoenzymes. These serum studies are commonly referred to as **cardiac markers** and include troponin, creatine kinase-MB, and myoglobin.

Troponin is a myocardial muscle protein released into the bloodstream with injury to myocardial muscle. Troponins T and I are not found in healthy patients, so any rise in values indicates cardiac necrosis or acute MI. Specific markers of myocardial injury, troponins T and I, have a wide diagnostic time frame, making them useful for patients who present several hours after the onset of chest pain. Even low levels of troponin T are treated aggressively because of increased risk for death from cardiovascular disease (CVD). Obtaining cardiac markers at the bedside in the emergency department can be done as “point of care” (POC) testing for patients

CHART 35-3 LABORATORY PROFILE

Cardiovascular Assessment

NORMAL RANGE	SIGNIFICANCE OF ABNORMAL FINDINGS
Serum Cardiac Enzymes	
Creatine kinase (CK) Females: 30-135 units/L Males: 55-170 units/L Values higher after exercise	Elevations indicate possible brain, myocardial, and skeletal muscle necrosis or injury.
CK-MB (CK ₂) 0% of total CK	Elevations occur with myocardial injury or after percutaneous transluminal angioplasty and intracoronary streptokinase infusion.
Serum Lipids	
Total lipids 400-1000 mg/dL	Elevation indicates increased risk for coronary artery disease (CAD).
Cholesterol 122-200 mg/dL, or 3.16-6.5 mmol/L Older adult (>70 yr): 144-280 mg/dL	Elevation indicates increased risk for CAD.
Triglycerides Females: 35-135 mg/dL Males: 40-160 mg/dL Older adult (>65 yr): 55-260 mg/dL	Elevation indicates increased risk for CAD.
Plasma high-density lipoproteins (HDLs) Females: >55 mg/dL Males: >45 mg/dL Older adult: range increases with age	Elevations protect against CAD.
Plasma low-density lipoproteins (LDLs) 60-180 mg/dL Older adult (>65 yr): 92-221 mg/dL	Elevation indicates increased risk for CAD.
HDL:LDL ratio 3:1	Elevated ratios may protect against CAD.
VLDL 25%-50%	Elevated level indicates risk for CAD.
C-reactive protein (CRP) <1.0 mg/dL	Elevation may indicate tissue infarction or damage.
Serum Markers	
Troponins Cardiac troponin T <0.20 ng/mL Cardiac troponin I <0.03 ng/mL	Elevations indicate myocardial injury or infarction.
Myoglobin <90 mcg/L	Elevation indicates myocardial infarction.

VLDL, Very-low-density lipoproteins.

experiencing or at risk for acute MI, with results available within 15 to 20 minutes. These markers are evaluated in addition to clinical signs and symptoms and ECG changes when identifying at-risk patients.

Creatine kinase (CK) is an enzyme specific to cells of the brain, myocardium, and skeletal muscle. The appearance of CK in the blood indicates tissue necrosis or injury, with levels following a predictable rise and fall during a specified period. Cardiac specificity must be determined by measuring

isoenzyme activity. There are three isoenzymes of CK: CK-MM is the predominant isoenzyme of skeletal muscle; CK-MB is found in myocardial muscle; and CK-BB occurs in the brain. CK-MB activity is most specific for MI and shows a predictable rise and fall during 3 days; a peak level occurs about 24 hours after the onset of chest pain.

Treatment modalities for early intervention after acute MI and acute ischemia require more rapid diagnosis of MI. An assay using monoclonal anti-CK-MB antibodies (stat CK) can detect myocardial necrosis accurately 3 hours after emergency department admission when examined with an ECG. Two subforms of CK-MB (CK-MB₁ and CK-MB₂) have also been identified. Abnormal elevations of these CK subforms may occur as early as 2 hours after MI. They remain elevated for up to 12 hours after MI and appear to be very sensitive and specific early diagnostic markers of MI.

Another early marker of an MI is myoglobin. **Myoglobin**, a low-molecular-weight heme protein found in cardiac and skeletal muscle, is the earliest marker detected—as early as 2 hours after an MI with rapid decline after 7 hours. Because myoglobin is not cardiac specific and is found in skeletal and cardiac muscle, its clinical usefulness is more limited than troponin.

Serum Lipids. Elevated lipid levels are considered a risk factor for coronary artery disease (CAD). **Cholesterol**, **triglycerides**, and the protein components of **high-density lipoproteins (HDLs)** and **low-density lipoproteins (LDLs)** are evaluated to assess the risk for CAD. The desired ranges for lipids are (Pagana & Pagana, 2010):

- Total cholesterol less than 200 mg/dL
- Triglyceride less than 150 mg/dL
- HDL more than 40 mg/dL (“good” cholesterol)
- LDL less than 70 mg/dL in high-risk cardiovascular patients, less than 100 mg/dL in patients with moderate risk factors

Each of the lipoproteins contains varying proportions of cholesterol, triglyceride, protein, and phospholipid. HDL contains mainly protein and 20% cholesterol, whereas LDL is mainly cholesterol. Elevated LDL levels are positively correlated with CAD, whereas elevated HDL levels are negatively correlated and appear to be protective for heart disease. LDL pattern size is of significant importance in determining risk for CVD. LDL pattern A is associated with non-insulin resistance; normal glucose, insulin, and HDL levels; and a normal blood pressure. LDL pattern B is associated with insulin resistance; increased glucose, insulin, and triglyceride levels; and hypertension.

A fasting blood sample for the measurement of serum cholesterol levels is preferable to a nonfasting sample. If triglycerides are to be evaluated with cholesterol, the health care provider requests the specimen after a 12-hour fast

Lipoprotein-a, or Lp(a), is a modified form of LDL, the most common familial lipoprotein disorder in patients with premature coronary artery disease. Lp(a) is atherogenic (increases atherosclerotic plaques) and prothrombotic (increases clots). Therefore the desired outcome is a value less than 30 mg/dL. The patient should be fasting and avoid smoking before the test (Pagana & Pagana, 2010).

Other Serum Tests. **Homocysteine** is an amino acid that is produced when proteins break down. A certain amount of homocysteine is present in the blood, but elevated values may be an independent risk factor for the development of CVD.

Although the relationship between homocysteine and CVD remains controversial, elevated levels of homocysteine may increase the risk for disease as much as smoking and hyperlipemia, especially in women. High-risk patients who have a personal or family history of premature heart disease should be screened. A level less than 14 mmol/dL is considered optimal (Pagana & Pagana, 2010).

Inflammation is a common and critical component to the development of atherothrombosis. **Highly sensitive C-reactive protein (hsCRP)** has been the most studied marker of inflammation. Any inflammatory process can produce CRP in the blood. Elevations are seen also with hypertension, infection, and smoking. A level less than 1 mg/dL is considered low risk; a level over 3 mg/dL places the patient at high risk for heart disease. Recent guidelines suggest that the CRP is very helpful in determining treatment outcomes in patients at risk for coronary disease and in managing statin therapy after an acute myocardial infarction. (Howie-Esquivel & White, 2008). The most useful time to measure CRP appears to be for risk assessment in middle-aged or older persons.

Microalbuminuria, or small amounts of protein in the urine, has been shown to be a clear marker of widespread endothelial dysfunction in cardiovascular disease (along with elevated CRP). It should be screened annually in all patients with hypertension, metabolic syndrome, or diabetes mellitus. Microalbuminuria has also been used as a marker for renal disease, particularly in patients with hypertension and diabetes.

Blood coagulation studies evaluate the ability of the blood to clot. They are important in patients with a greater tendency to form thrombi (e.g., those with atrial fibrillation, prosthetic valves, or infective endocarditis). These tests are also essential for monitoring patients receiving anticoagulant therapy (e.g., during cardiac surgery, during treatment of an established thrombus).

Prothrombin time (PT) and **international normalized ratio (INR)** are used when initiating and maintaining therapy with oral anticoagulants, such as sodium warfarin (Coumadin, Warfilone ☛). They measure the activity of prothrombin, fibrinogen, and factors V, VII, and X. INR is the most reliable way to monitor anticoagulant status in warfarin therapy. The therapeutic ranges vary significantly based on the reason for the anticoagulation and the patient's history. The normal INR is 1.

Partial thromboplastin time (PTT) is assessed in patients who are receiving heparin (Hepalean ☛). It measures deficiencies in all coagulation factors except VII and XIII.

Arterial blood gas (ABG) determinations are often obtained in patients with CVD. Determination of tissue oxygenation, carbon dioxide removal, and acid-base status is essential to appropriate treatment. (See Chapter 14 for a complete discussion of ABGs.)

Fluid and electrolyte balance are essential for normal cardiovascular performance. Cardiac manifestations often occur when there is an imbalance in either fluids or *electrolytes* in the body. For example, the cardiac effects of hypokalemia (low serum potassium level) include increased electrical instability, ventricular dysrhythmias, and an increased risk for digitalis toxicity. The effects of hyperkalemia on the myocardium include slowed ventricular conduction, peaked T waves on the ECG, and contraction followed by asystole (cardiac standstill).

Cardiac manifestations of hypocalcemia are ventricular dysrhythmias, a prolonged QT interval, and cardiac arrest. Hypercalcemia shortens the QT interval and causes AV block, digitalis hypersensitivity, and cardiac arrest. Serum sodium values reflect fluid balance and may be decreased, indicating a fluid excess in patients with heart failure (dilutional hyponatremia).

Because magnesium regulates some aspects of myocardial electrical activity, hypomagnesemia has been implicated in some forms of ventricular dysrhythmias known as *torsades de pointes*. Hypomagnesemia prolongs the QT interval, causing this specific type of ventricular tachycardia. Chapter 13 describes these electrolytes in more detail.

The *erythrocyte (red blood cell [RBC]) count* is usually decreased in rheumatic fever and infective endocarditis. It is increased in heart diseases as needed to compensate for decreased available oxygen.

Decreased *hematocrit and hemoglobin* levels (e.g., caused by hemorrhage or hemolysis from prosthetic valves) indicate anemia and can lead to angina or aggravate heart failure. Vascular volume depletion with hemoconcentration (e.g., hypovolemic shock and excessive diuresis) results in an elevated hematocrit.

The *leukocyte (white blood cell [WBC]) count* is typically elevated after an MI and in various infectious and inflammatory diseases of the heart (e.g., infective endocarditis and pericarditis). An increased WBC has been implicated as a strong independent risk factor for stroke and heart disease, particularly in postmenopausal women (AHA, 2010b).

Other Diagnostic Assessment

Posteroanterior (PA) and left lateral *x-ray* views of the chest are routinely obtained to determine the size, silhouette, and position of the heart. In acutely ill patients, a simple anteroposterior (AP) view may be obtained at the bedside. Cardiac enlargement, pulmonary congestion, cardiac calcifications, and placement of central venous catheters, endotracheal tubes, and hemodynamic monitoring devices are assessed by x-ray.

Angiography of the arterial vessels, or **arteriography**, is an invasive diagnostic procedure that involves fluoroscopy and the use of contrast media. This procedure is performed when an arterial obstruction, narrowing, or aneurysm is suspected. The interventional radiologist performs selective arteriography to evaluate specific areas of the arterial system. For example, a coronary arteriography, which is performed during left-sided cardiac catheterization, assesses arterial circulation within the heart. It can also be performed on arteries in the extremities, mesentery, and cerebrum. Angiography is discussed under the appropriate associated diseases elsewhere in this text.

Cardiac Catheterization. The most definitive but most invasive test in the diagnosis of heart disease is cardiac catheterization. **Cardiac catheterization** may include studies of the right or left side of the heart and the coronary arteries. Some of the most common indications for cardiac catheterization are listed in Table 35-4.

Patient Preparation. Assess the patient's physical and psychosocial readiness and knowledge level about the procedure because many patients have anxiety and fear about cardiac catheterization. Review the purpose of the procedure, inform the patient about the length of the procedure, state

TABLE 35-4 INDICATIONS FOR CARDIAC CATHETERIZATION

- To confirm suspected heart disorders, including congenital abnormalities, coronary artery disease, myocardial disease, valvular disease, and valvular dysfunction
- To determine the location and extent of the disease process
- To assess:
 - Stable, severe angina unresponsive to medical management
 - Unstable angina pectoris
 - Uncontrolled heart failure, ventricular dysrhythmias, or cardiogenic shock associated with acute myocardial infarction, papillary muscle dysfunction, ventricular aneurysm, or septal perforation
- To determine best therapeutic option (percutaneous transluminal coronary angioplasty, stents, coronary artery bypass graft, valvulotomy versus valve replacement)
- To evaluate effects of medical or invasive treatment on cardiovascular function, percutaneous transluminal coronary angioplasty, or coronary artery bypass graft patency

TABLE 35-5 COMPLICATIONS OF CARDIAC CATHETERIZATION**Right-Sided Heart Catheterization**

- Thrombophlebitis
- Pulmonary embolism
- Vagal response

Left-Sided Heart Catheterization and Coronary Arteriography

- Myocardial infarction
- Stroke
- Arterial bleeding or thromboembolism
- Dysrhythmias

Right-Sided or Left-Sided Heart Catheterization*

- Cardiac tamponade
- Hypovolemia
- Pulmonary edema
- Hematoma or blood loss at insertion site
- Reaction to contrast medium

*In addition to those cited for each procedure.

who will be present, and describe the appearance of the catheterization laboratory. Tell the patient about the sensations he or she may experience during the procedure, such as palpitations (as the catheter is passed up to the left ventricle), a feeling of heat or a hot flash (as the medium is injected into either side of the heart), and a desire to cough (as the medium is injected into the right side of the heart). Written, electronic, or illustrated materials or DVDs may be used to assist in understanding.

The risks of cardiac catheterization are usually explained by the cardiologist. The risks vary with the procedures to be performed and the patient's physical status (Table 35-5). Although not common, several serious complications may follow coronary arteriography, such as:

- Myocardial infarction (MI)
- Stroke
- Arterial bleeding
- Thromboembolism
- Lethal dysrhythmias
- Arterial dissection
- Death

The cardiologist or interventional radiologist obtains a written informed consent from the patient or responsible party before the procedure.

The patient is admitted to the hospital on the day of the catheterization procedure. He or she may be admitted earlier if there is renal dysfunction. Fluids and acetylcysteine (Mucosyst) may be given 12 to 24 hours before the procedure for renal protection. Contrast-induced renal dysfunction can result from vasoconstriction and the direct toxic effect of the contrast agent on the renal tubules. Hydration and the administration of acetylcysteine pre- and post-study help eliminate or minimize contrast-induced renal toxicity.

Standard preoperative tests are performed, which usually include a chest x-ray, complete blood count, coagulation studies, and 12-lead ECG. The patient receives nothing by mouth after midnight or has only a liquid breakfast if the catheterization is scheduled for the afternoon. The catheterization site is antiseptically prepared with hairs clipped according to agency policy.

Before the procedure, take the patient's vital signs, auscultate the heart and the lungs, and assess the peripheral pulses. Question him or her about any history of allergy to iodine-based contrast agents. An antihistamine or steroid may be given to a patient with a positive history or to prevent a reaction. Be sure that the signed informed consent is completed, as required by The Joint Commission's National Patient Safety Goals (NPSGs). A mild sedative is usually administered before the procedure. If the patient normally takes a digitalis preparation or diuretic, it is usually withheld before the catheterization. Analysis of electrolytes, blood urea nitrogen (BUN), creatinine, coagulation profile, and complete blood count (CBC) is essential before and after the procedure, and abnormalities are discussed with the health care provider.

Procedure. The patient is taken to the cardiac catheterization laboratory (sometimes referred to as the "cath lab"), placed in the supine position on the x-ray table, and securely strapped to the table. Inform him or her that this precaution is necessary because the table turns like a cradle during the procedure. The physician injects a local anesthetic at the insertion site. During the procedure, the patient is instructed to report any chest pain, pressure, or other symptoms to the staff.

The *right side of the heart* is catheterized first and may be the only side examined. The cardiologist inserts a catheter through the femoral vein to the inferior vena cava or through the basilic vein to the superior vena cava. The catheter is advanced through either the inferior or the superior vena cava and, guided by fluoroscopy, is advanced through the right atrium, through the right ventricle, and, at times, into the pulmonary artery. Intracardiac pressures (right atrial, right ventricular, pulmonary artery, and pulmonary artery wedge pressures) and blood samples are obtained. A contrast medium is usually injected to detect any cardiac shunts or regurgitation from the pulmonic or tricuspid valves.

In a *left-sided heart catheterization*, the cardiologist advances the catheter against the blood flow from the femoral or brachial artery up the aorta, across the aortic valve, and into the left ventricle (Fig. 35-8). Alternatively, the catheter may be passed from the right side of the heart through the atrial septum, using a special needle to puncture the septum. Intracardiac pressures and blood samples are obtained. The pressures of the left atrium, left ventricle, and aorta, as well as mitral and aortic valve status, are evaluated. The cardiologist injects contrast dye into the ventricle; cineangiograms (rapidly changing films) evaluate left ventricular motion.

FIG. 35-8 Left-sided cardiac catheterization.

Calculations are made regarding end-systolic volume, end-diastolic volume, stroke volume, and ejection fraction.

The technique for *coronary arteriography* is the same as for left-sided heart catheterization. The catheter is advanced into the aortic arch and positioned selectively in the right or left coronary artery. Injection of a contrast medium permits viewing the coronary arteries. By assessing the flow of the medium through the coronary arteries, information about the site and severity of coronary lesions is obtained.

An alternative to injecting a medium into the coronary arteries is **intravascular ultrasonography (IVUS)**, which introduces a flexible catheter with a miniature transducer at the distal tip to view the coronary arteries. The transducer emits sound waves, which reflect off the plaque and the arterial wall to create an image of the blood vessel. IVUS is more reliable than angiography in indicating plaque distribution and composition, arterial dissection, and degree of stenosis of the occluded artery.

Follow-up Care. The patient recovers in a specialty area equipped with monitored beds. After cardiac catheterization, restrict the patient to bedrest and keep the insertion site extremity straight. A soft knee brace can be applied to prevent bending of the affected extremity. *Some cardiologists allow the head of the bed to be elevated up to 30 degrees during the period of bedrest, whereas other cardiologists prefer that the patient remain supine. Current practice is for patients to remain in bed for 2 to 6 hours depending on the type of vascular closure device used.* Various types of vascular closure devices are used to eliminate the need for manual compression after the catheterization. Examples include arteriotomy sutures and collagen plugs to seal the insertion site.

Monitor the patient's vital signs every 15 minutes for 1 hour, then every 30 minutes for 2 hours or until vital signs are stable, and then every 4 hours or according to hospital policy. Assess the insertion site for bloody drainage or

hematoma formation. Complications with vascular closure devices are not common but can be very serious. Assess peripheral pulses in the affected extremity, as well as skin temperature and color, with every vital sign check. Observe for complications of cardiac catheterization (see Table 35-5).

! NURSING SAFETY PRIORITY

Critical Rescue

If the patient experiences symptoms of cardiac ischemia such as chest pain, dysrhythmias, bleeding, hematoma formation, or a dramatic change in peripheral pulses in the affected extremity, contact the Rapid Response Team or physician immediately to provide prompt intervention! Neurologic changes indicating a possible stroke, such as visual disturbances, slurred speech, swallowing difficulties, and extremity weakness, should also be reported immediately.

Because the contrast medium acts as an osmotic diuretic, monitor urine output and ensure that the patient receives sufficient oral and IV fluids for adequate excretion of the medium. Pain medication for insertion site or back discomfort may be given as prescribed.

Review home instructions and risk factor modification with the patient before discharge. Remind the patient to:

- Limit activity for several days, including avoiding lifting and exercise.
- Leave the dressing in place for at least the first day at home.
- Observe the insertion site over the next few weeks for increased swelling, redness, warmth, and pain. Bruising or a small hematoma is expected.

? DECISION-MAKING CHALLENGE

Patient-Centered Care; Safety; Informatics

A middle-aged, obese male is admitted to the telemetry unit with acute chest pain. His wife tells you that he is a CEO of a small business that has been struggling financially due to the recent recession. The patient smokes 2 packs of cigarettes and drinks 2 or 3 cocktails every day.

1. What contributing factors may have caused this patient's acute chest pain? Think of all the possibilities.
2. What assessment data will you gather and document on the EMR? Why?
3. The cardiologist scheduled the patient for a coronary arteriography this afternoon. What do you need to do before the angiogram to ensure his safety?
4. What education will you provide the patient and his family before the angiogram?
5. You transfer the patient to the cath lab for his angiogram. What information will you communicate to the cath lab RN upon transfer of care? Use the SBAR technique to help organize this information.

Electrocardiography

The electrocardiogram (ECG) is a routine part of every cardiovascular evaluation and is one of the most valuable diagnostic tests. Various forms are available: resting ECG, continuous ambulatory ECG (Holter monitoring), exercise ECG (stress test), signal-averaged ECG, and 30-day event monitoring. The resting ECG provides information about cardiac dysrhythmias, myocardial ischemia, the site and extent of MI, cardiac hypertrophy, electrolyte imbalances,

and the effectiveness of cardiac drugs. The normal ECG pattern and a detailed discussion of the interpretation of abnormal patterns are discussed in [Chapter 36](#).

Electrophysiologic Studies

An [electrophysiologic study \(EPS\)](#) is an invasive procedure during which programmed electrical stimulation of the heart is used to cause and evaluate lethal dysrhythmias and conduction abnormalities. Patients who have survived cardiac arrest, have recurrent tachydysrhythmias, or experience unexplained syncopal episodes may be referred for EPS. Induction of the dysrhythmia during EPS helps find an accurate diagnosis and aids in effective treatment. These procedures have risks similar to those for cardiac catheterization and are performed in a special catheterization laboratory, where conditions are strictly controlled and immediate treatment is available for any adverse effects. [Chapter 36](#) describes this diagnostic study in detail.

Exercise Electrocardiography (Stress Test)

The [exercise electrocardiography](#) test (also known as [exercise tolerance](#), or [stress test](#)) assesses cardiovascular response to an increased workload. The stress test helps determine the functional capacity of the heart and screens for asymptomatic coronary artery disease. Dysrhythmias that develop during exercise may be identified, and the effectiveness of antidysrhythmic drugs can be evaluated.

Patient Preparation. Because risks are associated with exercising, the patient must be adequately informed about the purpose of the test, the procedure, and the risks involved. Written consent must be obtained. Anxiety and fear are common before stress testing. Therefore assure the patient that the procedure is performed in a controlled environment in which prompt nursing and medical attention are available.

Instruct the patient to get plenty of rest the night before the procedure. He or she may have a light meal 2 hours before the test but should avoid smoking or drinking alcohol or caffeine-containing beverages on the day of the test. The cardiologist decides whether the patient should stop taking any cardiac medications. Usually, cardiovascular drugs such as beta blockers or calcium channel blockers are withheld on the day of the test to allow the heart rate to increase during the stress portion of the test. Patients are advised to wear comfortable, loose clothing and rubber-soled, supportive shoes. Remind them to tell the physician if symptoms such as chest pain, dizziness, shortness of breath, and an irregular heart-beat are experienced during the test.

Before the stress test, a resting 12-lead ECG, cardiovascular history, and physical examination are performed to check for any ECG abnormalities or medical factors that might interfere with the test. Check to see that all emergency supplies such as cardiac drugs, a defibrillator, and other necessary resuscitation equipment are available in the room in which the stress test is performed. It is important to be proficient in the use of resuscitation equipment when assisting the physician because chest pain, dysrhythmias, and other ECG changes may occur.

Procedure. The technician places electrodes on the patient's chest and attaches them to a multilead monitoring system. Note baseline blood pressure (BP), heart rate (HR), and respiratory rate. The two major modes of exercise available for stress testing are pedaling a bicycle ergometer and

walking on a treadmill. A bicycle ergometer has a wheel operated by pedals that can be adjusted to increase the resistance to pedaling. The treadmill is a motorized device with an adjustable conveyor belt. It can reach speeds of 1 to 10 miles/hr and can also be adjusted from a flat position to a 22-degree incline.

After the patient is shown how to use the bicycle or to walk on the treadmill, he or she begins to exercise. During the test, the BP and ECG are closely monitored as the resistance to cycling or the speed and incline of the treadmill are increased. The patient exercises until one of these findings occurs:

- A predetermined HR is reached and maintained.
- Signs and symptoms such as chest pain, fatigue, extreme dyspnea, vertigo, hypotension, and ventricular dysrhythmias appear.
- Significant ST segment depression or T wave inversion occurs.
- The 20-minute protocol is completed.

Follow-up Care. After the test, the nurse or other qualified health care team member monitors the ECG and BP until the patient has completely recovered. After recovery, he or she can return home if the test was performed on an ambulatory basis. Advise him or her to avoid a hot shower for 1 to 2 hours after the test because this may cause hypotension. If he or she does not recover but continues to have pain or ventricular dysrhythmias or appears medically unstable, admission to a telemetry unit for observation is needed.

For patients who cannot exercise because of conditions such as peripheral vascular disease or arthritis, pharmacologic stress testing with agents such as dobutamine (Dobutrex) may be indicated. The nursing considerations are similar to those for the patient who has undergone an exercise ECG.

Echocardiography

As a noninvasive, risk-free test, echocardiography is easily performed at the bedside or on an ambulatory care basis. [Echocardiography](#) uses ultrasound waves to assess cardiac structure and mobility, particularly of the valves. It helps assess and diagnose cardiomyopathy, valvular disorders, pericardial effusion, left ventricular function, ventricular aneurysms, and cardiac tumors.

There is no special *preparation* for echocardiography. Inform the patient that the test is painless and takes 30 to 60 minutes to complete. The patient is instructed to lie quietly during the test and on his or her left side with the head elevated 15 to 20 degrees.

During an echocardiogram, a small transducer lubricated with gel to facilitate movement and conduction is placed on the patient's chest at the level of the third or fourth intercostal space near the left sternal border. The transducer transmits high-frequency sound waves and receives them as they are reflected from different structures. These echoes are usually videotaped simultaneously with the echocardiogram and can be recorded on graph paper for a permanent record.

After the images are taped, cardiac measurements that require several images can be obtained. Routine measurements include chamber size, ejection fraction, and flow gradient across the valves. There is no specific *follow-up care* for a patient who has undergone an echocardiogram.

A slightly more aggressive form of echocardiogram is a **pharmacologic stress echocardiogram** using either dobutamine or dipyridamole. This test is usually used when patients cannot tolerate exercise. Dobutamine (Dobutrex) increases the heart's contractility; dipyridamole (Persantine, Apo-Dipyridamole) is a coronary artery dilator. Patients are required to be NPO status for 3 to 6 hours before the test except for sips of water with medications. The technician ensures that IV access is present before the procedure and monitors BP and pulse continuously throughout the procedure. After the procedure, vital signs are monitored until BP returns to baseline and the pulse rate slows to less than 100 beats/min.

Transesophageal Echocardiography

Echocardiograms may also be performed transesophageally (through the esophagus). **Transesophageal echocardiography (TEE)** examines cardiac structure and function with an ultrasound transducer placed immediately behind the heart in the esophagus or stomach. The transducer provides especially detailed views of posterior cardiac structures such as the left atrium, mitral valve, and aortic arch. Preparation and follow-up are similar to that for an upper GI endoscopic examination (see Chapter 55).

Myocardial Nuclear Perfusion Imaging

The use of radionuclide techniques in cardiovascular assessment is called **myocardial nuclear perfusion imaging (MNPI)**. Cardiovascular abnormalities can be viewed, recorded, and evaluated using radioactive tracer substances. These studies are useful for detecting myocardial infarction (MI) and decreased myocardial blood flow and for evaluating left ventricular ejection. Conducting myocardial nuclear imaging tests, in conjunction with exercise or the administration of vasodilating agents, allows clearer identification of how the heart responds to stress.

Inform the patient that these tests are noninvasive. Because the amount of radioisotope is small, radiation exposure risks are minimal. If a dilating agent is to be used, advise the patient to avoid cigarettes and caffeinated food or drinks for 4 hours before administration of the vasodilator.

Common tests in nuclear cardiology include technetium (^{99m}Tc) pyrophosphate scanning, thallium imaging, and multigated cardiac blood pool imaging. Each test requires the injection of different types of radioactive isotopes into the antecubital vein. After the cells and tissues have time to take up the radioactive substances, usually 10 minutes to 2 hours, nuclear imaging can detect the difference between healthy and unhealthy tissue.

During the *technetium scan*, radioisotopes (^{99m}Tc pyrophosphate) accumulate in damaged myocardial tissue, which appears as a “hot spot” during the scan. This test helps detect the location and size of acute myocardial infarctions.

Alternatively, during the *thallium imaging scan*, necrotic or ischemic tissue does not absorb the radioisotope (thallium-201) and appears as “cold spots” on the scan. Thallium imaging is used to assess myocardial scarring and perfusion, to detect the location and extent of an acute or chronic myocardial infarction, to evaluate graft patency after coronary bypass surgery, and to evaluate antianginal therapy, thrombolytic therapy, or balloon angioplasty.

Thallium imaging may be performed during an exercise test or with the patient at rest. Thallium imaging performed during an exercise test may demonstrate perfusion deficits

not apparent at rest. First, the stress test procedure is performed. After the patient reaches maximum activity level, a small dose of thallium-201 is injected IV. The patient continues to exercise for about 1 to 2 minutes, after which the scanning is performed. Nuclear cardiologists often compare the resting and stress images to differentiate between fixed and reversible defects in the myocardium.

If a patient cannot exercise on a bike or treadmill, Dipyridamole (Persantine, Apo-Dipyridamole) or dobutamine hydrochloride (Dobutrex) is administered to simulate the effects of exercise. Tell the patient that these vasodilators may cause flushing, headache, dyspnea, and chest tightness for a few moments after injection.

Cardiac blood pool imaging is a noninvasive test for evaluating cardiac motion and calculating ejection fraction. It uses a computer to synchronize the patient's ECG with pictures taken by a special camera. The technician attaches the patient to an ECG and injects a small amount of ^{99m}Tc IV. The radioisotope is not taken up by tissue but remains “tagged” to red blood cells in the circulation. The camera may take pictures of the radioactive material as it makes its first pass through the heart.

During **multigated blood pool scanning**, the computer breaks the time between R waves on the ECG into fractions of a second, called “gates.” The camera records blood flow through the heart during each of these gates. By analyzing the information from multiple gates, the computer can evaluate the ventricular wall motion and calculate ejection fraction (percentage of the left ventricular volume that is ejected with each contraction) and ejection velocity. Areas of decreased, absent, or paradoxical movement of the left ventricle may also be identified.

Positron emission tomography (PET) scans are used to compare cardiac perfusion and metabolic function and differentiate normal from diseased myocardium. The technician administers the first radioisotope (nitrogen-13-ammonia) and then begins a 20-minute scan to detect myocardial perfusion. Next, the technician administers a second radioisotope (fluoro-18-deoxyglucose). After a pause, a second scan is performed to detect the metabolically active myocardium, which is using glucose.

The two scans are compared. In a normal heart, performance and metabolic function will match. In an ischemic heart, there will be a mismatch—a reduction in perfusion and increased glucose uptake by the ischemic myocardium. The scanning procedure takes 2 to 3 hours, and the patient may be asked to use a treadmill or exercise bicycle in conjunction with the scan.

Depending on which test is performed, the patient may report fatigue or discomfort at the antecubital injection site. If a stress test was paired with the study, he or she will need follow-up care for the stress test.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a noninvasive diagnostic option. An image of the heart or great vessels is produced through the interaction of magnetic fields, radio waves, and atomic nuclei showing hydrogen density. Simply put, the radio waves “bounce off” the body tissue being examined. Because each tissue has its own density, the computer image clearly differentiates between various types of tissues. MRI permits determination of cardiac wall thickness, chamber dilation, valve and ventricular function, and blood movement

in the great vessels. Improved MRI techniques allow coronary artery blood flow to be mapped with nearly the accuracy of a cardiac catheterization.

Before an MRI, ensure that the patient has removed all metallic objects, including watches, jewelry, clothing with metal fasteners, and hair clips. Patients with pacemakers or implanted defibrillators may not be able to have an MRI because the magnetic fields can deactivate them. However, some newer MRI machines have eliminated this complication. A few patients experience claustrophobia during the 15 to 60 minutes required to complete the scan.

Electronic-Beam Computed Tomography Scan

Electronic-beam computed tomography (EBCT) is a valuable tool in cardiovascular diagnostics. This test helps determine whether calcifications are present in the arteries; calcifications are a common component of arterial plaque. The 64-slice CT is used to determine the **coronary artery calcium (CAC) score**, which is a measure of the amount of coronary artery calcification. The test cannot predict the site of future events or determine the severity of the risk. According to the American Heart Association (AHA) clinical expert consensus document on calcium scoring, a CAC score of greater than 400 requires intensive preventive therapies (Greenland et al., 2007).

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

The nurse is caring for a client with coronary artery disease who has just undergone a coronary angiogram. What is the priority intervention when caring for this client immediately postprocedure?

- A. Place the client in high Fowler's to prevent aspiration.
- B. Educate the client on anticoagulant medications.
- C. Assess for bleeding at the insertion site.
- D. Monitor for elevated cardiac enzymes.

Hemodynamic Monitoring

Hemodynamic monitoring is an invasive system used in critical care areas to provide quantitative information about vascular capacity, blood volume, pump effectiveness, and tissue perfusion. It directly measures pressures in the heart and great vessels. These procedures are usually performed for more seriously ill patients and can provide more accurate measurements of blood pressure, heart function, and volume status. Although medical-surgical nurses do not manage these systems on general hospital units, they should be familiar with the interpretation of some of the major hemodynamic pressures as they relate to patient assessment.

Hemodynamic monitoring does involve significant risks, although complications are uncommon. Therefore informed consent is required. After obtaining consent, the nurse prepares a pressure-monitoring system. The components of this system are a catheter with an infusion system, a transducer, and a monitor. The catheter receives the pressure waves (mechanical energy) from the heart or the great vessels. The transducer converts the mechanical energy into electrical energy, which is displayed as waveforms or numbers on the monitor. Patency of the catheter is maintained with a slow continuous flush of normal saline, usually infused at 3 to 4 mL/hr under pressure to prevent the backup of blood and occlusion of the catheter.

CHART 35-4 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Identification of the Phlebostatic Axis

1. Position the patient supine.
2. Palpate the fourth intercostal space at the sternum.

3. Follow the fourth intercostal space to the side of the patient's chest.
4. Determine the midway point between anterior and posterior.
5. Find the intersection between the midway point and the line from the fourth intercostal space, and mark it with an X in indelible ink. This is the phlebostatic axis.

To prepare the transducer, balance and calibrate it according to hospital policy and the manufacturer's specifications. Finally, identify the phlebostatic axis (Chart 35-4) and level the transducer to it. The physician inserts a balloon-tipped catheter percutaneously through a large vein, usually the internal jugular or subclavian, and directs it to the right atrium (RA). When the catheter tip reaches the RA, the physician inflates the balloon. The catheter advances with the flow of blood through the tricuspid valve, into the right ventricle, past the pulmonic valve, and into a branch of the pulmonary artery. The balloon is deflated after the catheter tip reaches the pulmonary artery. Waveforms are viewed on the monitor as the pulmonary artery catheter is advanced (Fig. 35-9). A chest x-ray is used to check the location of the catheter.

A pulmonary artery catheter is a multi-lumen catheter with the capacity to measure right atrial and indirect left atrial pressures or pulmonary artery wedge pressure (PAWP), also known as the **pulmonary artery occlusive pressure (PAOP)**. A cardiac output measurement may also be obtained, as well as cardiac index and systemic and pulmonary vascular resistance.

Right atrial pressure is measured by a pressure sensor on the catheter inside the RA. Normal RA pressure ranges from 1 to 8 mm Hg. *Increased RA pressures may occur with right*

FIG. 35-9 Cardiac pressure waveforms can be seen on the monitor.

ventricular failure, whereas low RA pressures usually indicate hypovolemia.

Normal pulmonary artery pressure (PAP) ranges from 15 to 26 mm Hg systolic/5 to 15 mm Hg diastolic (mean, 15) and is constantly visible on the monitor. When the balloon at the catheter tip is inflated, the catheter advances and wedges in a branch of the pulmonary artery. The tip of the catheter can sense pressures transmitted from the left atrium, which reflect left ventricular end-diastolic pressure (LVEDP). The pressure measured during balloon inflation is called the **pulmonary artery wedge pressure (PAWP)**. PAWP closely reflects left atrial pressure and LVEDP in patients with normal left ventricular function, normal heart rates, and no mitral valve disease. The PAWP is a mean pressure and normally ranges between 4 and 12 mm Hg.

Elevated PAWP measurements may indicate left ventricular failure, hypervolemia, mitral regurgitation, or intracardiac shunt. A decreased PAWP is seen with hypovolemia or after-load reduction. Individual values may be less important than the trend in values.

The critical care nurse obtains and records RA pressure, PAP, and PAWP at appropriate intervals (usually every 1 to 4 hours). The trend of these pressures helps guide medical therapy. During pressure recording, it is important that the transducer be at the level of the phlebostatic axis. The patient is usually supine with the head elevated up to 45 degrees during hemodynamic readings, although the position may not affect results (Giuliano et al., 2003). If the balloon remains in the wedge position after PAWP measurement, try to change the catheter's position by asking the patient to cough or by changing his or her position. *If these methods are not successful, notify the physician immediately.*

Change the occlusive sterile dressing over the catheter according to hospital policy. Inspect the insertion site for redness, induration, swelling, drainage, and intactness of the sutures. Detailed discussion of the management and care of

patients with pulmonary artery catheters can be found in textbooks on critical care nursing.

Be sure to assess for a number of complications associated with pulmonary artery catheters. For example, pulmonary infarction or pulmonary rupture may occur if the catheter remains in the wedge position. Air embolism is possible if the balloon has ruptured and repeated attempts are made to inflate it. Ventricular dysrhythmias may occur during insertion or if the catheter tip slips back into the right ventricle and irritates the myocardium. Thrombus and embolus formation may occur at the catheter site. Infection may result, and bleeding may be pronounced if the infusion system becomes disconnected.

Direct measurement of *arterial BP* is done by invasive arterial catheter in critically ill patients. The physician or specially trained health care professional inserts an intra-arterial catheter into the radial or femoral artery. After the catheter is inserted, it is attached to pressure tubing. A normal saline flush solution is infused constantly under pressure to maintain the integrity of the system. A transducer attached to the tubing allows continuous direct monitoring of the arterial BP. Direct measurements of BP are usually 10 to 15 mm Hg greater than indirect (cuff) measurements. The arterial catheter may also be used to obtain blood samples for arterial blood gas values and other blood tests.

Because the arterial vasculature is a high-pressure system, frequent assessment of the arterial site and infusion system is essential. *Note any bleeding around the intra-arterial catheter or any loose connections, and correct the situation immediately.* Collateral circulation must be assessed by Doppler before and while the arterial catheter is in place. Carefully monitor color, pulse, and temperature distal to the insertion site for any early signs of circulatory compromise. Complications of systemic intra-arterial monitoring include pain, infection, arteriospasm, or obstruction at the site with the potential for distal infarction, air embolism, and hemorrhage.

Unlike conventional hemodynamic monitoring, **impedance cardiography (ICG)** is a flexible and fast-acting noninvasive monitoring system that consists of four ICG electrodes, four electrocardiogram (ECG) electrodes, and a portable ICG monitor. Simply stated, it measures the total impedance (resistance) to the flow of electricity in the heart. ICG can be used in any setting including the intensive care unit (ICU),

the emergency department (ED), and the home. It is used to assess, plan, and individualize the treatment plan for patients with heart failure, severe trauma, or fluid management. The system provides measures of thoracic fluid, left ventricular function (cardiac output and cardiac index), preload, afterload, and contractility of the heart.

NURSING CONCEPT REVIEW

What should you NOTICE in a patient with adequate oxygenation and perfusion related to the cardiovascular system?

Physical Assessment

- Vital signs within normal limits or baseline
- No abnormal heart sounds
- Strong and equal peripheral pulses
- Even and unlabored respirations
- Regular heartbeat
- No pallor, cyanosis, or clubbing

- No syncope, fatigue, or chest pain
- No edema
- Can perform ADLs without dyspnea

Diagnostic Assessment

- No serum markers of myocardial damage
- Serum lipids within normal ranges
- Normal C-reactive protein and homocysteine
- Normal electrocardiogram (ECG)

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Assess the older adult for cardiovascular changes associated with aging as described in [Chart 35-1](#).
- Assess patients for allergy to iodine-based contrast media before having diagnostic tests requiring a contrast agent.
- After invasive cardiovascular diagnostic testing, such as angiography and cardiac catheterization, monitor the insertion site for bleeding and hematoma formation.
- Assess vital signs carefully in patients having invasive cardiovascular testing; report new dysrhythmias after testing.

Health Promotion and Maintenance

- Identify patients at risk for cardiovascular disease, especially those with hyperlipidemia, hypertension, excess weight, physical inactivity, smoking, psychological stress, a positive family history, and diabetes.
- Teach patients how to reduce the risk for heart disease through exercise, diet modification, smoking cessation, and medications, as needed.
- Inform patients that genetics and other nonmodifiable risk factors, such as family history and gender, contribute to the development of CAD.

Psychosocial Integrity

- Discuss with the patient any feelings or concerns he or she might have about the stress of cardiac illness, diagnostic testing, or other issues, and use therapeutic measures to decrease anxiety.

- Recognize that denial is a common and normal response to help patients cope with threatening circumstances.
- Be aware that coping behaviors of those who have cardiovascular problems vary from patient to patient.
- Allow the patient to express feelings about an actual or perceived loss of health or social status related to cardiovascular disease.

Physiological Integrity

- Assess the patient's report of pain to differentiate the pain of angina and myocardial infarction (MI) from other non-cardiac causes; *discomfort*, *indigestion*, *squeezing*, *heaviness*, and *viselike* are common terms used to describe chest pain of cardiac origin.
- Recall that syncope is a transient loss of consciousness and is common in older adults.
- Use jugular venous pressure to assess the filling volume and pressure on the right side of the heart.
- Assess for bruits, which are swishing sounds that develop in narrowed arteries.
- Auscultate the heart for normal first and second sounds, as well as for abnormalities such as an S₃, S₄, murmur, or gallop.
- Monitor serum markers of myocardial damage and other cardiac-related laboratory tests as listed in [Chart 35-3](#).
- Prepare patients having a cardiac catheterization for expectations of the procedure and postprocedure care.
- Assess patients having cardiac catheterizations for potential complications as listed in [Table 35-5](#).
- Hemodynamic monitoring is an invasive method for directly assessing cardiac and arterial pressures.

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Provide a safe environment for patients and staff when using a cardiac defibrillator.

Health Promotion and Maintenance

2. Teach patients and their families about drug therapy used for common dysrhythmias.
3. Educate patients and families about procedures and other interventions for common dysrhythmias.

Physiological Integrity

4. Identify typical physical assessment findings associated with common dysrhythmias.
5. Explain how to perform an electrocardiogram (ECG) test.

6. Analyze an ECG rhythm strip to identify normal sinus rhythm and common or life-threatening dysrhythmias.
7. Plan collaborative care for patients experiencing common dysrhythmias.
8. Explain the purpose and types of pacing used as interventions for patients with dysrhythmias.
9. Connect and maintain pacing devices.
10. Explain how to perform emergency care procedures, such as cardiopulmonary resuscitation (CPR) and automated external defibrillation.
11. Plan community-based care for a patient after pacemaker or implantable cardioverter/defibrillator insertion.

Cardiac dysrhythmias are abnormal rhythms of the heart's electrical system that can affect its ability to effectively pump *oxygenated* blood throughout the body. Some dysrhythmias are life threatening, and others are not. They are the result of disturbances of cardiac electrical impulse formation, conduction, or both. When the heart does not work effectively as a pump, *perfusion and oxygenation* to vital organs and peripheral tissues can be impaired, resulting in organ dysfunction or failure.

Many health problems, especially coronary artery disease (CAD), electrolyte imbalances, changes in oxygenation, and drug toxicity, can cause abnormal heart rhythms. Dysrhythmias can occur in people of any age but occur most often in older adults. To provide collaborative patient-centered care

using best practices, a *basic* understanding of cardiac electrophysiology, the conduction system of the heart, and the principles of electrocardiography is needed as a medical-surgical nurse. Specialty nurses and advanced practice nurses have a more in-depth knowledge as they manage patients with these cardiac problems in critical care areas.

REVIEW OF CARDIAC CONDUCTION SYSTEM

The cardiac conduction system consists of specialized myocardial cells (*Fig. 36-1*). The electrophysiologic properties of those cells regulate heart rate and rhythm and possess unique properties: automaticity, excitability, conductivity, and contractility.

FIG. 36-1 The cardiac conduction system.

Automaticity (pacing function) is the ability of cardiac cells to generate an electrical impulse spontaneously and repetitively. Normally, only primary pacemaker cells (sinoatrial [SA] node) can generate an electrical impulse. Under certain conditions, such as myocardial ischemia (decreased blood flow), electrolyte imbalance, hypoxia, drug toxicity, and infarction (cell death), any cardiac cell may produce electrical impulses independently and create dysrhythmias. Disturbances in automaticity may involve either an increase or a decrease in pacing function.

Excitability is the ability of non-pacemaker heart cells to respond to an electrical impulse that begins in pacemaker cells and to depolarize. **Depolarization** occurs when the normally negatively charged cells within the heart muscle develop a positive charge.

Conductivity is the ability to send an electrical stimulus from cell membrane to cell membrane. As a result, excitable cells depolarize in rapid succession from cell to cell until all cells have depolarized. *The wave of depolarization causes the deflections of the electrocardiogram (ECG) waveforms that are recognized as the P wave and the QRS complex.* Disturbances in conduction result when conduction is too rapid or too slow, when the pathway is totally blocked, or when the electrical impulse travels an abnormal pathway.

Contractility is the ability of atrial and ventricular muscle cells to shorten their fiber length in response to electrical stimulation, causing sufficient pressure to push blood forward through the heart. In other words, *contractility is the mechanical activity of the heart.*

Specialized cells of the myocardium are responsible for cardiac conduction. They consist of the sinoatrial node, atrioventricular junctional area, and bundle branch system.

Conduction begins with the **sinoatrial (SA) node** (also called the *sinus node*), located close to the surface of the right atrium near its junction with the superior vena cava. *The SA node is the heart's primary pacemaker.* It can spontaneously and rhythmically generate electrical impulses at a rate of 60

to 100 beats per minute and therefore has the greatest degree of automaticity.

The SA node is richly supplied by the sympathetic and parasympathetic nervous systems, which increase and decrease the rate of discharge of the sinus node, respectively. This process results in changes in the heart rate.

Impulses from the sinus node move directly through atrial muscle and lead to atrial depolarization, which is *reflected in a P wave on the ECG.* Atrial muscle contraction should follow. Within the atrial muscle are slow and fast conduction pathways leading to the atrioventricular (AV) node.

The **atrioventricular (AV) junctional** area consists of a transitional cell zone, the AV node itself, and the bundle of His. The AV node lies just beneath the right atrial endocardium, between the tricuspid valve and the ostium of the coronary sinus. Here T-cells (transitional cells) cause impulses to slow down or to be delayed in the AV node before proceeding to the ventricles. This delay is *reflected in the PR segment on the ECG.* This slow conduction provides a short delay, allowing the atria to contract and the ventricles to fill. The contraction is known as "atrial kick" and contributes additional blood volume for a greater cardiac output. The AV node is also controlled by both the sympathetic and the parasympathetic nervous systems. The bundle of His connects with the distal portion of the AV node and continues through the interventricular septum.

The *bundle of His* extends as a right bundle branch down the right side of the interventricular septum to the apex of the right ventricle. On the left side, it extends as a left bundle branch, which further divides.

At the ends of both the right and the left bundle branch systems are the Purkinje fibers. These fibers are an interweaving network located on the endocardial surface of both ventricles, from apex to base. The fibers then partially penetrate into the myocardium. **Purkinje cells** make up the bundle of His, bundle branches, and terminal Purkinje fibers. These cells are responsible for the rapid conduction of electrical

impulses throughout the ventricles, leading to ventricular depolarization and the subsequent ventricular muscle contraction. A few nodal cells in the ventricles also occasionally demonstrate automaticity, giving rise to ventricular beats or rhythms.

ELECTROCARDIOGRAPHY

The **electrocardiogram (ECG)** provides a graphic representation, or picture, of cardiac electrical activity. The cardiac electrical currents are transmitted to the body surface. Electrodes, consisting of a conductive gel on an adhesive pad, are placed on specific sites on the body and attached to cables connected to an ECG machine or to a monitor. The cardiac electrical current is transmitted via the electrodes and through the lead wires to the machine or monitor, which displays the cardiac electrical activity.

A **lead** provides one view of the heart's electrical activity. Multiple leads, or views, can be obtained. Electrode placement is the same for male and female patients.

Lead systems are made up of a positive pole and a negative pole. An imaginary line joining these two poles is called the **lead axis**. The direction of electrical current flow in the heart is the **cardiac axis**. The relationship between the cardiac axis and the lead axis is responsible for the deflections seen on the ECG pattern:

- The baseline is the **isoelectric** line. It occurs when there is no current flow in the heart after complete depolarization and also after complete repolarization. Positive deflections occur above this line, and negative deflections occur below it. Deflections represent depolarization and repolarization of cells.
- If the direction of electrical current flow in the heart (cardiac axis) is toward the positive pole, a **positive deflection** (above the baseline) is viewed (Fig. 36-2, A).

FIG. 36-2 A, The cardiac axis (*bold arrow*) is parallel to the lead axis (*the line between the negative and the positive electrodes*), going toward the positive electrode; a positive deflection is inscribed. **B,** The cardiac axis is parallel to the lead axis, going toward the negative electrode; a negative deflection is inscribed. **C,** The cardiac axis is perpendicular to the lead axis, going neither toward the positive electrode nor toward the negative electrode; a biphasic deflection is inscribed.

- If the direction of electrical current flow in the heart (cardiac axis) is moving away from the positive pole toward the negative pole, a **negative deflection** (below the baseline) is viewed (Fig. 36-2, B).
- If the cardiac axis is moving neither toward nor away from the positive pole, a biphasic complex (both above and below baseline) will result (Fig. 36-2, C).

Lead Systems

The standard 12-lead ECG consists of 12 leads (or views) of the heart's electrical activity. Six of the leads are called **limb leads** because the electrodes are placed on the four extremities in the frontal plane. The remaining six leads are called **chest (precordial) leads** because the electrodes are placed on the chest in the horizontal plane.

Standard bipolar **limb leads** consist of three leads (I, II, and III) that each measures the electrical activity between two points and a fourth lead (right leg) that acts as a ground electrode. Of the three measuring leads, the right arm is always negative, the left leg is always positive, and the left arm can be either positive or negative.

Other lead systems include the 18-lead ECG, which adds six leads placed on the horizontal plane on the right side of the chest to view the right side of the heart. This is sometimes referred to as a "right-sided ECG." The extra leads are sometimes placed on the back. The latest evidence indicates an 80-lead ECG, which looks at the heart from 80 views instead of only 12 and gives a 360-degree view of the heart. Evaluation of this 80-lead ECG revealed a 15% increase in diagnosing myocardial infarctions (MIs), particularly in the posterior wall, which was missed in the 12-lead ECG (*New 80-lead ECG is easy to interpret, 2008*).

Unipolar limb leads consist of a positive electrode only. The unipolar limb leads are aVR, aVL, and aVF, with *a* meaning augmented. *V* is a designation for a unipolar lead. The third letter denotes the positive electrode placement: *R* for right arm, *L* for left arm, and *F* for foot (left leg). The positive electrode is at one end of the lead axis. The other end is the center of the electrical field, at about the center of the heart (Table 36-1).

There are six unipolar (or *V*) **chest leads**, determined by the placement of the chest electrode. The four limb electrodes are placed on the extremities, as designated on each electrode (right arm, left arm, right leg, and left leg). The fifth (chest) electrode on a monitor system is the positive, or exploring, electrode and is placed in one of six designated positions to obtain the desired chest lead. With a 12-lead ECG, four leads are placed on the limbs and six are placed on the chest, eliminating the need to move any electrodes about the chest.

Positioning of the electrodes is crucial in obtaining an accurate ECG. Comparisons of ECGs taken at different times will be valid only when electrode placement is accurate and identical at each test. Positioning is particularly important when working with patients with chest deformities or large breasts. Patients may be asked to move the breasts to ensure proper electrode placement.

While obtaining a 12-lead ECG, remind the patient to be as still as possible in a semi-reclined position, breathing normally. Any repetitive movement will cause artifact and could lead to inaccurate interpretation of the ECG.

Nurses are sometimes responsible for obtaining 12-lead ECGs, but more commonly, technicians are trained to

TABLE 36-1 ELECTRODE PLACEMENT FOR 12 LEADS

LEAD	NEGATIVE ELECTRODE	POSITIVE ELECTRODE	GROUND ELECTRODE
I	Right arm or under the right clavicle	Left arm or under the left clavicle	Right leg or lowest rib, left midclavicular line
II	Right arm or under the right clavicle	Left leg or lowest rib, left midclavicular line	Right leg or under the left clavicle
III	Left arm or under the left clavicle	Left leg or lowest rib, left midclavicular line	Right leg or under the right clavicle
aVR	Average potential of left arm (or under the left clavicle) and left leg (or lowest rib, left midclavicular line)	Right arm or under the right clavicle	Right leg or lowest rib, right midclavicular line
aVL	Average potential of right arm (or under the right clavicle) and left leg (or lowest rib, left midclavicular line)	Left arm or under the left clavicle	Same as for aVR
aVF	Average potential of right arm (or under the right clavicle) and left arm (or under the left clavicle)	Left leg or lowest rib, left midclavicular line	Same as for aVR
V ₁	Average potential of right arm, left arm, and left leg	Fourth intercostal space (ICS), right sternal border	Same as for aVR
V ₂	Same as for V ₁	Fourth ICS, left sternal border	Same as for aVR
V ₃	Same as for V ₁	Midway between V ₂ and V ₄	Same as for aVR
V ₄	Same as for V ₁	Fifth ICS, left midclavicular line	Same as for aVR
V ₅	Same as for V ₁	Horizontal to V ₄ , left anterior axillary line	Same as for aVR
V ₆	Same as for V ₁	Horizontal to V ₄ , left midaxillary line	Same as for aVR

perform this skill. Remind the technician to notify the nurse or physician of any suspected abnormality. A nurse may direct a technician to take a 12-lead ECG on a patient experiencing chest pain to observe for diagnostic changes, but it is ultimately the physician's responsibility to interpret the ECG.

Continuous Electrocardiographic Monitoring

For continuous ECG monitoring, the electrodes are not placed on the limbs because movement of the extremities causes "noise," or motion artifact, on the ECG signal. Place the electrodes on the trunk, a more stable area, to minimize such artifacts and to obtain a clearer signal. If the monitoring system provides five electrode cables, place the electrodes as follows:

- Right arm electrode just below the right clavicle
- Left arm electrode just below the left clavicle
- Right leg electrode on the lowest palpable rib, on the right midclavicular line
- Left leg electrode on the lowest palpable rib, on the left midclavicular line
- Fifth electrode placed to obtain one of the six chest leads

With this placement, the monitor lead select control may be changed to provide lead I, II, III, aVR, aVL, or aVF or one chest lead. The monitor automatically alters the polarity of the electrodes to provide the lead selected.

The clarity of continuous ECG monitor recordings is affected by skin preparation and electrode quality. To ensure the best signal transmission and to decrease skin impedance, clean the skin and clip hairs or shave the area if needed. Make sure the area for electrode placement is dry. The gel on each electrode must be moist and fresh. Attach the electrode to the lead cable and then to the contact site. The contact site should be free of any lotion, tincture, or other substance that increases skin impedance. Electrodes cannot be placed on irritated skin or over scar tissue. The application of electrodes may be done by unlicensed assistive personnel (UAP), but the nurse must

determine which lead to select and check for correct electrode placement. Assess the quality of the ECG rhythm transmission to the monitoring system.

The ECG cables can be attached directly to a wall-mounted monitor (a hard-wired system) if the patient's activity is restricted to bedrest and sitting in a chair, as in a critical care unit. For an ambulatory patient, the ECG cable is attached to a battery-operated transmitter (a **telemetry** system) held in a pouch. The ECG is transmitted to a remote monitor via antennae located in strategic places, usually in the ceiling. Telemetry allows freedom of movement within a certain area without losing transmission of the ECG.

Most acute care facilities have monitor technicians (monitor "techs") who are educated in ECG rhythm interpretation and are responsible for:

- Watching a bank of monitors on a unit
- Printing ECG rhythm strips routinely and as needed
- Interpreting rhythms
- Reporting the patient's rhythm and significant changes to the nurse

The technical support is particularly helpful on a telemetry unit that does not have monitors at the bedside. The nurse remains ultimately responsible for accurate ECG rhythm interpretation, as well as for patient assessment and management.

Some units have full-disclosure monitors, which continuously store ECG rhythms in memory up to a certain amount of time, allowing nurses and health care providers to access and print them for more thorough patient assessment and management. Routine strips, as well as any changes in rhythm, are printed and documented in the patient's record.

The health care provider is responsible for determining when monitoring can be suspended, such as during showering. He or she also determines whether monitoring is needed during off-unit testing procedures and for transportation to other facilities.

Prehospital personnel, such as paramedics and emergency medical technicians (EMTs) with advanced training,

FIG. 36-3 Electrocardiographic waveforms are measured in amplitude (voltage) and duration (time).

FIG. 36-4 Each segment between the dark lines (*above the monitor strip*) represents 3 seconds when the monitor is set at a speed of 25 mm/sec. To estimate the ventricular rate, count the QRS complexes in a 6-second strip and then multiply that number by 10 to estimate the rate for 1 minute. In this example, there are 9 QRS complexes in 6 seconds. Therefore the heart rate can be estimated to be 90 beats/min.

frequently monitor ECG rhythms at the scene and on the way to a health care facility. They function under medical direction and protocols but may also be communicating with a nurse in the emergency department.

The ECG strip is printed on graph paper (Fig. 36-3), with each small block measuring 1 mm in height and width. ECG recorders and monitors are standardized at a speed of 25 mm/sec. Time is measured on the horizontal axis. At this speed, each small block represents 0.04 second. Five small blocks make up one large block, defined by darker bold lines and representing 0.20 second. Five large blocks represent 1 second, and 30 large blocks represent 6 seconds. Vertical lines in the top margin of the graph paper are usually 15 large blocks apart, representing 3-second segments (Fig. 36-4).

Electrocardiographic Complexes, Segments, and Intervals

Complexes that make up a normal ECG consist of a P wave, a QRS complex, a T wave, and possibly a U wave. Segments include the PR segment, the ST segment, and the TP segment. Intervals include the PR interval, the QRS duration, and the QT interval (Fig. 36-5).

The **P wave** is a deflection representing atrial depolarization. The shape of the P wave may be a positive, negative, or

biphasic (both positive and negative) deflection, depending on the lead selected. When the electrical impulse is consistently generated from the sinoatrial (SA) node, the P waves have a consistent shape in a given lead. If an impulse is then generated from a different (ectopic) focus, such as atrial tissue, the shape of the P wave changes in that lead, indicating that an ectopic focus has fired.

The **PR segment** is the isoelectric line from the end of the P wave to the beginning of the QRS complex, when the electrical impulse is traveling through the atrioventricular (AV) node, where it is delayed. It then travels through the ventricular conduction system to the Purkinje fibers.

The **PR interval** is measured from the beginning of the P wave to the end of the PR segment. It represents the time required for atrial depolarization as well as the impulse delay in the AV node and the travel time to the Purkinje fibers. It normally measures from 0.12 to 0.20 second (five small blocks).

The **QRS complex** represents ventricular depolarization. The shape of the QRS complex depends on the lead selected. The Q wave is the first negative deflection and is not present in all leads. When present, it is small and represents initial ventricular septal depolarization. When the Q wave is abnormally present in a lead, it represents myocardial necrosis (cell

- P wave:** Represents atrial depolarization.
- PR segment:** Represents the time required for the impulse to travel through the AV node, where it is delayed, and through the bundle of His, bundle branches, and Purkinje fiber network, just before ventricular depolarization.
- PR interval:** Represents the time required for atrial depolarization as well as impulse travel through the conduction system and Purkinje fiber network, inclusive of the P wave and PR segment. It is measured from the beginning of the P wave to the end of the PR segment.
- QRS complex:** Represents ventricular depolarization and is measured from the beginning of the Q (or R) wave to the end of the S wave.
- J point:** Represents the junction where the QRS complex ends and the ST segment begins.
- ST segment:** Represents early ventricular repolarization.
- T wave:** Represents ventricular repolarization.
- U wave:** Represents late ventricular repolarization.
- QT interval:** Represents the total time required for ventricular depolarization and repolarization and is measured from the beginning of the QRS complex to the end of the T wave.

FIG. 36-5 The components of a normal electrocardiogram.

death). The R wave is the first positive deflection. It may be small, large, or absent, depending on the lead. The S wave is a negative deflection following the R wave and is not present in all leads.

The **QRS duration** represents the time required for depolarization of both ventricles. It is measured from the beginning of the QRS complex to the J point (the junction where the QRS complex ends and the ST segment begins). It

normally measures from 0.04 to 0.10 second (up to three small blocks).

The **ST segment** is normally an isoelectric line and represents early ventricular repolarization. It occurs from the J point to the beginning of the T wave. Its length varies with changes in the heart rate, the administration of medications, and electrolyte disturbances. It is normally not elevated more than 1 mm or depressed more than 0.5 mm from the

FIG. 36-6 In this example, the heart rate using the big block method is $300 \div 4$ big blocks (between QRS complexes), or 75 beats/min. The memory method is also demonstrated with a heart rate of 75 beats/min.

isoelectric line. Its amplitude is measured at a point 1.5 to 2 mm after the J point. ST elevation or depression can be caused by myocardial injury, ischemia or infarction, conduction abnormalities, or the administration of medications.

The **T wave** follows the ST segment and represents ventricular repolarization. It is usually positive, rounded, and slightly asymmetric. If an ectopic stimulus excites the ventricles during this time, it may cause ventricular irritability, lethal dysrhythmias, and possible cardiac arrest in the vulnerable heart. This is known as the *R-on-T phenomenon*. T waves may become tall and peaked, inverted (negative), or flat as a result of myocardial ischemia, potassium or calcium imbalances, medications, or autonomic nervous system effects.

The **U wave**, when present, follows the T wave and may result from slow repolarization of ventricular Purkinje fibers. It is of the same polarity as the T wave, although generally it is smaller. It is not normally seen in all leads and is more common in lead V₃. An abnormal U wave may suggest an electrolyte abnormality (particularly hypokalemia) or other disturbance. Correct identification is important so that it is not mistaken for a P wave. If in doubt, notify the health care provider and request that a potassium level be obtained.

The **QT interval** represents the total time required for ventricular depolarization and repolarization. The QT interval is measured from the beginning of the QRS complex to the end of the T wave. This interval varies with the patient's age and gender and changes with the heart rate, lengthening with slower heart rates and shortening with faster rates. It may be prolonged by certain medications, electrolyte disturbances, Prinzmetal's angina, or subarachnoid hemorrhage. A prolonged QT interval may lead to a unique type of ventricular tachycardia called *torsades de pointes*.

Artifact is interference seen on the monitor or rhythm strip, which may look like a wandering or fuzzy baseline. It can be caused by patient movement, loose or defective electrodes, improper grounding, or faulty ECG equipment, such as broken wires or cables. Some artifact can mimic lethal

dysrhythmias like ventricular tachycardia (with tooth brushing) or ventricular fibrillation (with tapping on the electrode). *Assess the patient to differentiate artifact from actual lethal rhythms! Do not rely only on the ECG monitor.*

Determination of Heart Rate

The heart rate can be estimated by counting the number of QRS complexes in 6 seconds and multiplying that number by 10 to calculate the rate for a full minute. This is called the *6-second strip method* and is a quick method to determine the mean or average heart rate. This method is the least accurate; however, it is the method of choice for irregular rhythms.

For accuracy, the *big block method* is used if the QRS complexes are regular or evenly spaced. Count the number of big blocks between the same point in any two successive QRS complexes (usually R wave to R wave) and divide into 300. There are 300 big blocks in 1 minute. It is easiest to use a QRS that falls on a dark line. If little blocks are left over when counting big blocks, count each little block as 0.2, add this to the number of big blocks, and then divide that total into 300 (Fig. 36-6).

Count the number of large blocks in an interval and divide into 300 (the number of large blocks in 1 minute). For example, three large blocks equals a heart rate of 100 beats per minute ($300 \div 3 = 100$).

Another method (called the *memory method*) relies on memorizing this sequence: 300, 150, 100, 75, 60, 50, 43, 37, 33, 30. This is the big block method with the math already done. Find a QRS complex that falls on the dark line representing 0.2 second or a big block, and count backwards to the next QRS complex. Each dark line is a memorized number. This is the method most widely used in hospitals for calculating heart rates for regular rhythms.

Commercially prepared ECG rate rulers are based on these calculations and may be used for regular rhythms. Current monitoring systems will display a continuous heart rate and print the heart rate on the ECG strip. *Use caution and confirm that the rate is correct by assessing the patient's heart rate*

directly. Many factors can incorrectly alter the rate displayed by the monitor.

Electrocardiographic Rhythm Analysis

Analysis of an ECG rhythm strip requires a systematic approach using a six-step method facilitated by use of a measurement tool called an **ECG caliper**:

1. **Determine the heart rate.** If the atrial and ventricular rhythms are regular, use any of the methods previously described to calculate the heart rate. If the rhythms are irregular, use the 6-second strip method for accuracy. Normal heart rates fall between 60 and 100 beats/min. A rate less than 60 beats/min is called **bradycardia**. A rate greater than 100 beats/min is called **tachycardia**.
2. **Determine the heart rhythm.** Heart rhythms can be either regular or irregular. Irregular rhythms can be regularly irregular, occasionally irregular, or irregularly irregular. Check the regularity of the atrial rhythm by assessing the PP intervals, placing one caliper point on a P wave and placing the other point on the precise spot on the next P wave. Then move the caliper from P wave to P wave along the entire strip ("walking out" the P waves) to determine the regularity of the rhythm. P waves of a different shape (ectopic waves), if present, create an irregularity and do not walk out with the other P waves. A slight irregularity in the PP intervals, varying no more than three small blocks, is considered essentially regular if the P waves are all of the same shape. This alteration is caused by changes in intrathoracic pressure during the respiratory cycle.
Check the regularity of the ventricular rhythm by assessing the RR intervals, placing one caliper point on a portion of the QRS complex (usually the most prominent portion of the deflection) and the other point on the precise spot of the next QRS complex. Move the caliper from QRS complex to QRS complex along the entire strip (walking out the QRS complexes) to determine the regularity of the rhythm. QRS complexes of a different shape (ectopic QRS complexes), if present, create an irregularity and do not walk out with the other QRS complexes. A slight irregularity of no more than three small blocks between intervals is considered essentially regular if the QRS complexes are all of the same shape.
3. **Analyze the P waves.** Check that the P wave shape is consistent throughout the strip, indicating that atrial depolarization is occurring from impulses originating from one focus, normally the SA node. Determine whether there is one P wave occurring before each QRS complex, establishing that a relationship exists between the P wave and the QRS complex. This relationship indicates that an impulse from one focus is responsible for both atrial and ventricular depolarization. The nurse may observe more than one P wave shape, more P waves than QRS complexes, absent P waves, or P waves coming after the QRS, each indicating that a dysrhythmia exists. Ask these five questions when analyzing P waves:
 - Are P waves present?
 - Are the P waves occurring regularly?
 - Is there one P wave for each QRS complex?

- Are the P waves smooth, rounded, and upright in appearance, or are they inverted?
 - Do all the P waves look similar?
4. **Measure the PR interval.** Place one caliper point at the beginning of the P wave and the other point at the end of the PR segment. The PR interval normally measures between 0.12 and 0.20 second. The measurement should be constant throughout the strip. The PR interval cannot be determined if there are no P waves or if P waves occur after the QRS complex. Ask these three questions about the PR interval:
 - Are PR intervals greater than 0.20 second?
 - Are PR intervals less than 0.12 second?
 - Are PR intervals constant across the ECG strip?
 5. **Measure the QRS duration.** Place one caliper point at the beginning of the QRS complex and the other at the J point, where the QRS complex ends and the ST segment begins. The QRS duration normally measures between 0.04 and 0.10 second. The measurement should be constant throughout the entire strip. Check that the QRS complexes are consistent throughout the strip. When the QRS is narrow (0.10 second or less), this indicates that the impulse was not formed in the ventricles and is referred to as *supraventricular* or *above the ventricles*. When the QRS complex is wide (greater than 0.10 second), this indicates that the impulse is either of ventricular origin or of supraventricular origin with aberrant conduction, meaning deviating from the normal course or pattern. More than one QRS complex pattern or occasionally missing QRS complexes may be observed, indicating a dysrhythmia.
Ask these questions to evaluate QRS intervals:
 - Are QRS intervals less than or greater than 0.12 second?
 - Are the QRS complexes similar in appearance across the ECG paper?
 6. **Interpret the rhythm.** Using steps 1 to 5, you can interpret the cardiac rhythm and differentiate normal and abnormal cardiac rhythms.

NORMAL RHYTHMS

Normal sinus rhythm (NSR) is the rhythm originating from the sinoatrial (SA) node (dominant pacemaker) that meets these ECG criteria (Fig. 36-7):

- **Rate:** Atrial and ventricular rates of 60 to 100 beats/min
- **Rhythm:** Atrial and ventricular rhythms regular
- **P waves:** Present, consistent configuration, one P wave before each QRS complex
- **PR interval:** 0.12 to 0.20 second and constant
- **QRS duration:** 0.04 to 0.10 second and constant

Sinus arrhythmia is a variant of NSR. It results from changes in intrathoracic pressure during breathing. In this context, the term *arrhythmia* does not mean an absence of rhythm, as the term suggests. Instead, the heart rate increases slightly during inspiration and decreases slightly during exhalation. This irregular rhythm is frequently observed in healthy children as well as adults.

Sinus arrhythmia has all the characteristics of NSR except for its irregularity. The PP and RR intervals vary, with the difference between the shortest and the longest intervals being greater than 0.12 second (three small blocks):

FIG. 36-7 Normal sinus rhythm. Both atrial and ventricular rhythms are essentially regular (a slight variation in rhythm is normal). Atrial and ventricular rates are both 87 beats/min. There is one P wave before each QRS complex, and all the P waves are of a consistent morphology, or shape. The PR interval measures 0.18 second and is constant; the QRS complex measures 0.06 second and is constant.

- **Rate:** Atrial and ventricular rates between 60 and 100 beats/min
- **Rhythm:** Atrial and ventricular rhythms irregular, with the shortest PP or RR interval varying at least 0.12 second from the longest PP or RR interval
- **P waves:** One P wave before each QRS complex; consistent configuration
- **PR interval:** Normal, constant
- **QRS duration:** Normal, constant

Sinus arrhythmias occasionally are due to nonrespiratory causes, such as digitalis or morphine. These drugs enhance vagal tone and cause decreased heart rate and irregularity unrelated to the respiratory cycle.

DYSRHYTHMIAS

Overview

Any disorder of the heartbeat is called a **dysrhythmia**. Historically, the term *arrhythmia* has been used in the literature. Although the terms are often used interchangeably, *dysrhythmia* is more accurate. Dysrhythmias result from:

- A disturbance in the relationship between electrical conductivity and the mechanical response of the myocardium
- A disturbance in impulse formation (either from an abnormal rate or from an ectopic focus)
- A disturbance in impulse conduction (delays and blocks)
- The combination of several mechanisms

Although many dysrhythmias have no clinical manifestations, many others have serious consequences if not treated. A summary of key features is found in [Chart 36-1](#).

Dysrhythmia Terminology

Tachydysrhythmias are heart rates greater than 100 beats per minute. They are a major concern in the adult patient with coronary artery disease (CAD). Coronary artery blood flow occurs mostly during diastole when the aortic valve is closed and is determined by diastolic time and blood pressure in the root of the aorta. Tachydysrhythmias are serious because they:

- Shorten the diastolic time and therefore the coronary perfusion time (the amount of time available for blood to flow through the coronary arteries to the myocardium).
- Initially increase cardiac output and blood pressure. However, a continued rise in heart rate decreases the ventricular filling time because of a shortened diastole, decreasing the stroke volume. Consequently, cardiac output and blood pressure will begin to decrease, reducing aortic pressure and therefore coronary perfusion pressure.
- Increase the work of the heart, increasing myocardial oxygen demand.

The patient with a tachydysrhythmia may have:

- Palpitations
- Chest discomfort (pressure or pain from myocardial ischemia or infarction)
- Restlessness and anxiety
- Pale, cool skin
- Syncope (“blackout”) from hypotension

Tachydysrhythmias may also lead to heart failure. Presenting symptoms of heart failure may include dyspnea, lung

crackles, distended neck veins, fatigue, and weakness (see Chapter 37).

Bradydysrhythmias occur when the heart rate is less than 60 beats per minute. These rhythms can also be significant because:

- Myocardial oxygen demand is reduced from the slow heart rate, which can be beneficial.
- Coronary perfusion time may be adequate because of a prolonged diastole, which is desirable.
- Coronary perfusion pressure may decrease if the heart rate is too slow to provide adequate cardiac output and blood pressure; this is a serious consequence.

Therefore the patient may tolerate the bradydysrhythmia well if the blood pressure is adequate. If the blood pressure is not adequate, symptomatic bradydysrhythmias may lead to myocardial ischemia or infarction, dysrhythmias, hypotension, and heart failure.

Premature complexes are early rhythm complexes. They occur when a cardiac cell or cell group, other than the sinoatrial (SA) node, becomes irritable and fires an impulse before the next sinus impulse is produced. The abnormal focus is called an *ectopic focus* and may be generated by atrial, junctional, or ventricular tissue. After the premature complex, there is a pause before the next normal complex, creating an irregularity in the rhythm. The patient with premature complexes may be unaware of them or may feel **palpitations** or a “skipping” of the heartbeat. If premature complexes, especially those that are ventricular, become more frequent, the patient may experience symptoms of decreased cardiac output.

Premature complexes may occur *repetitively in a rhythmic fashion*:

- **Bigeminy** exists when normal complexes and premature complexes occur alternately in a repetitive two-beat pattern, with a pause occurring after each premature complex so that complexes occur in pairs.
- **Trigeminy** is a repeated three-beat pattern, usually occurring as two sequential normal complexes followed by a premature complex and a pause, with the same pattern repeating itself in triplets.
- **Quadrigeminy** is a repeated four-beat pattern, usually occurring as three sequential normal complexes followed by a premature complex and a pause, with the same pattern repeating itself in a four-beat pattern.

Such patterns may occur with atrial, junctional, or ventricular premature complexes. Patients may be unaware of the premature beats, or they may feel palpitations.

Classification of Dysrhythmias

Dysrhythmias are classified according to their site of origin. The sites include the SA node, atrial tissue, AV node, junctional tissue, and ventricular tissue. Dysrhythmias may be caused by a disturbance in impulse formation or by conduction delays or blocks. The incidence and the prevalence of dysrhythmias are not known because they usually result from an underlying condition, such as heart disease. This chapter is limited to the most common dysrhythmias and those that are potentially life threatening.

Sinus Dysrhythmias. The sinus node is the **pacemaker** in all sinus dysrhythmias. Innervation from sympathetic and parasympathetic nerves is normally in balance to ensure a normal sinus rhythm (NSR). An imbalance increases or

decreases the rate of SA node discharge either as a normal response to activity or physiologic changes or as a pathologic response to disease.

Sinus Tachycardia. Sympathetic nervous system stimulation or vagal (parasympathetic) inhibition results in an increased rate of SA node discharge, which increases the heart rate. When the rate of SA node discharge is more than 100 beats per minute, the rhythm is called **sinus tachycardia** (Fig. 36-8, A). Sinus tachycardia, with temporary heart rates of 200 to 220 beats per minute, may be normal in infants and children. The rate gradually decreases until age 10 years. From age 10 years to adulthood, the heart rate normally does not exceed 100 beats per minute except in response to activity, and then usually does not exceed 160 beats per minute. Rarely does the heart rate reach 180 beats per minute.

Sinus tachycardia initially increases cardiac output and blood pressure. However, continued increases in heart rate decrease coronary perfusion time, diastolic filling time, and coronary perfusion pressure while increasing myocardial oxygen demand.

Increased sympathetic stimulation is a normal response to physical activity but may also be caused by anxiety, pain, stress, fear, fever, anemia, hypoxemia, hyperthyroidism, and pulmonary embolism. Drugs such as epinephrine, atropine, caffeine, alcohol, nicotine, aminophylline, and thyroid medications may also increase the heart rate. In some cases, sinus tachycardia is a compensatory response to decreased cardiac output or blood pressure, as occurs in hypovolemic shock, myocardial infarction (MI), infection, and heart failure.

The patient may be asymptomatic except for an increased pulse rate. However, if the rhythm is not well tolerated, he or she may have symptoms.

! NURSING SAFETY PRIORITY

Action Alert

For patients with sinus tachycardia, assess for fatigue, weakness, shortness of breath, orthopnea, decreased oxygen saturation, and decreased blood pressure. Also assess for restlessness and anxiety from decreased cerebral perfusion and for decreased urine output from impaired renal perfusion. The patient may also have anginal pain and palpitations. The ECG pattern may show T-wave inversion or ST-segment elevation or depression in response to myocardial ischemia.

The desired outcome is to decrease the heart rate to normal levels by treating the underlying cause. Teach the patient to remain on bedrest if the tachycardia is causing hypotension or weakness.

Sinus Bradycardia. Excessive vagal (parasympathetic) stimulation to the heart causes a decreased rate of sinus node discharge. It may result from carotid sinus massage, vomiting, suctioning, **Valsalva maneuvers** (e.g., bearing down for a bowel movement or gagging), ocular pressure, or pain. Increased parasympathetic stimuli may also result from hypoxia, inferior wall MI, and the administration of drugs such as beta-adrenergic blocking agents, calcium channel blockers, and digitalis.

The stimuli slow the heart rate and decrease the speed of conduction through the heart. When the sinus node discharge rate is less than 60 beats/min, the rhythm is called **sinus bradycardia** (Fig. 36-8, B). Sinus bradycardia increases

FIG. 36-8 Sinus rhythms. **A**, Sinus tachycardia (heart rate, 115 beats/min; PR interval, 0.12 second; QRS complex, 0.08 second). **B**, Sinus bradycardia (heart rate, 52 beats/min; PR interval, 0.18 second; QRS complex, 0.08 second).

coronary perfusion time, but it may decrease coronary perfusion pressure. However, myocardial oxygen demand is *decreased*. Well-conditioned athletes who are bradycardic have a hypereffective heart, in which the strong heart muscle provides an adequate stroke volume and a low heart rate to achieve a normal cardiac output.

The patient with sinus bradycardia may be asymptomatic except for the decreased pulse rate. At times, however, the rhythm may not be well tolerated. Assess the patient for:

- Syncope (“blackouts” or fainting)
- Dizziness and weakness
- Confusion
- Hypotension
- Diaphoresis (excessive sweating)
- Shortness of breath
- Chest pain

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

An older client has been taking metoprolol (Toprol) for hypertension for the past 3 days. Her daughter states that she has become confused, dizzy, and weak since starting the drug. How will the telephone triage nurse respond to the daughter’s concerns?

- A. “She’s getting older, so confusion is common from aging.”
- B. “Did your mother pass out at any time in the past few days?”
- C. “Tell your mother to stop taking the metoprolol for a week.”
- D. “Tell your mother to only take half of the drug today.”

If the patient has any of these symptoms and the underlying cause cannot be determined, the treatment is to administer drug therapy, increase intravascular volume via IV fluids, and apply oxygen. If the heart rate does not increase sufficiently, pacing may be needed to increase the heart rate.

Atrial Dysrhythmias. With atrial dysrhythmias, the focus of impulse generation shifts away from the sinus node to the atrial tissues. The shift changes the axis (direction) of atrial depolarization, resulting in a P-wave shape that differs from normal P waves. The most common atrial dysrhythmias are:

- Premature atrial complexes
- Supraventricular tachycardia
- Atrial fibrillation

Premature Atrial Complexes. A **premature atrial complex (PAC)** occurs when atrial tissue becomes irritable. This ectopic focus fires an impulse before the next sinus impulse is due. The premature P wave may not always be clearly visible because it can be hidden in the preceding T wave. Examine the T wave closely for any change in shape, and compare with other T waves. A PAC is usually followed by a pause.

The causes of atrial irritability include:

- Stress
- Fatigue
- Anxiety
- Inflammation
- Infection
- Caffeine, nicotine, or alcohol

- Drugs such as epinephrine, sympathomimetics, amphetamines, digitalis, or anesthetic agents

PACs may also result from myocardial ischemia, hypermetabolic states, electrolyte imbalance, or atrial stretch. Atrial stretch can result from congestive heart failure, valvular disease, and pulmonary hypertension with cor pulmonale.

The patient usually has no symptoms except for possible heart palpitations. No intervention is needed except to treat causes such as heart failure. If PACs occur frequently, they may lead to more serious atrial tachydysrhythmias and therefore may need treatment. Administration of prescribed antidysrhythmic drugs may be necessary. Teach the patient measures to manage stress and substances to avoid, such as caffeine and alcohol, that are known to increase atrial irritability.

Supraventricular Tachycardia. **Supraventricular tachycardia (SVT)** involves the rapid stimulation of atrial tissue at a rate of 100 to 280 beats/min in adults. During SVT, P waves may not be visible, especially if there is a 1:1 conduction with rapid rates, because the P waves are embedded in the preceding T wave. *SVT may occur in healthy young people, especially women.*

SVT is usually due to a re-entry mechanism in which one impulse circulates repeatedly throughout the atrial pathway, re-stimulating the atrial tissue at a rapid rate. The term **paroxysmal supraventricular tachycardia (PSVT)** is used when the rhythm is intermittent. It is initiated suddenly by a premature complex such as a PAC and terminated suddenly with or without intervention.

The clinical manifestations depend on the duration of the SVT and the rate of the ventricular response. In patients with a *sustained* rapid ventricular response, assess for palpitations, chest pain, weakness, fatigue, shortness of breath, nervousness, anxiety, hypotension, and syncope. Cardiovascular deterioration may occur if the rate does not sustain adequate blood pressure. In that case, SVT can result in angina, heart failure, and cardiogenic shock. With a *nonsustained* or slower ventricular response, the patient may be asymptomatic except for occasional palpitations.

If SVT occurs in a healthy person and stops on its own, no intervention may be needed other than eliminating identified causes. If it continues, the patient should be studied in the electrophysiology study (EPS) laboratory. The preferred treatment for recurrent SVT is radiofrequency catheter ablation, described later in this chapter. In sustained SVT with a rapid ventricular response, the desired outcomes of treatment

are to decrease the ventricular response, convert the dysrhythmia to a sinus rhythm, and treat the cause. **Chart 36-2** lists drugs that may be used for SVT.

Atrial Fibrillation

Pathophysiology. **Atrial fibrillation (AF)** is the most common dysrhythmia seen in clinical practice. It impairs quality of life, causes considerable morbidity and mortality, and imposes a large economic burden on health care systems (Dagres & Anastasiou-Nana, 2010).

AF is associated with atrial fibrosis and loss of muscle mass. A mutation in the *lamin AC* (LMAC) gene has been linked to atrial fibrosis and dilation (Hardin & Steele, 2008). These structural changes are common in heart diseases such as hypertension, heart failure, and coronary artery disease. As AF progresses, cardiac output decreases by as much as 20 to 30 percent.

Currently, approximately 2.3 million people in the United States are diagnosed with AF; it is estimated that more than 12 million people will have AF by the year 2050 (Tedrow et al., 2010). The incidence of AF increases with age; AF causes serious problems in older people, leading to stroke and/or heart failure. Risk factors include hypertension (HTN), previous ischemic stroke, transient ischemic attack (TIA) or other thromboembolic event, coronary heart disease, diabetes mellitus, heart failure, and mitral valve disease (Holding et al., 2009).

In addition to advanced age, obesity, Caucasian race, and excessive alcohol have been identified as risk factors for AF (see the Evidence-Based Practice box on p. 727). About half of obese adults may develop AF (Chilukuri et al., 2010). Caucasians are more at risk for AF than African Americans and other ethnic groups, perhaps because of the larger left atrial diameter in Caucasians (Marcus et al., 2010). AF that is temporary and reversible is associated with excessive alcohol consumption (sometimes called *holiday heart syndrome*) (McDonough, 2009).

In patients with AF, multiple rapid impulses from many atrial foci depolarize the atria in a totally disorganized manner at a rate of 350 to 600 times per minute; ventricular response is usually 120 to 200 beats per minute. The result is a chaotic rhythm with no clear P waves, no atrial contractions, loss of atrial kick, and an irregular ventricular response (Fig. 36-9). The atria merely quiver in fibrillation (commonly called “A fib”). Often the ventricles beat with a rapid rate in response to the numerous atrial impulses. Heart dilation and blood pooling in the atria can lead to thrombus formation, and this increases the risk for stroke or other embolic events. The rapid and irregular ventricular rate decreases ventricular filling and reduces cardiac output, further impairing the heart’s perfusion ability.

Patient-Centered Collaborative Care. AF may be intermittent or chronic. Symptoms depend on the ventricular rate. If the ventricular rate is rapid, the presenting symptoms may be similar to those described earlier for supraventricular tachycardia. Because of loss of atrial kick, however, the patient in uncontrolled AF is at greater risk for an inadequate cardiac output. Assess the patient for fatigue, weakness, shortness of breath, dizziness, anxiety, syncope, palpitations, chest discomfort or pain, and hypotension. Some patients may be asymptomatic.

The loss of coordinated atrial contractions in AF can lead to stagnation of blood resulting in thrombus formation. The

DECISION-MAKING CHALLENGE

Patient-Centered Care; Safety

A 40-year-old female patient is admitted to the telemetry unit where you work reporting palpitations. About an hour after admission, she becomes short of breath and diaphoretic. Her vital signs are as follows: pulse 166, respirations 32, oxygen saturation 98%, BP 120/80, and pain 6 on a scale of 0-10. The ECG waveform shows paroxysmal supraventricular tachycardia (PSVT).

1. What other questions would you ask this patient for assessment?
2. What could be the underlying causes of the patient’s tachycardia?
3. Does this dysrhythmia need treatment? Why or why not? What intervention would you implement first? What is the source of evidence that supports your answer?
4. What drug therapy is indicated? What nonpharmacologic interventions could you try?

Common Dysrhythmias

DRUG	USUAL DOSAGE	NURSING INTERVENTIONS	RATIONALES
Class I Drugs			
Type IA			
Disopyramide phosphate (Norpace) Used for AF, WPW, PSVT, PVCs, VT	100-200 mg orally every 6 hr	Monitor BP. Watch for shortness of breath and weight gain. Monitor for widening QRS complex, prolonged QT or PR interval, or heart block.	Hypotension is a common side effect. Disopyramide can cause heart failure in a patient with CAD. Toxic side effects necessitate stopping disopyramide administration.
Type IB			
Lidocaine (Xylocaine) Used for PVCs, VT, VF	1-1.5 mg/kg IV bolus, then 0.5-0.75 mg/kg IV boluses every 5-10 min to a loading dose of 3 mg/kg, followed by 2-4 mg/min infusion For VF or pulseless VT: 1-1.5 mg/kg IV bolus every 3-5 min to a loading dose of 3 mg/kg, followed by 2-4 mg/min infusion	Watch for confusion, paresthesias, slurring of speech, drowsiness, or seizure activity.	CNS adverse effects predominate; they may require a decrease in dosage or discontinuation of the infusion.
Mexiletine hydrochloride (Mexitil) Used for PVCs, VT, VF	200-300 mg orally every 8 hr with food 125-250 mg IV bolus for 5-10 min 0.5-1.5 mg/min infusion	Monitor BP and heart rate. Assess for tremors, blurred vision, dizziness, ataxia, or confusion.	Hypotension and bradycardia may occur. CNS adverse reactions predominate.
Tocainide hydrochloride (Tonocard) Used for PVCs, VT, VF	400 mg orally every 8 hr initially 400-800 mg orally every 8 hr Maximum of 2.4 g daily Take with food	Watch for tremors. Monitor heart rate and BP. Teach patient to report shortness of breath, wheezing, chest pain, or cough, as well as dyspnea and distended neck veins or swelling of the extremities.	Tremors indicate that the maximum dose is being approached. Bradycardia and hypotension may occur. Pulmonary fibrosis is a serious side effect, which necessitates discontinuation of the drug; the drug may also cause CHF.
Type IC			
Flecainide acetate (Tambocor) Used for AF, PSVT, life-threatening ventricular dysrhythmias	100 mg orally twice daily Maximum dose of 400 mg	Monitor for an increase in frequency and severity of dysrhythmias. Monitor heart rate and BP. Monitor for CHF, dizziness, visual disturbances, paresthesias, and tremors.	Flecainide can induce dysrhythmias. Bradycardia and hypotension may occur. Side effects may require a decrease in dosage or discontinuation of the drug.
Propafenone hydrochloride (Rythmol) Used for PAF, WPW, life-threatening ventricular dysrhythmias	150-300 mg orally every 8 hr	Monitor for an increase in dysrhythmias. Monitor heart rate and BP. Monitor for CNS effects, dizziness, anxiety, ataxia, insomnia, confusion, and seizures, as well as CHF and GI distress.	Propafenone can induce dysrhythmias. Bradycardia and hypotension may occur. Side effects may require a decrease in dosage or discontinuation of the drug.
Class II Drugs			
Propranolol hydrochloride (Inderal, Apo-Propranolol)  Used for AF, atrial flutter, PSVT, PVCs	10-80 mg orally four times daily before meals 0.1 mg/kg slow IV bolus divided into 3 equal doses given at intervals of 2-3 min at rate of 1 mg/min	Monitor heart rate and BP. Assess for shortness of breath or wheezing. Assess for insomnia, fatigue, and dizziness.	Bradycardia and decreased BP are expected effects. Beta ₂ -blocking effects on the lungs can cause bronchospasm. Side effects may require decrease in dosage or discontinuation of the drug.
Acebutolol hydrochloride (Sectral) Used for AF, atrial flutter, PSVT, PVCs	600-1200 mg orally daily	Monitor heart rate and BP. Assess for shortness of breath or wheezing. Assess for insomnia, fatigue, and dizziness.	Bradycardia and decreased BP are expected effects. Beta ₂ -blocking effects on the lungs can cause bronchospasm. Side effects may require a decrease in dosage or discontinuation of the drug.

CHART 36-2 COMMON EXAMPLES OF DRUG THERAPY

Common Dysrhythmias—cont'd

DRUG	USUAL DOSAGE	NURSING INTERVENTIONS	RATIONALES
Esmolol hydrochloride (Brevibloc) Used for AF, atrial flutter, PSVT, PVCs	Initially, 500 mcg/kg/min for 1 min, then 50 mcg/kg/min for 4 min IV Titrate up if necessary	Monitor heart rate and BP. Assess for shortness of breath or wheezing. Assess for insomnia, fatigue, and seizures.	Bradycardia and decreased BP are expected effects. Beta ₂ -blocking effects on the lungs can cause bronchospasm. Side effects may require a decrease in dosage or discontinuation of the drug.
Sotalol hydrochloride (Betapace) Used for AF, PAF, PSVT, life-threatening ventricular dysrhythmias	Initial dose of 80 mg orally twice daily Dosage may be increased every 2-3 days, if necessary, to 240-320 mg daily in 2-3 divided doses	Assess ECG rhythm for torsades de pointes and other serious new ventricular dysrhythmias. Assess for fatigue, bradycardia, dyspnea, CHF, chest pain, hypotension, dizziness, hypoglycemia, nausea, and vomiting. Sotalol should not be administered to patients with hypokalemia or hypomagnesemia before correction of these imbalances. Sotalol is contraindicated in patients with bronchial asthma, sinus bradycardia, or second- and third-degree AV block (unless a functioning pacemaker is present), prolonged QT syndrome, cardiogenic shock, or CHF.	Sotalol may have proarrhythmic effects. Adverse reactions may warrant drug discontinuation. Hypokalemia or hypomagnesemia may prolong the QT interval and cause torsades de pointes. Sotalol has beta-blocking (class II) effects and class III effects.
Class III Drugs Amiodarone hydrochloride (Cordarone) Used for AF, PAF, PSVT, life-threatening ventricular dysrhythmias	800-1600 mg orally daily in divided doses for 1-3 wk, then 600-800 mg daily for 1 mo, then 200-600 mg daily (average of 400 mg daily) Rapid loading dose: 150 mg IV over first 10 min (15 mg/min); slow loading dose: 360 mg IV over next 6 hr (1 mg/min); maintenance infusion: 540 mg IV over next 18 hr (0.5 mg/min), then 720 mg/24 hr (0.5 mg/min)	Use volumetric infusion pump and polyvinyl chloride tubing with in-line filter, and infuse via central line. Rapid-loading IV dose must not be administered faster than 10 min. Must stay with patient and monitor heart rate and BP. Continually monitor ECG rhythm during IV infusion; measure QT and QTc. Assess the patient's knowledge of the treatment regimen and side effects. Monitor heart rate, BP, and cardiac rhythm when initiating therapy. Teach patients to report any muscle weakness, tremors, or difficulty with ambulation. Teach patients to report shortness of breath, cough, pleuritic pain, or fever. Teach patients to report any visual disturbances and to wear sunglasses outdoors in the daytime if they have photophobia. Teach patients to use barrier sunscreens. Teach patients to report any signs of thyroid problems or hepatotoxicity.	Drug is irritating to peripheral vasculature; drug is more stable in glass bottle. Hypotension may occur. It should be treated by slowing the infusion and other standard therapy. Cordarone should not be discontinued unless necessary. Bradycardia and AV block may occur and are treated by slowing the infusion rate and providing pacemaker therapy, if necessary. May cause a worsening of ventricular dysrhythmias. Drug has major side effects, which make noncompliance a problem; patients may take the drug for 1½-3 mo before full clinical effects are apparent. Bradycardia, hypotension, and worsening dysrhythmia can occur. Muscle-related side effects usually develop during the first week of treatment. Pulmonary side effects may indicate drug-induced pulmonary toxicity. Corneal pigmentation occurs in most patients but generally does not interfere with vision; if it does, the dosage is decreased. Photosensitivity reactions may occur. Thyroid problems or hepatotoxicity may occur, necessitating a decrease in dosage or discontinuation of the drug.

Dronedarone (Multaq) Used for AF, atrial flutter	400 mg twice daily with meals	Monitor heart rate, BP, and cardiac rhythm when initiating therapy. Monitor BUN, creatinine, and liver function panel. Teach patients to take with a meal. Do not take with grapefruit juice. Teach patient to notify the doctor if signs of worsening heart failure such as weight gain, dependent edema, or increasing shortness of breath. Teach patient if a dose is missed, take at next regularly scheduled dose. Do not double dose. Advise patient to report all medications to doctor (prescription, OTC, and herbal products, especially St. John's wort).	Bradycardia and worsening dysrhythmia can occur. May cause worsening renal function. Drug is contraindicated for patients with severe hepatic impairment. Better absorbed with food. Grapefruit juice alters drug effectiveness. Drug is contraindicated for patients with heart failure.
Ibutilide fumarate (Corvert) Used for AF, atrial flutter	1 mg IV over 10 min for patients >60 kg; 0.01 mg/kg over 10 min for patients <60 kg May repeat dose 10 min after completion of first infusion if necessary	Stop infusion as soon as dysrhythmia is terminated, or in event of sustained or nonsustained VT, or marked prolongation of QT or QTc. Observe patients with continuous ECG monitoring and measure QT or QTc for at least 4 hr after infusion or until QTc has returned to baseline. Patients with atrial fibrillation of >2-3 days' duration must be adequately anticoagulated for at least 2 wk. Hypokalemia and hypomagnesemia must be corrected before Corvert infusion. Teach patients to change positions slowly. Inform patients that dosages will be adjusted, depending on their creatinine clearance level. Monitor patients on telemetry for several days; observe for and report bradycardia and hypotension.	May have serious drug interaction and cause potentially fatal dysrhythmias. Drug may cause potentially fatal dysrhythmias.
Dofetilide (Tikosyn) Used for AF, atrial flutter	125-500 mcg orally twice daily	Observe patients with atrial fibrillation of >2-3 days' duration must be adequately anticoagulated for at least 2 wk. Hypokalemia and hypomagnesemia must be corrected before Corvert infusion. Teach patients to change positions slowly. Inform patients that dosages will be adjusted, depending on their creatinine clearance level. Monitor patients on telemetry for several days; observe for and report bradycardia and hypotension.	Acute ventricular dysrhythmias must be promptly identified and treated. Patient may develop heart blocks. Atrial fibrillation is associated with formation of thrombi in atrial chambers. This is important to reduce potential for proarrhythmic effects. Orthostatic hypotension is a common side effect of the drug. The patient must have adequate creatinine clearance to prevent drug toxicity. Bradycardia and hypotension are common side effects.
Class IV Drugs			
Verapamil hydrochloride (Calan, Isoptin ) Used for AF, atrial flutter, PSVT	2.5-5 mg IV for 1-2 min for narrow-complex SVT or PSVT; after 15-30 min may give 5-10 mg IV for 1-2 min, if necessary, and repeat to a maximum of 20 mg 80-120 mg orally every 6-8 hr	Monitor heart rate and BP. Teach patients to remain recumbent for at least 1 hr after IV administration. Teach patients to change positions slowly when receiving oral therapy. Teach patients to report dyspnea, orthopnea, distended neck veins, or swelling of the extremities.	Bradycardia and hypotension are common side effects. Hypotension may occur; may be reversed with calcium chloride (CaCl₂), 0.5-1 g slow IV. Dizziness and orthostatic hypotension often occur until tolerance develops. Heart failure may occur, necessitating a decrease in dosage or discontinuation of the drug.

Continued

CHART 36-2 COMMON EXAMPLES OF DRUG THERAPY

Common Dysrhythmias—cont'd

DRUG	USUAL DOSAGE	NURSING INTERVENTIONS	RATIONALES
Diltiazem hydrochloride (Cardizem) Used for AF, atrial flutter, PSVT	0.25 mg/kg IV for 2 min After 15 min, give 0.35 mg/kg IV for 2 min 5-15 mg/hr IV infusion	Monitor heart rate and BP. Teach patients to remain recumbent for at least 1 hr after IV administration. Teach patients to report dyspnea, orthopnea, distended neck veins, or swelling of the extremities.	Bradycardia and hypotension are common side effects. Hypotension may occur. Heart failure may occur, necessitating a decrease in dosage or discontinuation of the drug.
Other Drugs			
Digoxin (Lanoxin, Novodigoxin) ✱ Used for CHF, AF, atrial flutter, PSVT	Rapid digitalization: 0.5-1 mg orally or IV initially; 0.125-0.5 mg orally every 6 hr or IV until a total of 1-1.5 mg is reached Maintenance: 0.125-0.25 mg orally or IV daily or every other day (may be less for older adults)	Assess apical heart rate for 1 min before each dose. Assess for sudden increase in heart rate and change of rhythm from regular to irregular, or irregular to regular. Teach patients to report anorexia, nausea, vomiting, diarrhea, paresthesias, confusion, or visual disturbances. Monitor serum potassium levels.	Decreased heart rate is an expected response, but bradycardia may indicate toxicity. Changes in heart rate or rhythm may indicate toxicity. Side effect can indicate toxicity.
Atropine sulfate Used for bradycardia	0.5-1 mg IV bolus may be repeated every 3-5 min, if necessary, to a maximum of 0.04 mg/kg	Monitor serum creatinine levels. Monitor heart rate and rhythm after administration. Assess for chest pain after administration. Assess for urinary retention and dry mouth after administration. Avoid using in patients with acute angle-closure glaucoma.	Hypokalemia increases the risk for toxicity and ventricular dysrhythmias. Impaired renal function can cause toxicity; the dosage is altered if this occurs. Increased heart rate is expected. Increased heart rate may cause ischemia in patients with CAD. Atropine is an anticholinergic agent. Atropine increases intraocular pressure.
Adenosine (Adenocard) Used for PSVT, WPW	6 mg IV for 1-3 sec followed by 20-mL saline flush; repeat in 1-2 min at 12 mg IV for 1-3 sec with 20-mL flush	Monitor heart rate and rhythm after administration.	A short period of asystole is common after administration; bradycardia and hypotension may occur. These side effects commonly occur.
Magnesium sulfate Used for torsades de pointes	1-2 g diluted in 100 mL of D ₅ W administered IV for 1-2 min for VF or VT 1-2 g in 50-100 mL of D ₅ W for 5-60 min for loading dose; 0.5-1 g/hr for 24 hr for supplementation	Assess patients for facial flushing, shortness of breath, dyspnea, and chest pain. Assess patients for recurrence of PSVT or ventricular ectopy. Assess ECG rhythm for conversion to sinus rhythm. Assess patients for facial flushing, hypotension, and respiratory and CNS depression.	Recurrence of PSVT is common; PVCs may occur. Hypomagnesemia may precipitate refractory VF. Magnesium sulfate causes vasodilation and respiratory and CNS depression.

AF, Atrial fibrillation; AV, atrioventricular; BP, blood pressure; CAD, coronary artery disease; CHF, congestive heart failure; CNS, central nervous system; D₅W, 5% dextrose in water; ECG, electrocardiogram; EMD, electromechanical dissociation; OTC, over-the-counter; PAF, paroxysmal atrial fibrillation/flutter; PEA, pulseless electrical activity; PSVT, paroxysmal supraventricular tachycardia; PVC, premature ventricular complex; SVT, supraventricular tachycardia; VF, ventricular fibrillation; VT, ventricular tachycardia; W/PW, Wolff-Parkinson-White.

EVIDENCE-BASED PRACTICE

Is There a Relationship Between Obesity and Atrial Fibrillation?

Tedrow, U.B., Conen, D., Ridker, P.M., Cook, N.R., Koplan, B.A., Manson, J.E., et al. (2010). The long- and short-term impact of elevated body mass index on the risk of new atrial fibrillation: The WHS (Women's Health Study). *Journal of the American College of Cardiology*, 55(21), 2319-2327.

There has been an increase in atrial fibrillation (AF) in recent years that is not explained by aging alone. Modifiable risk factors must be identified. Recent evidence estimates that 32.2% of adults are obese (body mass index [BMI] >30) and 6.9% of women are extremely obese (BMI >40). This study used data from the WHS and included 34,309 women who were followed for approximately 12.9 years. Participants reported their weight on questionnaires at 24-, 36-, 60-, 72-, and 108-month intervals. During this time, 834 AF events were confirmed. BMI was linearly associated with AF risk, and being overweight and/or obese was associated with short-term increases in AF risk. Participants who became obese had a 41% risk for developing AF. Study limitations include the heterogeneous population with self-reported height/weight, and lack of electrocardiograph (ECG) screening. The researchers concluded that weight-control strategies may reduce AF incidence.

Level of Evidence: 1

The evidence was obtained from a randomized trial of a very large longitudinal national study using multiple methods of data collection.

Commentary: Implications for Nursing Practice and Research

Obesity is a major health concern in the United States. Cases of AF are increasing. Both affect the economy of health care because of complications and hospital admissions. Nurses need to recognize AF risk factors and provide proactive education to patients at risk for obesity, cardiovascular disease, and atrial fibrillation. Further research is needed to replicate the study on different populations, to determine the economic impact on health care, and to determine if weight loss reduces the incidence of AF.

patient is at risk for pulmonary embolism. Thrombi may form within the right atrium and then move through the right ventricle to the lungs. In addition, the patient is at risk for systemic emboli, particularly an embolic stroke, which may cause severe neurologic impairment or death. Patients with

AF who have valvular disease are particularly at risk for venous thromboembolism (VTE). Monitor patients carefully for these complications (see Chapter 38).

Traditional interventions for AF include antidysrhythmic drugs to slow the ventricular conduction or to convert the AF to normal sinus rhythm (NSR). Examples of these drugs are calcium channel blockers like diltiazem (Cardizem) or, for more difficult-to-control AF, amiodarone (Cordarone). Dronedarone (Multaq) is a new drug similar to amiodarone, yet better tolerated by patients, for maintenance of sinus rhythm after cardioversion (Cheng, 2010). However, dronedarone should not be used in patients with a history or current congestive heart failure because it can cause an exacerbation of cardiac symptoms.

Beta blockers, such as metoprolol (Toprol, Dutoprol) and esmolol (Brevibloc), may also be used to slow ventricular response. Digoxin (Lanoxin, Novo-Digoxin) is given for patients with heart failure and AF.

Anticoagulants, such as heparin, enoxaparin (Lovenox), and warfarin (Coumadin), may also be given for patients at high risk for emboli. Because of the unpredictable drug response, laboratory monitoring (e.g., international normalized ratio [INR]), and many food/drug interactions with warfarin, clinical trials are ongoing for newer, more effective medications (Garlitski & Estes, 2010). When taking warfarin, teach patients the importance of avoiding high vitamin K foods and avoiding herbs, such as ginger, ginseng, goldenseal, *Ginkgo biloba*, and St. John's wort, which could interfere with the drug's action. Chapter 38 describes anticoagulant therapy in detail on p. 800.

Because of the problems associated with warfarin, alternative anticoagulant agents may be given on a long-term basis to prevent strokes associated with AF. Examples include antiplatelet drugs, such as aspirin and clopidogrel (Plavix), or one

! NURSING SAFETY PRIORITY**Drug Alert**

Teach patients taking any type of anticoagulant drug to report bruising, bleeding nose or gums, and other signs of bleeding to their health care provider immediately. Also remind them to take aspirin with food to prevent GI distress.

FIG. 36-9 Atrial fibrillation. Note wavy baseline with atrial electrical activity and irregular ventricular rhythm.

of the newer direct thrombin inhibitors, such as dabigatran (Pradaxa). These drugs should be used cautiously in patients over 75 years of age due to their risk of falls (Sellers & Newby, 2011).

Cardioversion is the electrical treatment of choice when drugs are not effective. Before elective cardioversion, the health care provider prescribes anticoagulation therapy for about 6 weeks to prevent a thromboembolic event if the rhythm is successfully converted. To assess for the presence of atrial clots, a contraindication for cardioversion, the physician may order a transesophageal echocardiogram (TEE) before attempting emergency cardioversion (see Chapter 35). When AF has persisted more than 12 months, it is not likely to convert to a sinus rhythm by drug therapies and may fail to respond to electrical cardioversion, which is discussed on p. 737.

AF resistant to medical therapies may be treated with *percutaneous radiofrequency catheter ablation*. Pulmonary vein ablation creates scar tissue that blocks impulses and disconnects the pathway of the abnormal rhythm. The evidence indicates an increase in the number and complexity of catheter ablation procedures for AF. Data from 85 international centers indicated an 80% success rate defined as freedom from AF with or without drugs, and a complication rate of 4.5%. The United States is establishing the *Safety of AF Ablation Registry Initiative* to collect data that should be a valuable source of statistics on the safety and efficacy of AF ablation procedures (Garlitski & Estes, 2010). Patients with AF with a rapid ventricular rate not responsive to drug therapy may have AV nodal ablation performed to totally disconnect the conduction from the atria to the ventricles. However, this treatment requires implantation of a permanent ventricular pacemaker.

Bi-ventricular pacing may be another alternative for patients with heart failure and conduction disorders. Bi-atrial pacing, anti-tachycardia pacing, and implantable atrial defibrillators are other methods used to suppress or resolve AF. All of these methods are discussed on p. 733.

Patients in AF with heart failure (discussed in Chapter 37) may benefit from the *surgical maze procedure*, an open-chest surgical technique often performed with coronary artery bypass grafting (CABG). Before this procedure, electrophysiologic mapping studies are done to confirm the diagnosis of AF. The surgeon places a maze of sutures in strategic places in the atrial myocardium, pulmonary artery, and possibly the superior vena cava to prevent electrical circuits from developing and continuing AF. Sinus impulses can then depolarize the atria before reaching the AV node and preserve the atrial kick. Postoperative care is similar to that after other open-heart surgical procedures (see Chapter 40).

The *catheter maze procedure* is done by inserting a catheter through a leg vein into the atria and dragging a heated ablating catheter along the atria to create lines (scars) of conduction block. Patients having this minimally invasive form of the procedure have fewer complications, less pain, and a quicker recovery than those with the open, surgical maze procedure.

Ventricular Dysrhythmias. Ventricular dysrhythmias are potentially more life threatening than atrial dysrhythmias because the left ventricle pumps oxygenated blood throughout the body to perfuse vital organs and other tissues. The most common or life-threatening ventricular dysrhythmias include:

- Premature ventricular complexes
- Ventricular tachycardia
- Ventricular fibrillation
- Ventricular asystole

Premature Ventricular Complexes. **Premature ventricular complexes (PVCs)**, also called premature ventricular contractions, result from increased irritability of ventricular cells and are seen as early ventricular complexes followed by a pause. When multiple PVCs are present, the QRS complexes may be unifocal or uniform, meaning that they are of the same shape (Fig. 36-10, A), or multifocal or multiform, meaning that they are of different shapes (Fig. 36-10, B). PVCs frequently occur in repetitive rhythms, such as bigeminy (two), trigeminy (three), and quadrigeminy (four). Two sequential PVCs are a pair, or couplet. Three or more successive PVCs are usually called **nonsustained ventricular tachycardia (NSVT)**.

Premature ventricular contractions are common, and their frequency increases with age. They may be insignificant or may occur with problems such as myocardial infarction, chronic heart failure, chronic obstructive pulmonary disease (COPD), and anemia. PVCs may also be present in patients with hypokalemia or hypomagnesemia. Sympathomimetic agents, anesthesia drugs, stress, nicotine, caffeine, alcohol, infection, or surgery can also cause PVCs, especially in older adults. Postmenopausal women often find that caffeine causes palpitations and PVCs.

The patient may be asymptomatic or experience palpitations or chest discomfort caused by increased stroke volume of the normal beat after the pause. Peripheral pulses may be diminished or absent with the PVCs themselves because the decreased stroke volume of the premature beats may decrease peripheral perfusion.

! NURSING SAFETY PRIORITY

Action Alert

Because other dysrhythmias can cause widened QRS complexes, assess whether the premature complexes perfuse to the extremities. Palpate the carotid, brachial, or femoral arteries while observing the monitor for widened complexes or auscultating apical heart sounds. With acute MI, PVCs may be considered as a warning, possibly triggering life-threatening ventricular tachycardia (VT) or ventricular fibrillation (VF).

If there is no underlying heart disease, PVCs are not usually treated other than by eliminating any contributing cause (e.g., caffeine, stress). With acute myocardial ischemia or MI, PVCs are managed by administering oxygen and amiodarone (Cordarone) as prescribed. Potassium is given for replacement therapy if hypokalemia is the cause. People with more than 5000 PVCs in a 24-hour period are usually placed on beta blockers.

Ventricular Tachycardia. **Ventricular tachycardia (VT)**, sometimes referred to as “V tach,” occurs with repetitive firing of an irritable ventricular ectopic focus, usually at a rate of 140 to 180 beats/min or more (Fig. 36-11). VT may result from increased automaticity or a re-entry mechanism. It may be intermittent (nonsustained VT) or sustained, lasting longer than 15 to 30 seconds. The sinus node may continue to discharge independently, depolarizing the atria but not the ventricles, although P waves are seldom seen in sustained VT.

FIG. 36-10 Ventricular dysrhythmias. **A**, Normal sinus rhythm with unifocal premature ventricular complexes (PVCs). **B**, Normal sinus rhythm with multifocal PVCs (one negative and the other positive).

FIG. 36-11 Sustained ventricular tachycardia at a rate of 166 beats/min.

Ventricular tachycardia may occur in patients with ischemic heart disease, MI, cardiomyopathy, hypokalemia, hypomagnesemia, valvular heart disease, heart failure, drug toxicity, hypotension, or ventricular aneurysm. *In patients who go into cardiac arrest, VT is commonly the initial rhythm before deterioration into ventricular fibrillation (VF) as the terminal rhythm!*

Clinical manifestations of sustained VT partially depend on the ventricular rate. Slower rates are better tolerated.

Current Advanced Cardiac Life Support (ACLS) guidelines state that elective cardioversion is highly recommended for stable VT. The physician may prescribe an oral antidysrhythmic agent, such as mexiletine (Mexitil) or sotalol (Beta-pace, Sotacor ) to prevent further occurrences. *Unstable* VT

! NURSING SAFETY PRIORITY

Critical Rescue

In some patients, VT causes cardiac arrest. Assess the patient's airway, breathing, circulation, level of consciousness, and oxygenation level. For the *stable* patient with sustained VT, administer oxygen and confirm the rhythm via a 12-lead ECG. Amiodarone, lidocaine, or magnesium sulfate may be given.

without a pulse is treated the same way as ventricular fibrillation, described next.

Ventricular Fibrillation

Pathophysiology. **Ventricular fibrillation (VF)**, sometimes called "V fib," is the result of electrical chaos in the

FIG. 36-12 Ventricular dysrhythmias. **A**, Coarse ventricular fibrillation. **B**, Ventricular asystole with one idioventricular complex.

ventricles and is *life threatening*! Impulses from many irritable foci fire in a totally disorganized manner so that ventricular contraction cannot occur. There are no recognizable ECG deflections (Fig. 36-12, A). The ventricles merely quiver, consuming a tremendous amount of oxygen. *There is no cardiac output or pulse and therefore no cerebral, myocardial, or systemic perfusion. This rhythm is rapidly fatal if not successfully ended within 3 to 5 minutes.*

VF may be the first manifestation of coronary artery disease (CAD). Patients with myocardial infarction (MI) are at great risk for VF. It may also occur in those with hypokalemia, hypomagnesemia, hemorrhage, antidysrhythmic therapy, rapid supraventricular tachycardia (SVT), or shock. Surgery or trauma may also cause VF.

Emergency Care: Ventricular Fibrillation. When VF begins, the patient becomes faint, immediately loses consciousness, and becomes pulseless and apneic (no breathing). There is no blood pressure, and heart sounds are absent. Respiratory and metabolic acidosis develop. Seizures may occur. Within minutes, the pupils become fixed and dilated and the skin becomes cold and mottled. *Death results without prompt intervention.*

The desired outcomes of collaborative care are to resolve VF promptly and convert it to an organized rhythm. *Therefore the priority is to defibrillate the patient immediately according to ACLS protocol.* If a defibrillator is not readily available, CPR must be continued until the defibrillator arrives. An automatic external defibrillator (AED) is frequently used because it is simple for both medical and lay personnel. Defibrillation is discussed on p. 737.

If the VF does not end after one defibrillator shock, the nurse and resuscitation team resume high-quality CPR and provide airway management. The team also gives oxygen and drug therapy, which could include vasopressin, epinephrine, amiodarone, lidocaine, and magnesium sulfate, alternating with defibrillation. If VF is successfully converted to an organized rhythm, supportive therapy is continued.

Ventricular Asystole

Pathophysiology. **Ventricular asystole**, sometimes called *ventricular standstill*, is the complete absence of any ventricular rhythm (Fig. 36-12, B). There are no electrical impulses in the ventricles and therefore *no* ventricular depolarization, no QRS complex, no contraction, no cardiac output, and no pulse, respirations, or blood pressure. *The patient is in full cardiac arrest.* The sinoatrial (SA) node, in some cases, may continue to fire and depolarize the atria, with only P waves seen on the ECG. The sinus impulses, however, do not conduct to the ventricles, and QRS complexes remain absent. In most cases, the entire conduction system is electrically silent, with no P waves seen on the ECG.

Ventricular asystole usually results from myocardial hypoxia, which may be a consequence of advanced heart failure. It may also be caused by severe hyperkalemia and acidosis. If P waves are seen, asystole is likely because of severe ventricular conduction blocks.

Emergency Care: Ventricular Asystole. The expected outcome of treatment is to restore cardiac electrical activity.

Collaborate with the resuscitation team to manage the airway and administer oxygen, epinephrine, and atropine. *The prognosis for patients with asystole is poor. Health care*

! NURSING SAFETY PRIORITY**Critical Rescue**

If asystole occurs, call for assistance and begin high-quality CPR immediately (unless there is a do-not-resuscitate [DNR] order). *Check another ECG lead to ensure the rhythm is asystole and not fine VF, which requires immediate defibrillation. Do NOT shock asystole!*

providers should consider ending resuscitation efforts if there is no response after standard interventions have been implemented and when cessation is approved by an authorized physician.

An emerging clinical practice is allowing or encouraging family presence at resuscitation attempts. This can be a positive experience for family members and significant others because it promotes closure after the death of a loved one. Although there may be staff resistance and some limits to family presence, overall it is a beneficial practice that should be considered in all resuscitation attempts.

? NCLEX EXAMINATION CHALLENGE**Safe and Effective Care Environment**

A client is on a cardiac monitor. The nurse suddenly notices there are no ECG complexes and the alarm sounds. What is the priority action of the nurse?

- A. Begin chest compressions and ventilations.
- B. Assess the client and check lead placement.
- C. Call a code blue and shout for help.
- D. Press the record button to get an ECG strip.

Atrioventricular Blocks. Several types of heart blocks, such as AV blocks, often require immediate intervention, depending on the type and severity. **Atrioventricular (AV) blocks** exist when supraventricular impulses are excessively delayed or totally blocked in the AV node or ventricular conduction system. Conduction may be temporarily or permanently abnormal for a number of reasons. The SA node continues to function normally, and atrial depolarizations and P waves occur regularly. Because of the conduction dysfunction, ventricular depolarizations and QRS complexes are either delayed or blocked.

The degrees of heart blocks include:

- In *first-degree* AV block, all sinus impulses eventually reach the ventricles.
- In *second-degree* heart block, some sinus impulses reach the ventricles but others do not because they are blocked.
- In *third-degree* heart block (complete heart block), none of the sinus impulses reach the ventricles. The ventricles are therefore depolarized by a second, independent pacemaker.

AV blocks are differentiated by their PR intervals. Interventions depend on the severity of the block. Oxygen, drug therapy, pacing, and/or permanent pacemakers may be used, depending on the degree of the AV block.

PATIENT-CENTERED COLLABORATIVE CARE**ASSESSMENT**

Patients may or may not realize they have a dysrhythmia, and some patients who have a dysrhythmia may be asymptomatic. Therefore assessment of the patient's past and current history

CHART 36-3 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE**Care of the Patient with Dysrhythmias**

- Assess vital signs at least every 4 hours and as needed.
- Monitor patient for cardiac dysrhythmias.
- Evaluate and document the patient's response to dysrhythmias.
- Encourage the patient to notify the nurse when chest pain occurs.
- Assess chest pain (e.g., location, intensity, duration, radiation, and precipitating and alleviating factors).
- Assess peripheral circulation (e.g., palpate for presence of peripheral pulses, edema, capillary refill, color, and temperature of extremity).
- Provide antidysrhythmic therapy according to unit policy (e.g., antidysrhythmic medication, cardioversion, or defibrillation), as appropriate.
- Monitor and document patient's response to antidysrhythmic medications or interventions.
- Monitor appropriate laboratory values (e.g., cardiac enzymes, electrolyte levels).
- Monitor the patient's activity tolerance and schedule exercise/rest periods to avoid fatigue.
- Observe for respiratory difficulty (e.g., shortness of breath, rapid breathing, labored respirations).
- Promote stress reduction.
- Offer spiritual support to the patient and/or family (e.g., contact clergy), as appropriate.

is essential because dysrhythmias are associated with acute and chronic health problems and medical/surgical therapies. Assessment also includes taking vital signs and placing the patient on an ECG monitor. Continuous monitoring of the patient's ECG rhythm is needed to assess for manifestations associated with dysrhythmias, such as abnormal pulse rate and rhythm, palpitations, chest pain, syncope, decreased blood pressure, and dyspnea. When these manifestations are present, the patient is "symptomatic." Assessment findings were discussed earlier in this chapter for each specific type of dysrhythmia.

It is also important to assess the psychosocial impact of dysrhythmias on patients and families and the effectiveness of their coping skills. Patients with any type of dysrhythmia are often very anxious and fearful that their heart will stop functioning.

PLANNING AND IMPLEMENTATION**Planning: Expected Outcomes**

The patient with dysrhythmias is expected to have adequate blood flow ejected (pumped) from the left ventricle to provide oxygenation and perfusion to vital organs and the periphery.

Interventions

The nurse's major priority for care is to assess for complications and monitor the patient for response to treatment (Chart 36-3). Interventions are specific to the type of dysrhythmia, the cause, the effect it has on cardiac output, and the risk it presents to the patient.

Assess the patient's apical and radial pulses for a full minute for any irregularity, which may occur with problems such as premature beats, atrial fibrillation (AF), and second-degree heart blocks. If the apical pulse rate differs from the radial pulse rate, a pulse deficit exists and suggests that the

heart is not pumping adequately to perfuse the body. Clinical manifestations of sustained tachydysrhythmias and bradydysrhythmias are summarized in [Chart 36-1](#). Review the interpretation of the patient's 12-lead ECG and other diagnostic assessment.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

What is the most appropriate assessment for the nurse to evaluate whether a client has adequate cardiac output and tissue perfusion?

- A. Assess for cyanosis of the hands and feet.
- B. Assess for pulmonary edema.
- C. Monitor respiratory status for shortness of breath.
- D. Monitor blood pressure and urine output.

Nonsurgical Management. Nonsurgical management of dysrhythmias includes oxygen therapy, drug therapy, temporary pacing, cardioversion, CPR, defibrillation, and catheter ablation. The Joint Commission's National Patient Safety Goals (NPSGs) include standardizing and limiting the number of drug concentrations used by organizations, identifying and listing look-alike/sound-alike medications to prevent errors, and labeling all medications and medication containers. Many types of drugs are given to manage dysrhythmias (see the Evidence-Based Practice box on at right).

Drug Therapy. Drug therapy for dysrhythmias often includes those from one or more classes of antidysrhythmic agents (see [Chart 36-2](#)). The **Vaughn-Williams classification** is commonly used to categorize drugs according to their effects on the action potential of cardiac cells (classes I through IV). Other drugs also have antidysrhythmic effects but do not fit the Vaughn-Williams classification.

Class I antidysrhythmics are membrane-stabilizing agents used to decrease automaticity. The three subclassifications in this group include type IA drugs, which moderately slow conduction and prolong repolarization, prolonging the QT interval. These drugs are used to treat or to prevent supraventricular and ventricular premature beats and tachydysrhythmias, but they are not as commonly used as other drugs. An example is procainamide hydrochloride (Pronestyl). Type IB drugs shorten repolarization. These drugs are used to treat or prevent ventricular premature beats, ventricular tachycardia (VT), and ventricular fibrillation (VF). Examples include lidocaine and mexiletine hydrochloride (Mexitil). Type IC drugs markedly slow conduction and widen the QRS complex. These agents are used primarily to treat or to prevent recurrent, life-threatening ventricular premature beats, VT, and VF. Examples include flecainide acetate (Tambocor) and propafenone hydrochloride (Rythmol).

Class II antidysrhythmics control dysrhythmias associated with excessive beta-adrenergic stimulation by competing for receptor sites and thereby decreasing heart rate and conduction velocity. Beta-adrenergic blocking agents, such as propranolol (Inderal) and esmolol hydrochloride (Brevibloc), are class II drugs. They are used to treat or to prevent supraventricular and ventricular premature beats and tachydysrhythmias. Sotalol hydrochloride (Betapace, Sotacor ) is an antidysrhythmic agent with both non-cardioselective beta-adrenergic blocking effects (class II) and action potential duration prolongation properties (class III). It is an oral agent

EVIDENCE BASED PRACTICE

What are the Latest Recommendations for Preventing Medication Errors?

Michaels, A.D., Spinler, S.A., Leeper, B., Ohman, E.M., Alexander, K.P., Newby, L.K., et al. (2010). Medication errors in acute cardiovascular and stroke patients: A scientific statement from the American Heart Association. *Circulation*, 121, 1664-1682.

Medical errors are the eighth leading cause of death in the United States, and medication errors are the most common type of medical error. Cardiovascular medications prescribed to inpatients account for a large number of these errors. Although public safety has become a predominant focus of health care, the impact of medication errors on patient safety remains a significant issue. A current assessment of the evidence was performed, and recommendations were supported by the evidence. Medication errors included improper dosing or timing, delivery of an incorrect or unnecessary medication, administration to the wrong patient, and failure to prescribe appropriate medication therapy or needed monitoring of medication therapy.

Level of Evidence: 2

The evidence was obtained from clinical trials or registries.

Commentary: Implications for Nursing Practice and Research

The following are recommendations for medication safety in acute cardiovascular care:

1. An accurate weight should be obtained on admission.
2. Estimated creatinine clearance should be calculated on admission and as changes in serum creatinine occur.
3. Because of age-related changes in pharmacokinetics, pharmacodynamics, and renal function, medication dosage adjustments and heightened surveillance for adverse medication events are recommended.
4. Order forms and protocols for anticoagulation should be standardized.
5. Pharmacists and nurses should be integrated within the cardiovascular care teams in the ED, ICU, and inpatient wards to enhance communication and medication safety.
6. Computerized provider order entry, medication bar-coding technology, and smart infusion pumps should be implemented throughout all inpatient wards, including the ED.
7. Staff should be educated on high-alert medications (especially anticoagulants), safe medication administration techniques, medication reconciliation procedures, look-alike/sound-alike medications, and automated dispensing device technologies.
8. An organizational culture of safety that promotes no-fault internal and external medication error reporting and interdisciplinary quality improvement review processes to reduce the frequency and impact of medication errors is recommended.

Many organizations have already begun implementing these recommendations to improve patient medication safety.

that may be used for the treatment of documented ventricular dysrhythmias, such as VT, that are life threatening.

Class III antidysrhythmics lengthen the absolute refractory period and prolong repolarization and the action potential duration of ischemic cells. Class III drugs include amiodarone (Cordarone) and ibutilide (Corvert) and are used to treat or prevent ventricular premature beats, VT, and VF.

Class IV antidysrhythmics slow the flow of calcium into the cell during depolarization, thereby depressing the automaticity of the sinoatrial (SA) and atrioventricular (AV) nodes, decreasing the heart rate, and prolonging the AV nodal refractory period and conduction. Calcium channel blockers,

such as verapamil hydrochloride (Calan, Isoptin ) and diltiazem hydrochloride (Cardizem), are class IV drugs. They are used to treat supraventricular tachycardia (SVT), atrial flutter, and atrial fibrillation (AF) to slow the ventricular response.

Other drugs, such as digoxin, atropine, adenosine, and magnesium sulfate, may be used to treat dysrhythmias. Digoxin (Lanoxin, Novodigoxin ) increases vagal tone, slowing AV nodal conduction. It is useful in treating chronic AF by controlling the rate of ventricular response. However, digoxin does not convert AF to sinus rhythm. Atropine is a parasympatholytic or vagolytic agent used to treat vagally-induced symptomatic bradycardias. Adenosine is an endogenous nucleoside that slows AV nodal conduction to interrupt re-entry pathways. Magnesium sulfate is an electrolyte administered to treat refractory VT or VF because these patients may be hypomagnesemic, with increased ventricular irritability. The drug is also used for a life-threatening VT called **torsades de pointes** that can result from certain anti-dysrhythmics, such as amiodarone.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client reports “not feeling well for the past week” after taking digoxin (Lanoxin), which was prescribed a month ago. Which statement by the client indicates possible digoxin toxicity?

- A. “I am short of breath and my hands are swollen.”
- B. “I have chest pain and tingling in my fingers.”
- C. “I have double vision and feel sick to my stomach.”
- D. “I am constipated and have trouble sleeping.”

In addition to antidysrhythmics, several other *drugs are used during cardiac arrest* (Chart 36-4). *Epinephrine* (Adrenalin) is usually a first-line agent in all cardiac arrests. It is given mainly for its alpha-adrenergic effects to increase vasomotor tone for myocardial and cerebral perfusion. Its beta-adrenergic effects may stimulate the heart and increase myocardial contractility to improve cardiac output. Recent evidence suggests that epinephrine may be problematic during cardiopulmonary resuscitation because the alpha-adrenergic actions caused an increase in cerebral ischemia (Ristagno et al., 2009). Another study by Grigoriyan et al. (2009) found poorer survival rates for patients who received vasopressors before cardiac arrest. Vasopressin has potent vasoconstricting effects and is equivalent to epinephrine in VF and pulseless VT. It has a long half-life and is given one time as an IV bolus of 40 units. Dopamine hydrochloride (Intropin) is generally used for its beta-adrenergic effects after cardiac arrest but may be used for its alpha-adrenergic effects during resuscitation. Dobutamine hydrochloride (Dobutrex) is a beta-adrenergic agent used to improve myocardial contractility and increase cardiac output.

Norepinephrine (Levophed) or phenylephrine hydrochloride (Neo-Synephrine) may be used for its alpha-adrenergic effects to increase vasomotor tone and increase perfusion pressure. Sodium bicarbonate, along with regular insulin and calcium chloride, may be administered during cardiac arrest for patients who are hyperkalemic. It may also be used, if necessary, to treat a documented base deficit metabolic acidosis, as occurs in diabetic ketoacidosis or tricyclic antidepressant overdose. In addition to hyperkalemia, calcium

chloride is given for hypocalcemia or calcium channel blocker toxicity because the conditions may cause cell damage and cerebrovascular vasospasm. Isoproterenol (Isuprel) is indicated to increase the heart rate in heart transplant patients, but pacing is preferred.

Vagal Maneuvers. Vagal maneuvers induce vagal stimulation of the cardiac conduction system, specifically the SA and AV nodes. Although not as common today, vagal maneuvers may be attempted to treat supraventricular tachycardias and include carotid sinus massage and Valsalva maneuvers. The results of these interventions, however, are often temporary and may cause “rebound” tachycardia or severe bradycardia. Further therapy must be initiated.

In **carotid sinus massage**, the physician massages over one carotid artery for a few seconds, observing for a change in cardiac rhythm. This intervention causes vagal stimulation, slowing SA and AV nodal conduction. Prepare the patient for the procedure, instruct him or her to turn the head slightly away from the side to be massaged, and observe the cardiac monitor for a change in rhythm. An ECG rhythm strip is recorded before, during, and after the procedure. After the procedure, assess vital signs and the level of consciousness. *Complications include bradycardias, asystole, VF, and cerebral damage. Because of these risks, carotid massage is not commonly performed. A defibrillator and resuscitative equipment must be immediately available during the procedure.*

To stimulate a *vagal reflex*, the health care provider instructs the patient to bear down as if straining to have a bowel movement. Assess the patient’s heart rate, heart rhythm, and blood pressure; observe the cardiac monitor; and record an ECG rhythm strip before, during, and after the procedure to determine the effect of therapy.

NURSING SAFETY PRIORITY

Action Alert

Unintended vagal stimulation can occur. Therefore be very cautious when performing procedures that may accidentally cause it. To prevent vagal stimulation or bradycardia, avoid:

- Tracheal suctioning
- Enema administration
- Rectal temperature
- Straining during bowel movements
- Vomiting or gagging during oral hygiene
- Tight collars and neckties
- Raising arms above the head

Temporary Pacing. Temporary pacing is a nonsurgical intervention that provides a timed electrical stimulus to the heart when either the impulse initiation or the conduction system of the heart is defective. The electrical stimulus then spreads throughout the heart to depolarize the cells, which should be followed by contraction and cardiac output. Electrical stimuli may be delivered to the right atrium or right ventricle (single-chamber pacemakers) or to both (dual-chamber pacemakers).

When a pacing stimulus is delivered to the heart, a spike (or pacemaker artifact) is seen on the monitor or ECG strip. The spike should be followed by evidence of depolarization (i.e., a P wave, indicating atrial depolarization, or a QRS complex, indicating ventricular depolarization). This pattern is referred to as *capture*, indicating that the pacemaker has successfully depolarized, or captured, the chamber.

CHART 36-4 COMMON EXAMPLES OF DRUG THERAPY

Cardiac Arrest

DRUG	USUAL DOSAGE	NURSING INTERVENTIONS	RATIONALES
Epinephrine (Adrenalin) Used for asystole, VF, VT, PEA, hypotension, anaphylaxis	1-mg IV bolus followed by 20-mL saline flush every 3-5 min	Monitor for return of rhythm and pulse when used for asystole or VF. Assess for tachycardia, dysrhythmias, or hypertension. Assess for the development of coarse VF when given during the VF.	Return of rhythm and pulse is the expected response. Adverse reactions can occur with a dramatic response. This may improve the response to defibrillation.
Amiodarone hydrochloride (Cordarone) Used for AF, PAF, PSVT, life-threatening ventricular dysrhythmias	300 mg IV push for cardiac arrest in VF/pulseless VT 150 mg IVP over 10 min (15 mg/min), followed by 360 mg IV over next 6 hr (1 mg/min), followed by 540 mg IV over next 18 hr (0.5 mg/min) After first 24 hr, continue maintenance infusion of 720 mg/24 hr (0.5 mg/min)	Monitor for return of rhythm and pulse when used for recurrent unstable VT or VF. Use with extreme caution in patients receiving other antiarrhythmics. Use caution in patients with pulmonary, hepatic, or thyroid disease. Perform continuous cardiac monitoring while the patient is receiving the loading dose.	Return of rhythm and pulse is the expected response. Amiodarone reduces the hepatic and renal clearance of certain antiarrhythmics, specifically procainamide, quinidine, and flecainide. Amiodarone can cause fatal toxicity, especially in patients receiving more than 600 mg daily. There is a slow onset of antiarrhythmic effect and a high risk for life-threatening dysrhythmias.
Dopamine hydrochloride (Intropin) Used for hypotension, shock, CHF, renal failure	2.5 mcg/kg/min IV infusion; titrate to desired clinical response 1-2 mcg/kg/min for renal and mesenteric vasodilation 2-10 mcg/kg/min for beta-adrenergic effects 10-20 mcg/kg/min for alpha-adrenergic effects	Assess patients for increased BP. Monitor for tachycardia, dysrhythmias, or hypertension. Monitor IV site for infiltration. Assess for urine output <30 mL/hr, pallor, cyanosis, pain, or numbness in the extremities.	Increased BP is the expected response. Adverse reactions may occur. Extravasation of drug can occur, causing necrosis. Dosages >10 mcg/kg/min cause vasoconstriction of renal and peripheral blood vessels; dosages of 2-5 mcg/kg/min may improve urine output by causing renal vasodilation and improving renal blood flow.
Dobutamine hydrochloride (Dobutrex) Used for short-term management of cardiac decompensation	2-20 mcg/kg/min IV infusion	Assess for increased BP. Assess for hypertension and dysrhythmias.	Increased BP is the expected response. Adverse reactions may occur.
Norepinephrine (Levophed) Used for cardiogenic shock, hypotension	0.5-1 mcg/min IV infusion, titrate to desired effect, up to 8-30 mcg/min	Assess for increased BP. Monitor for bradycardia. Monitor for hypertension and dysrhythmias. Administer drug through central IV line. Assess for urine output <30 mL/hr, pallor, cyanosis, pain, or numbness in the extremities. Assess for chest pain after resuscitation.	Increased BP is the expected response. Reflex bradycardia may occur with a rise in BP. Adverse reactions may occur with a dramatic response. Extravasation can occur. Norepinephrine is a powerful vasoconstrictor.
Sodium bicarbonate Used for acid-base imbalance, metabolic acidosis	1 mEq/kg IV bolus given after the first 10 min of cardiac arrest if necessary 0.5 mEq/kg IV bolus every 10 min thereafter if necessary	Assess arterial blood gas values for metabolic acidosis.	Norepinephrine increases myocardial oxygen demand. Administration without evidence of metabolic acidosis can result in alkalosis, which can hinder resuscitation efforts.
Isoproterenol (Isuprel) Used for bradycardia, torsades de pointes, beta blocker OD	2-10 mcg/min IV infusion; titrate to desired clinical response	Assess for increased heart rate. Assess for tachycardia, hypotension, or hypertension. Assess for chest pain after resuscitation. Monitor for ventricular dysrhythmias.	Increased heart rate is the expected response. Adverse reactions may occur with a dramatic response. Isoproterenol increases myocardial oxygen demand. Isoproterenol increases ventricular irritability, especially in patients who are hypokalemic or who are receiving digitalis.
Calcium chloride (CaCl ₂) Used for hyperkalemia, hypocalcemia, calcium channel or beta blocker OD	2-4 mg/kg IV slowly; may repeat every 10 min if necessary	Calcium chloride is indicated only for cardiac arrest associated with hyperkalemia, hypocalcemia, or calcium channel blocker toxicity.	Calcium chloride may cause cellular damage and cerebrovascular spasm.
Vasopressin Used for VF, asystole, PEA, shock	40 units IV bolus, one time	Monitor for return of rhythm and pulse when used for VF or pulseless VT.	Return of rhythm and pulse is the expected response.

AF, Atrial fibrillation; BP, blood pressure; CHF, congestive heart failure; IVP, IV push; OD, overdose; PAF, paroxysmal AF; PEA, pulseless electrical activity; PSVT, paroxysmal supraventricular tachycardia; VF, ventricular fibrillation; VT, ventricular tachycardia.

Temporary pacing is used for patients with symptomatic, atropine-refractory bradydysrhythmias (particularly second-degree heart block type II and third-degree heart block) or for patients with asystole. Temporary pacing may also be initiated prophylactically in stable patients with left bundle branch block in certain situations, such as insertion of a pulmonary artery catheter. *Have emergency equipment available in case the patient becomes more unstable or goes into cardiac arrest during this procedure.*

The two major modes of pacing are synchronous (demand) pacing and asynchronous (fixed-rate) pacing. Temporary pacing is *usually* done in the synchronous (demand) pacing mode. The pacemaker's sensitivity is set to sense the patient's own beats. When the patient's heart rate is above the rate set on the pulse generator, the pacemaker does not fire. When the patient's heart rate is less than the generator setting, the pacemaker provides electrical impulses.

The two basic types of *temporary* pacing are noninvasive (external) temporary pacing and invasive temporary pacing. **Noninvasive temporary pacing (NTP)** is accomplished through the application of two large external electrodes. The electrodes are attached to an external pulse generator. The generator emits electrical pulses, which are transmitted through the electrodes and then transcutaneously to stimulate ventricular depolarization when the patient's heart rate is slower than the rate set on the pacemaker.

Noninvasive temporary pacing is used as an emergency measure to provide demand ventricular pacing in a profoundly bradycardic or asystolic patient until invasive pacing can be used or the patient's heart rate returns to normal. It may be used prophylactically when performing procedures or transporting patients at risk for bradydysrhythmias. However, it is used only as a temporary measure to maintain heart rate and perfusion until a more permanent method of pacing is used.

Depending on the facility, nurses on telemetry units may perform noninvasive temporary pacing. In a nonemergent situation, explain NTP to the patient and family and prepare the equipment. Wash the skin gently with soap and water. Apply the electrodes on the chest according to package instructions, with one placed on the upper chest to the right of the sternum and one placed over the heart apex. Displace the female breast tissue to position the electrode underneath the breast.

Turn the pacer on, set the pacing rate as ordered, and establish the stimulation threshold (the lowest current that achieves capture with each pacing spike followed by a QRS complex). Set the current milliamperes (mA) output 2 mA above the dose at which consistent capture is observed. The rate should be adjusted according to patient response. The QRS complex is wide because one ventricle depolarizes first, followed by the other.

Palpate the right radial or carotid pulse, and assess the blood pressure using the patient's right arm, ensuring that each paced beat is perfused. Vital signs are not taken on the left side of the body because they may not be accurate, particularly if a high milliamperage is used.

Observe for discomfort from muscle stimulation, skin irritation, and diaphoresis (excessive sweating) from the patch electrodes. Be sure that the electrodes are in good contact with the skin and in the best location to achieve the lowest threshold. Give analgesics or sedatives as prescribed to provide comfort.

FIG. 36-13 Placement of pacemaker in chest and heart leads.

An **invasive temporary pacemaker** system consists of an external battery-operated pulse generator and pacing electrodes, or lead wires. These wires attach to the generator on one end and are in contact with the heart on the other end (Fig. 36-13). Electrical pulses, or stimuli, are emitted from the negative terminal of the generator, flow through a lead wire, and stimulate the cardiac cells to depolarize. The current seeks ground by returning through the other lead wire to the positive terminal of the generator, thus completing a circuit. The intensity of electrical current is set by selecting the appropriate current output, measured in milliamperes.

Patients do not usually feel invasive pacemaker stimuli. However, they occasionally feel an uncomfortable sensation from the stimuli if strong electrical currents (high milliamperage) are delivered by the pacemaker. The discomfort may be alleviated by decreasing the generator current if possible (Fig. 36-14).

Monitor for these complications of invasive temporary pacing, which may be serious and include:

- Infection or hematoma at the pacemaker wire insertion site
- Ectopic complexes (usually premature ventricular complexes [PVCs]) caused by irritability from the pacing wire in the ventricle, use of high current, or undersensing with pacemaker competition
- Loss of capture, noted by the presence of a pacing stimulus or spike but no QRS complex
- Undersensing or pacemaker competition, noted when pacing stimuli occur at a fixed rate in the presence of an adequate intrinsic rhythm
- Oversensing, noted when the pacemaker fails to fire in the presence of an inadequate intrinsic rhythm
- Electromagnetic interference, noted by altered generator variables
- Stimulation of the chest wall or diaphragm, noted by rhythmic contraction of the chest wall muscles or hiccups with the use of high current or from lead wire perforation, which could cause cardiac tamponade

FIG. 36-14 Temporary pacemaker generator.

! NURSING SAFETY PRIORITY

Action Alert

For patient safety, when the metal external ends of lead wires are not attached to a pulse generator, insulate the wire ends to prevent microshock. The fingertips of rubber gloves work well for this purpose, and the wire ends may then be looped and covered with nonconductive tape. All electrical equipment in the room must be properly grounded using a three-pronged plug. Report faulty electrical equipment, such as frayed or broken electrical wire, to the biomedical engineering department. Neither the patient nor the bed should be in contact with such equipment. The risk is that ungrounded electrical current may conduct through the lead wire, stimulate the heart, and cause ventricular fibrillation (VF). Remember to wear rubber gloves when touching any of the wires. Static electricity may be conducted from your hands to the patient, causing dysrhythmias if gloves are not worn.

Cardiopulmonary Resuscitation. When cardiac arrest occurs, cardiac output stops. The underlying rhythm is usually ventricular tachycardia (VT), ventricular fibrillation (VF), or asystole. Without cardiac output, the patient is pulseless and becomes unconscious because of inadequate cerebral perfusion and oxygenation. Shortly after cardiac arrest, respiratory arrest occurs.

Cardiopulmonary resuscitation (CPR), also known as *Basic Cardiac Life Support (BCLS)*, must be initiated immediately to help prevent brain damage and death. When finding an unresponsive patient, confirm unresponsiveness and call 911 or the emergency response team *before initiating CPR*. Guidelines for CPR recently changed from an ABC approach to the initial priorities of CAB (AHA, 2010).

- Start chest compressions, at least 100 compressions per minute and with a compression depth of at least 2 inches.
- Maintain a patent airway.

- Ventilate (breathing) with a mouth-to-mask device. Give rescue breaths at a rate of 10 to 12 breaths/min. If an advanced airway is in place, one ventilation should, if possible, be given every 6 to 8 seconds (8 to 10 breaths/min).

As soon as help arrives, a board is placed under the patient who is not on a firm surface. To make room for the resuscitation team and the crash cart, ask that the area be cleared of movable items and unnecessary personnel.

In 2000, the American Heart Association developed the National Registry of Cardiopulmonary Resuscitation (NRCPR) as an evidence-based performance improvement program to support patient safety, medical emergency team response, effective resuscitation, and post-emergency care. This tool also assists hospitals to meet The Joint Commission standards for evidence-based practice and monitoring of in-hospital arrests.

The NRCPR established “Gold Standards” for resuscitation efforts. Data from the NRCPR are used to make CPR process improvements in individual facilities. Scientists analyze and use the data to translate the resuscitation science into practice based on the evidence. The evidence also supports the need to add two new links to the chain of survival for in-hospital resuscitation—an early intervention and response link at the beginning and an early stabilization and intervention link at the end. Examples of the links in practice are Rapid Response Teams or medical emergency teams to support early intervention and response and the use of a hypothermia protocol post-resuscitation for early stabilization and intervention (Hunt et al., 2009).

Another area of research is the support of hands-only CPR, especially when the cardiac arrest occurs outside the hospital setting. Evidence suggests that chest compressions by themselves may be as effective as compressions *with* ventilation. Current American Heart Association recommendations include:

- Bystanders (laypeople) not trained in CPR should use only hands-only CPR.
- Bystanders trained in CPR who are confident in their ability to provide rescue breathing should use either the standard CPR procedure OR the hands-only technique.
- Bystanders trained in CPR who are *not* confident in their ability to provide rescue breathing should use only the hands-only technique.

Complications of CPR include:

- Rib fractures
- Fracture of the sternum
- Costochondral separation
- Lacerations of the liver and spleen
- Pneumothorax
- Hemothorax
- Cardiac tamponade
- Lung contusions
- Fat emboli

The desired outcome of resuscitation is the rapid return of a pulse, blood pressure, and consciousness. This is rarely achieved by CPR and basic measures alone. More definitive therapy must be initiated as soon as possible with Advanced Cardiac Life Support (ACLS) measures, including defibrillation, if needed.

Advanced Cardiac Life Support (ACLS). Whereas all nurses and other health care personnel should learn basic CPR, special training is required to perform ACLS. When the AED

or crash cart arrives, apply ECG electrodes to the patient's chest and turn on the monitor. Direct the team to continue CPR, and continue to coordinate the personnel who respond to the emergency. Keep interruptions to CPR to a minimum.

! NURSING SAFETY PRIORITY

Critical Rescue

If the patient is in VF or pulseless VT, the immediate priority is to defibrillate! After defibrillation, CPR is resumed. CPR must continue at all times except during defibrillation. The term "push hard and push fast" is used to improve circulation during resuscitation.

An oropharyngeal airway is inserted to facilitate proper ventilation. A manual resuscitation bag (MRB) with mask is attached to an oxygen flowmeter set at 10 to 15 L/min. Direct the person managing the airway to ventilate the lungs with the MRB, maintaining the proper head-tilt or chin-lift position of the patient. Start two large-bore IV lines if the patient does not have any infusing normal saline. These lines provide access for emergency drug administration. Suction equipment is also set up, with a tonsillar suction tube for suctioning vomitus and a suction catheter for endotracheal suctioning. Check carotid or femoral pulses with or without chest compressions, blood pressure, and pupils every few minutes. Document all assessments and findings, therapeutic measures, and the patient's responses throughout the resuscitation.

Additional measures include endotracheal intubation with ventilation and oxygenation, IV administration of emergency cardiac drugs, and occasionally external pacing. Chest compressions are continued as long as the patient remains pulseless or until a physician decides to terminate resuscitation attempts.

If ACLS is successful and the patient has a return of spontaneous circulation (ROSC), clinical evidence indicates that *therapeutic hypothermia* helps protect the nervous system, especially the brain. This therapy is indicated for patients who had VF, VT pulseless activity, or asystole and should be started as soon as possible after ROSC. The patient is cooled quickly with a cooling blanket, hypothermia pads, or other method to reach the target of 89.6° to 93.2° F (32° to 34° C). Maintain this temperature for 24 hours before slowly rewarming the patient at a rate of 0.5° to 1° C per hour. Cardiovascular support with drug therapy and other treatments are used as needed during this process. Recent evidence suggests that percutaneous coronary intervention combined with mild therapeutic hypothermia is not associated with increased cardiac or neurologic risk (Batista et al., 2010).

Cardioversion. **Cardioversion** is a *synchronized* countershock that may be performed in emergencies for unstable ventricular or supraventricular tachydysrhythmias or electively for stable tachydysrhythmias that are resistant to medical therapies. If the patient has been taking digoxin, the drug is withheld for up to 48 hours before an elective cardioversion. Digoxin increases ventricular irritability and puts the patient at risk for VF after the countershock. For elective cardioversion for atrial flutter or fibrillation, the patient must take anticoagulants for 4 to 6 weeks before the procedure to prevent clots from moving from the heart to the brain or lungs.

The shock depolarizes a large amount of myocardium during the cardiac depolarization. It is intended to stop the re-entry circuit and allow the sinus node to regain control of the heart. Emergency equipment must be available during the

procedure. The physician, advanced practice nurse, or other qualified nurse explains the procedure to the patient and family. Assist the patient in signing a consent form unless the procedure is an emergency for a life-threatening dysrhythmia. Because he or she is usually conscious, a short-acting anesthetic agent should be administered for sedation.

One electrode is placed to the left of the precordium, and the other is placed on the right next to the sternum and below the clavicle. The defibrillator should be set in the synchronized mode. This avoids discharging the shock during the T wave, which may increase ventricular irritability, causing ventricular fibrillation (VF). Charge the defibrillator to the energy level requested, usually starting at a low rate.

! NURSING SAFETY PRIORITY

Critical Rescue

For safety before cardioversion, turn oxygen off and away from patient; fire could result. Shout "CLEAR" before shock delivery for electrical safety!

After cardioversion, assess the patient's response and heart rhythm. Therapy is repeated, if necessary, until the desired result is obtained or alternative therapies are considered. If the patient's condition deteriorates into VF after cardioversion, check to see that the synchronizer is turned off so that immediate defibrillation can be administered.

Nursing care after cardioversion includes:

- Maintaining a patent airway
- Administering oxygen
- Assessing vital signs and the level of consciousness
- Administering antidysrhythmic drug therapy, as prescribed
- Monitoring for dysrhythmias
- Assessing for chest burns from electrodes
- Providing emotional support
- Documenting the results of cardioversion

Defibrillation. **Defibrillation**, an *asynchronous* countershock, depolarizes a critical mass of myocardium simultaneously to stop the re-entry circuit, allowing the sinus node to regain control of the heart.

Continue effective CPR until a defibrillator is available. The defibrillator is charged to 120 to 200 joules (biphasic) or 360 joules (monophasic) for one countershock from the defibrillator. Before defibrillation, loudly and clearly command all personnel to clear contact with the patient and the bed and check to see they are clear before the shock is delivered. Resume CPR immediately after the shock, and continue CPR for 5 cycles or about 2 minutes. Then reassess the rhythm, and if VF or pulseless VT continues, charge the defibrillator to give a second shock at the same energy level previously used. Resume CPR after the shock, and continue with the ACLS protocol. Nursing care for defibrillation is the same as for cardioversion.

! NURSING SAFETY PRIORITY

Critical Rescue

Early defibrillation is critical in resolving pulseless ventricular tachycardia (VT) or ventricular fibrillation (VF). It must not be delayed for any reason after the equipment and skilled personnel are present. The earlier defibrillation is performed, the greater the chance of survival!

DECISION MAKING CHALLENGE

Teamwork and Collaboration; Evidence-Based Practice; Safety

A 58-year-old male patient is being transported to the ICU from the ED with a diagnosis of chest pain to rule out myocardial infarction (MI). As the patient is transferred from the stretcher to the bed, the nurse notes the cardiac rhythm changes from normal sinus rhythm (NSR) to ventricular tachycardia (VT) with a pulse. His vital signs are the following: blood pressure 70/30 mm Hg, pulse 166/min, and respirations 26/min.

1. What is the initial treatment for this patient at this time?
2. What medications should you anticipate administering to this patient? Why are they indicated?
3. What evidence-based precautions must be taken to promote electrical safety for both the patient and the ACLS team?
4. If this rhythm deteriorates to ventricular fibrillation or VT without a pulse, what steps should you take to operate the defibrillator?

Automatic External Defibrillation. The American Heart Association promotes the use of automatic external defibrillators (AEDs) for use by laypersons and health care professionals responding to cardiac arrest emergencies (Fig. 36-15). These devices are found in many public places such as malls and commercial jets. The patient in cardiac arrest must be on a firm, dry surface. The rescuer places two large adhesive-patch electrodes on the patient's chest in the same positions as for defibrillator electrodes. The rescuer stops CPR and commands anyone present to move away, ensuring that no one is touching the patient. This measure eliminates motion artifact when the machine analyzes the rhythm. The rescuer presses the "analyze" button on the machine. After rhythm analysis, which may take up to 30 seconds, the machine either advises that a shock is necessary or advises that a shock is not indicated. *Shocks are recommended for VF or pulseless VT only.*

If a shock is indicated, issue a command to clear all contact with the patient and press the charge button. Once the AED is charged, press the shock button and the shock will be delivered according to ACLS protocol. The shock is delivered through the patches, so it is hands-off defibrillation, which is safer for the rescuer. The rescuer then resumes CPR until the AED instructs to "stop CPR" to analyze the rhythm. If the rhythm is VF or VT and another shock is indicated, the AED will instruct the rescuer to charge and deliver another shock. Newer AEDs perform rhythm analysis and defibrillation without the need for a rescuer to press a button to analyze or to shock the victim. It is essential that ACLS be provided as

soon as possible. Use of AEDs allows for earlier defibrillation. Therefore there is a greater chance of successful rhythm conversion and patient survival.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

While shopping at the local mall, a bystander witnesses a shopper grab his chest and fall to the floor. The bystander opens the victim's airway and begins CPR. The security guard arrives with the AED. What is the correct sequence of steps for using the AED? (Select in priority order.)

- A. Place AED pads on victim's chest.
- B. Press the button to analyze the rhythm.
- C. Turn on the AED.
- D. Connect pads to the AED.
- E. Press the button to shock if indicated.

Radiofrequency Catheter Ablation. Radiofrequency catheter ablation is an invasive procedure that may be used to destroy an irritable focus causing a supraventricular or ventricular tachydysrhythmia. The patient must first undergo electrophysiologic studies and mapping procedures to locate the focus. Then radiofrequency waves are delivered to abolish the irritable focus. When ablation is performed in the AV nodal or His bundle area, damage may also occur to the normal conduction system, causing heart blocks and requiring implantation of a permanent pacemaker.

Surgical Management. Patients who have life-threatening dysrhythmias may require surgical treatment for long-term management. The type of treatment depends on the nature of the dysrhythmia. Procedures include:

- Permanent pacing
- Coronary artery bypass grafting (CABG)
- Aneurysmectomy
- Implantable cardioverter/defibrillator
- Open-chest cardiac massage.

Permanent pacemaker insertion is performed to treat conduction disorders that are not temporary, including complete heart block. These pacemakers are usually powered by a lithium battery and have an average life span of 10 years. After the battery power is depleted, the generator must be replaced by a procedure done with the patient under local anesthesia. Some pacemakers are nuclear-powered and have a life span of 20 years or longer. Other pacemakers can be recharged externally. Combination pacemaker/defibrillator devices are also available.

A newer type of pacemaker may be utilized to coordinate contractions between the right and left ventricles. In addition to pacing used in the right side of the heart, an additional lead is placed in the left lateral wall of the left ventricle through the coronary sinus. This procedure allows synchronized depolarization of the ventricles and is used in patients with moderate to severe heart failure to improve functional ability.

The surgeon usually implants the pulse generator in a surgically made subcutaneous pocket at the shoulder in the right or left subclavicular area, which creates a visible bulge. The leads are introduced transvenously via the cephalic or the subclavian vein to the endocardium on the right side of the heart. After the procedure, monitor the ECG rhythm to check that the pacemaker is working correctly. Assess the implantation site for bleeding, swelling, redness, tenderness, and infection. The dressing over the site should remain clean and dry.

FIG. 36-15 Automated external defibrillator with electrodes.

The patient should be afebrile and have stable vital signs. The physician prescribes initial activity restrictions, which are then gradually changed. Complications of permanent pacemakers are similar to those of temporary invasive pacing.

Pacemaker checks are done on an ambulatory care basis at regular intervals. Reprogramming may be needed if pacemaker problems develop. The pulse generator is interrogated using an electronic device to determine the pacemaker settings and battery life (Fig. 36-16).

For patients who live far from the pacemaker clinic or physician's office, pacemaker information can be sent by telephone. The patient attaches ECG electrodes to the wrists or chest and places the telephone receiver in a transmitting unit. The sound signals are relayed via telephone lines to the clinic or office, where they are converted and recorded as the ECG rhythm strip and information about the pacemaker variables. Stress the need to keep clinic appointments for more detailed pacemaker checks and reprogramming, if necessary, as well as for assessment.

Coronary artery bypass grafting (CABG) is performed if the cause of the dysrhythmia is coronary artery insufficiency that is unresponsive to medical therapy. This procedure is described in [Chapter 40](#).

Ventricular aneurysms are a complication of myocardial infarction (MI) and may be the source of intractable ventricular tachydysrhythmias. The surgeon *resects the aneurysm*, a ballooning portion of the ventricular wall. Resection of the area eliminates the dangerous irritable focus and thus the cause of the dysrhythmias. Care of the patient is similar to that for CABG, described in [Chapter 40](#).

The *implantable cardioverter/defibrillator (ICD)* is indicated for patients who have experienced one or more episodes of spontaneous sustained ventricular tachycardia (VT) or ventricular fibrillation (VF) not caused by an MI. Collaborate with the physician and the electrophysiology nurse to prepare the patient for this procedure. A psychological profile is done to determine whether the patient can cope with the discomfort and fear associated with internal defibrillation from the ICD. Many patients report anxiety, depression, and decreased quality of life, which dissipates for the majority of patients after 12 months (Hallas et al., 2010).

The leads of the device are introduced through the skin, and the generator is implanted in the left pectoral area, similar to a permanent pacemaker insertion procedure. This procedure is performed in the electrophysiology laboratory. If ICD therapies are not successful and the patient remains in VF or pulseless VT, the qualified nurse or health care provider must promptly externally defibrillate.

The generator may be activated or deactivated by the physician placing a magnet over the implantation site for a few moments. The patient requires close monitoring in the postoperative period for dysrhythmias and complications such as bleeding and cardiac tamponade. The nurse must know whether the ICD is activated or deactivated. Care of the patient is similar to that after implantation of a permanent pacemaker.

Some patients use a lightweight, automatic wearable cardioverter/defibrillator (WCD), approved since 2002. This external vest-like device is worn 24 hours a day except when the patient showers or bathes. One popular brand is the Zoll Lifecor LifeVest, which is programmed to monitor ventricular tachycardia (VT) and ventricular fibrillation (VF). If the patient is conscious while experiencing VT, he or she can press a button to prevent a shock. This precaution is an advantage over implantable devices because ICDs are programmed to always deliver a shock when VT or VF occurs (Morrison & Smith, 2009).

When external chest compressions and ACLS measures are unsuccessful in resuscitating the patient in cardiac arrest, the physician may perform *open-chest cardiac massage* using a thoracotomy or sternotomy approach in post-cardiac surgery patients. Internal defibrillation may also be performed. This procedure is a drastic measure that frequently results in devastating consequences for the patient *and is therefore used as a last resort*.

Community-Based Care

For many patients, dysrhythmias are a disorder resulting from chronic cardiac and pulmonary diseases. Patients may be cared for in a variety of settings, including the acute care hospital, subacute unit, traditional nursing home, or their own home. They are admitted to the hospital when they experience life-threatening or potentially life-threatening dysrhythmias, often associated with an acute disorder. Others can be managed with office or clinic visits or in other settings.

Holding et al. (2009) described the impact of a nurse-led atrial fibrillation (AF) clinic in England. During the first 15 months of operation, the clinic had 314 referrals. Of these, 43% were found to be at high risk for stroke as a result of AF, 32% were at moderate risk, and 88% were referred for anticoagulation therapy. For patients who were asymptomatic, over 50% were at high risk for stroke. Early access, diagnosis, and treatment from this community clinic improved patient outcomes, reduced the number of hospitalizations, and led to prevention of strokes in clinic patients.

Home Care Management

Patients discharged from the hospital may have considerable needs, often more related to their underlying chronic diseases than to their dysrhythmias. A case manager or care coordinator can assess the need for health care resources and coordinate access to services.

FIG. 36-16 Permanent pacemaker, programmer, and rhythm strip.

The focus of the home care nurse's interventions is assessment and health teaching. Patients and families often fear recurrence of a life-threatening dysrhythmia. Patients with an ICD may dread or fear the activation of the device. The community-based nurse provides the patient and family members with an opportunity to verbalize their concerns and fears. Provide emotional support as well as information about support groups and referrals in the community. Assess the patient for possible side effects of antidysrhythmic agents or complications from a pacemaker or ICD.

Teaching for Self-Management

Teach the patient who has had a dysrhythmia caused by an acute problem, such as electrolyte imbalance or MI, about prevention, early recognition, and management of that disorder. Instruct the patient and family about lifestyle modifications designed to prevent, decrease, or control the occurrence of dysrhythmias, as outlined in [Chart 36-5](#). This teaching may be provided in the acute care setting, physician's office, health care clinic, or home setting.

Patients and their families must have a thorough understanding of the prescribed *drug therapy*, including antidysrhythmic agents. Pharmacies provide written instructions with filled prescriptions. Teach patients and families the generic and trade names of their drugs, as well as the drugs'

CHART 36-5 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

How to Prevent or Decrease Dysrhythmias

For Patients at Risk for Vasovagal Attacks Causing Bradydysrhythmias

- Avoid doing things that stimulate the vagus nerve, such as raising your arms above your head, applying pressure over your carotid artery, applying pressure on your eyes, bearing down or straining during a bowel movement, and stimulating a gag reflex when brushing your teeth or putting objects in your mouth.

For Patients with Premature Beats and Ectopic Rhythms

- Take the medications that have been prescribed for you, and report any adverse effects to your physician.
- Stop smoking, avoid caffeinated beverages as much as possible, and drink alcohol only in moderation.
- Learn ways to manage stress and avoid getting too tired.

For Patients with Ischemic Heart Disease

- If you have an angina attack, treat it promptly with rest and nitroglycerin administration as prescribed by your physician. This decreases your chances of experiencing a dysrhythmia.
- If chest pain is not relieved after taking the amount of nitroglycerin that has been prescribed for you, seek medical attention promptly. Also, seek prompt medical attention if the pain becomes more severe or you experience other symptoms, such as sweating, nausea, weakness, and palpitations.

For Patients at Risk for Potassium Imbalance

- Know the symptoms of decreased potassium levels, such as muscle weakness and cardiac irregularity.
- Eat foods high in potassium, such as tomatoes, beans, prunes, avocados, bananas, strawberries, and lettuce.
- Take the potassium supplements that have been prescribed for you.

CONSIDERATIONS FOR OLDER ADULTS

Older adults are at increased risk for dysrhythmias because of changes in their cardiac conduction system. The sinoatrial node has fewer pacemaker cells. There is a loss of fibers in the bundle branch system. Therefore older adults are at risk for sinus node dysfunction and may require pacemaker therapy. The most common dysrhythmias are premature atrial contractions, premature ventricular contractions, and atrial fibrillation. Dysrhythmias tend to be more serious in older patients because of underlying heart disease, causing cardiac decompensation. Consequently, blood flow to organs, which may already be decreased because of the aging process, is further compromised, leading to multisystem organ dysfunction. [Chart 36-6](#) highlights special considerations for older adults receiving antidysrhythmic therapy.

purposes, using basic terms that are easily understood. Clear instructions regarding dosage schedules and common side effects are important (see [Chart 36-2](#)). Emphasize the importance of reporting these side effects and any dizziness, nausea, vomiting, chest discomfort, or shortness of breath to the health care provider.

Teach all patients and their family members how to take a pulse and blood pressure. Remind them to report any signs

CHART 36-6 NURSING FOCUS ON THE OLDER ADULT

Dysrhythmias

Special nursing considerations for the older patient with dysrhythmias are:

- Evaluate the patient with dysrhythmias immediately for the presence of a life-threatening dysrhythmia or hemodynamic deterioration.
- Assess the patient with a dysrhythmia for angina, hypotension, heart failure, and decreased cerebral and renal perfusion.
- Consider these causes of dysrhythmias when taking the patient's history: hypoxia, drug toxicity, electrolyte imbalances, heart failure, and myocardial ischemia or infarction.
- Assess the patient's level of education, hearing, learning style, and ability to understand and recall instructions to determine the best approaches for teaching.
- Assess the patient's ability to read written instructions.
- Teach the patient the generic and trade names of prescribed antidysrhythmic drugs, as well as their purposes, dosage, side effects, and special instructions for their use.
- Provide clear written instructions in basic language and easy-to-read print.
- Provide a written drug dosage schedule for the patient, considering all the drugs the patient is taking and possible drug interactions.
- Assess the patient for possible side effects or adverse reactions to drugs considering age and health status.
- Teach the patient to take his or her pulse and to report significant changes in heart rate or rhythm to the health care provider.
- Inform the patient of available resources for blood pressure and pulse checks, such as blood pressure clinics, home health agencies, and cardiac rehabilitation programs.
- Instruct the patient on the importance of keeping follow-up appointments with the health care provider and reporting symptoms promptly.
- Include the patient's family members or significant other in all teaching whenever possible.
- Teach the patient to avoid drinking caffeinated beverages, to stop smoking, to drink alcohol only in moderation, and to follow his or her prescribed diet.

of a change in heart rhythm, such as a significant decrease in pulse rate, a rate more than 100 beats/min, or increased rhythm irregularity.

Give written and verbal information to patients who have a *permanent pacemaker* about the type and settings of their pacemaker. Teach the patient to report any pulse rate lower than that set on the pacemaker. Review the proper care of the pacemaker insertion site and the importance of reporting any fever or any redness, swelling, or drainage at the pacemaker insertion site. If the surgical incision is near either shoulder, teach and demonstrate range-of-motion exercises to perform to prevent shoulder stiffness.

! NURSING SAFETY PRIORITY

Action Alert

- Keep handheld cellular phones at least 6 inches away from the generator, with the handset on the ear opposite the side of the generator.
- Avoid sources of strong electromagnetic fields, such as magnets and telecommunications transmitters. These may cause interference and could change the pacemaker settings, causing a malfunction. Magnetic resonance imaging (MRI) is usually contraindicated, depending on the machine's technology.
- Remind patients to carry a pacemaker identification card and to wear a medical alert bracelet.

Chart 36-7 outlines the major points for patient and family teaching after the insertion of a permanent pacemaker.

Patients with an *implantable cardioverter/defibrillator* (ICD) usually continue to receive antidysrhythmic drugs after discharge from the hospital. Provide clear instructions about the purposes of drug therapy, dosage schedules, special instructions, and side effects that need to be reported. If patients experience an internal defibrillator shock, remind them to sit or lie down immediately and notify the physician. Some patients describe the experience of a shock as a quick thud or kick in the chest, whereas others relate severe discomfort similar to that of external defibrillation. Usually the shock is not as severe because the heart is sandwiched by the defibrillation pads, thus requiring less electrical current to convert the dysrhythmia. Inform family members that they may feel an electrical shock if they are touching the patient during delivery of the shock but that it is not harmful. Provide information about how to access the emergency medical services (EMS) system in the community. Recommend resources for the family to learn how to perform CPR.

Remind patients with an ICD to avoid sources of strong electromagnetic fields, such as large electrical generators and radio or television transmitters. Tell the patient that these items may inhibit tachydysrhythmia detection and therapy or may cause pacing or shocks. MRI should not be used for patients with ICDs. Handheld cellular phones must be at least 6 inches away from the generator, with the handset held to the ear opposite the side of the ICD. If the pulse generator emits a beeping sound or provides some other indicator, the patient must move away from the area as quickly as possible to prevent deactivation of the device. Teach the patient with an ICD to carry an ICD identification card and wear a medical alert bracelet. Chart 36-8 highlights the important points for teaching patients and family members and significant others.

Health Care Resources

The cardiac rehabilitation nurse typically provides written and oral information about dysrhythmias, antidysrhythmic drugs, pacemakers, and ICDs, as well as information about cardiac exercise programs, educational programs, and support groups. The office or ambulatory care nurse may also provide information about resources. Teach the patient how to contact the local chapter of the American Heart Association

CHART 36-7 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Permanent Pacemakers

- Follow the instructions for pacemaker site skin care that have been specifically prepared for you. Report any fever or redness, swelling, or drainage from the incision site to your physician.
- Keep your pacemaker identification card in your wallet, and wear a medical alert bracelet.
- Take your pulse for 1 full minute at the same time each day, and record the rate in your pacemaker diary. Take your pulse any time you feel symptoms of a possible pacemaker failure, and report your heart rate and symptoms to your physician.
- Know the rate at which your pacemaker is set and the basic functioning of your pacemaker. Know what rate changes to report to your physician.
- Do not apply pressure over your generator. Avoid tight clothing or belts.
- You may take baths or showers without concern for your pacemaker.
- Inform other physicians and dentists that you have a pacemaker. Certain tests they may wish to perform (e.g., magnetic resonance imaging) could affect or damage your pacemaker.
- Know the indications of battery failure for your pacemaker as you were instructed, and report these findings to your physician if they occur.
- Do not operate electrical appliances directly over your pacemaker site because this may cause your pacemaker to malfunction.
- Do not lean over electrical or gasoline engines or motors. Be sure that electrical appliances or motors are properly grounded.
- Avoid all transmitter towers for radio, television, and radar. Radio, television, other home appliances, and antennas do not pose a hazard.
- Be aware that antitheft devices in stores may cause temporary pacemaker malfunction. If symptoms develop, move away from the device.
- Inform airport personnel of your pacemaker before passing through a metal detector, and show them your pacemaker identification card. The metal in your pacemaker will trigger the alarm in the metal detector device.
- Stay away from any arc welding equipment.
- Be aware that it is safe to operate a microwave oven unless it does not have proper shielding (old microwave ovens) or is defective.
- Report any of these symptoms to your physician if you experience them: difficulty breathing, dizziness, fainting, chest pain, weight gain, and prolonged hiccups. If you have any of these symptoms, check your pulse rate and call your physician.
- If you feel symptoms when near any device, move 5 to 10 feet away from it and then check your pulse. Your pulse rate should return to normal.
- Keep all of your physician and pacemaker clinic appointments.
- Take all medications prescribed for you as instructed.
- Follow your prescribed diet.
- Follow instructions on restrictions on physical activity, such as no sudden, jerky movement for 8 weeks to allow the pacemaker to settle in place.

CHART 36-8 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Implantable Cardioverter/Defibrillator

- Follow the instructions for implantable cardioverter/defibrillator (ICD) site skin care that have been specifically prepared for you.
- Report to your physician any fever or redness, swelling, soreness, or drainage from your incision site.
- Do not wear tight clothing or belts that could cause irritation over the ICD generator.
- Avoid activities that involve rough contact with the ICD implantation site.
- Keep your ICD identification card in your wallet, and consider wearing a medical alert bracelet.
- Know the basic functioning of your ICD device and its rate cutoff, as well as the number of consecutive shocks it can deliver.
- Avoid magnets directly over your ICD because they can inactivate the device. If beeping tones are coming from the ICD, move away from the electromagnetic field immediately (within 30 seconds) before the inactivation sequence is completed, and notify your physician.
- Inform all physicians and dentists caring for you that you have an ICD implanted, because certain diagnostic tests and procedures must be avoided to prevent ICD malfunction. These include diathermy, electrocautery, and nuclear magnetic resonance tests.
- Avoid other sources of electromagnetic interference, such as devices emitting microwaves (not microwave ovens); transformers; radio, television, and radar transmitters; large electrical generators; metal detectors, including handheld security devices at airports; antitheft devices; arc welding equipment; and sources of 60-cycle (Hz) interference. Also avoid leaning directly over the alternator of a running motor of a car or boat.
- Report to your physician symptoms such as fainting, nausea, weakness, blackout, and rapid pulse rates.
- Take all medications prescribed for you as instructed.
- Follow instructions on restrictions on physical activity, such as not swimming, driving motor vehicles, or operating dangerous equipment.
- Follow your prescribed diet.
- Keep all physician and ICD clinic appointments.
- Sit or lie down immediately if you feel dizzy or faint to avoid falling if the ICD discharges.
- Post emergency telephone numbers.
- Know how to contact the local emergency medical services (EMS) systems in your community. Inform them in advance that you have an ICD so that they can be prepared if they need to respond to an emergency call for you.
- Know how to perform cough cardiopulmonary resuscitation (CPR) as instructed.
- Encourage family members to learn how to perform CPR. Family members should know that if they are touching you when the device discharges, they may feel a slight shock but that this is not harmful to them.
- Follow instructions on what to do if the ICD successfully discharges, after which you feel well. This may include maintaining a diary of the date, the time, activity preceding the shock, symptoms, the number of shocks delivered, and how you feel after the shock. The physician may wish to be notified each time the device discharges.
- Avoid strenuous activities that may cause your heart rate to meet or exceed the rate cutoff of your ICD because this causes the device to discharge inappropriately.
- Notify your physician for information regarding access to health care if you are leaving town or are relocating.

(www.americanheart.org) or the provincial chapter of the Heart and Stroke Foundation in Canada (www.heartandstroke.ca) for information about dysrhythmias, pacemakers, and CPR training.

Manufacturers of pacemakers and ICDs provide helpful booklets and videotapes to give patients and their families a better understanding of these therapies. Teach patients how to use telephonic systems for transmission of their rhythms to the ambulatory care setting or health care provider's office. Stress the importance of keeping scheduled appointments for visits with the cardiologist and pacemaker or ICD clinic.

Instruct patients to contact the local ambulance or paramedic services and emergency facilities to let them know that they have these devices implanted. Encourage the patient and family to attend pacemaker or ICD support groups.

EVALUATION: OUTCOMES

Evaluate the care of the patient with dysrhythmias on the basis of the identified priority patient problems. The primary expected outcome is that the patient will have adequate blood flow from the left ventricle to support systemic blood pressure and promote tissue perfusion.

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing inadequate oxygenation and tissue perfusion as a result of dysrhythmias?

- Report of chest discomfort or pain
- Report of dizziness or syncope
- Shortness of breath
- Weakness and fatigue
- Decreased urine output
- Pale, cool skin
- Diaphoresis
- Anxiety or restlessness

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate oxygenation and perfusion as a result of dysrhythmias?

Perform and Interpret Physical Assessment, Including:

- Taking vital signs (may have hypotension and weak pulse)
- Checking for pulse deficit
- Asking if patient has palpitations
- Checking capillary refill (decreased)
- Listening to lung and heart sounds
- Assessing cognition
- Taking an ECG
- Checking oxygen saturation

Respond By:

- Applying oxygen
- Keeping the head of the bed elevated unless patient is very hypotensive

NURSING CONCEPT REVIEW—cont'd

- Maintaining or starting an IV line
- Notifying the health care provider or Rapid Response Team
- Giving drug therapy as prescribed
- Assisting with other procedures as needed, for example, defibrillation

On what should you REFLECT?

- Evaluate patient's response to drug therapy.
- Observe for evidence of increased oxygenation and perfusion.
- Think about what else you could have done to assist the patient with this problem.

GET READY FOR THE NCLEX® EXAMINATION!**KEY POINTS**

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Be very careful to protect patients and staff to prevent electrical injury when assisting with invasive pacemakers, cardioversion, and defibrillation.
- Use infection control precautions during resuscitation efforts for a patient with a dysrhythmia.

Health Promotion and Maintenance

- Teach patients with dysrhythmias the correct drug, dose, route, time, and side effects of prescribed medications, and teach them to notify their physicians if adverse effects occur (see [Chart 36-2](#)).
- Teach family members where to learn cardiopulmonary resuscitation (CPR) to decrease their anxiety while living with a patient with dysrhythmias.
- Teach patients the importance of adhering to their prescribed cardiac regimen, such as checking their pulse to ascertain pacemaker function.

Physiological Integrity

- Assess patients with dysrhythmias for a decrease in cardiac output resulting in inadequate oxygenation and perfusion to vital organs (see [Chart 36-1](#)).

- Monitor patients with dysrhythmias, including conducting a physical assessment and health history, as well as interpreting ECG rhythm strips. Report significant changes to the health care provider.
- Interpret common dysrhythmias, especially bradycardia, tachycardia, atrial fibrillation and ventricular fibrillation (VF), premature ventricular contractions (PVCs), and asystole, using ECG analysis (see [Figs. 36-8 through 36-12](#)).
- Use the special considerations when caring for older adults with dysrhythmias, as described in [Chart 36-6](#).
- Noninvasive pacing is an emergency measure to provide demand ventricular pacing in patients with profound bradycardia or asystole. Teach patients to expect possible discomfort.
- Identify and intervene in life-threatening situations by providing cardiopulmonary resuscitation, electrical therapy, or drug administration.
- Automated external defibrillators are used by medical and lay personnel as an essential intervention for VF.
- Do not perform CPR while the patient is being defibrillated.
- Use [Charts 36-7 and 36-8](#) to educate patients with permanent pacemakers or ICDs.

Concept Map Creator

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Evaluate the status of patients with end-stage heart disease regarding advance directives.
2. Provide the patient with heart failure (HF) and the family information on discharge to home, hospice, or other community-based setting.
3. Collaborate with the interdisciplinary team when providing care to patients with cardiac problems.

Health Promotion and Maintenance

4. Identify community resources for patients with cardiac problems and their families.
5. Provide special care needs of older adults with heart failure.
6. Teach patients about actions to maintain health and prevent worsening HF.

Psychosocial Integrity

7. Assess the patient and family response to living with chronic HF and possible transplantation.

Physiological Integrity

8. Explain the pathophysiology of HF.
9. Compare and contrast left-sided and right-sided HF.
10. Identify priority problems for patients with HF.
11. Perform a comprehensive assessment of patients experiencing cardiac problems.

12. Explain how common drug therapies improve cardiac output and prevent worsening of HF.
13. Assess patients for adverse effects of drug therapy for cardiac problems.
14. Monitor the laboratory values for patients with cardiac problems.
15. Plan nursing interventions to improve the patient's cardiovascular status when needed.
16. Provide emergency care for patients experiencing life-threatening complications, such as cardiac tamponade and pulmonary edema.
17. Identify the four Heart Failure Core Measures required by The Joint Commission.
18. Describe essential focused assessments used by the home care nurse for patients with heart failure.
19. Compare and contrast common valvular disorders.
20. Describe surgical management for patients with valvular disease.
21. Develop a teaching/learning plan for patients with valvular disease.
22. Differentiate between common cardiac inflammations and infections—endocarditis, pericarditis, and rheumatic carditis.
23. Provide postoperative care for patients having a heart transplant.
24. Identify clinical assessment findings for patients with cardiomyopathy.

This chapter focuses on heart failure and its common causes in the adult population; coronary artery disease is discussed in [Chapter 40](#). Heart failure is the most common reason for hospital stays in patients older than 65 years in the United States. When the heart is diseased, it cannot effectively pump an adequate amount of arterial blood to the rest of the body. Arterial blood carries *oxygen* and nutrients to vital organs, such as the kidneys and brain, and peripheral tissues. When these organs and other body tissues are not adequately *perfused*, they may not function properly.

HEART FAILURE

Heart failure, sometimes referred to as **pump failure**, is a general term for the inability of the heart to work effectively as a pump. It results from a number of acute and chronic cardiovascular problems that are discussed later in this chapter and elsewhere in the cardiovascular unit.

Pathophysiology

Heart failure (HF) is a common *chronic* health problem, with acute episodes often causing hospitalization. Acute coronary disease and other structural or functional problems of the heart can lead to *acute* heart failure. Both acute and chronic HF can be life threatening if they are not adequately treated or if the patient does not respond to treatment.

Types of Heart Failure

The major types of heart failure are:

- Left-sided heart failure
- Right-sided heart failure
- High-output failure

Because the two ventricles of the heart represent two separate pumping systems, it is possible for one to fail by itself for a short period. *Most heart failure begins with failure of the left ventricle and progresses to failure of both ventricles.* Typical causes of **left-sided heart (ventricular) failure** include hypertension, coronary artery disease, and valvular disease involving the mitral or aortic valve. Decreased tissue perfusion from poor cardiac output and pulmonary congestion from increased pressure in the pulmonary vessels indicate left ventricular failure (LVF).

Left-sided heart failure was formerly referred to as **congestive heart failure (CHF)**; however, not all cases of LVF involve fluid accumulation. In the clinical setting, though, the term *CHF* is still commonly used. Left-sided failure may be acute or chronic and mild to severe. It can be further divided into two subtypes: systolic heart failure and diastolic heart failure.

Systolic heart failure (systolic ventricular dysfunction) results when the heart cannot contract forcefully enough during systole to eject adequate amounts of blood into the circulation. Preload increases with decreased contractility, and afterload increases as a result of increased peripheral resistance (e.g., hypertension) (McCance et al., 2010). The **ejection fraction** (the percentage of blood ejected from the heart during systole) drops from a normal of 50% to 70% to below 40% with ventricular dilation. As it decreases, tissue perfusion diminishes and blood accumulates in the pulmonary vessels. Manifestations of systolic dysfunction may include symptoms of inadequate tissue perfusion or pulmonary and systemic congestion. Systolic heart failure is often called “forward failure” because cardiac output is decreased

and fluid backs up into the pulmonary system. Because these patients are at high risk for sudden cardiac death, patients with an ejection fraction of less than 30% are considered candidates for an implantable cardioverter/defibrillator (ICD; also known as an *internal cardioverter/defibrillator*) (see [Chapter 36](#)).

In contrast, **diastolic heart failure** (heart failure with preserved left ventricular function) occurs when the left ventricle cannot relax adequately during diastole. Inadequate relaxation or “stiffening” prevents the ventricle from filling with sufficient blood to ensure an adequate cardiac output. Although ejection fraction is more than 40%, the ventricle becomes less compliant over time because more pressure is needed to move the same amount of volume as compared with a healthy heart. Diastolic failure represents about 20% to 40% of all heart failure, primarily in older adults and in women who have chronic hypertension and undetected coronary artery disease. Clinical manifestations and management of diastolic failure are similar to those of systolic dysfunction (McCance et al., 2010).

Right-sided heart (ventricular) failure may be caused by left ventricular failure, right ventricular myocardial infarction (MI), or pulmonary hypertension. In this type of heart failure (HF), the right ventricle cannot empty completely. Increased volume and pressure develop in the venous system, and peripheral edema results.

High-output heart failure can occur when cardiac output remains normal or above normal, unlike left- and right-sided heart failure, which are typically low-output states. High-output failure is caused by increased metabolic needs or hyperkinetic conditions, such as septicemia, high fever, anemia, and hyperthyroidism. This type of heart failure is not as common as other types.

Classification and Staging of Heart Failure

The American College of Cardiology (ACC) and American Heart Association (AHA) have developed evidence-based guidelines for staging and managing heart failure as a chronic, progressive disease. These guidelines do not replace the New York Heart Association (NYHA) functional classification system, which is used to describe symptoms a patient may exhibit (see [Table 35-2](#) in [Chapter 35](#)).

The ACC/AHA staging system when compared with the NYHA system categorizes patients as:

- A. Patients at high risk for developing heart failure (class I NYHA)
- B. Patients with cardiac structural abnormalities or remodeling who have not developed HF symptoms (class I NYHA)
- C. Patients with current or prior symptoms of heart failure (class II or III NYHA)
- D. Patients with refractory end-stage heart failure (class IV NYHA)

Another method for staging HF is the Killip classification system, which is based on the heart’s hemodynamic ability. [Table 40-3](#) in [Chapter 40](#) outlines this system.

Compensatory Mechanisms

When cardiac output is insufficient to meet the demands of the body, compensatory mechanisms work to improve cardiac output ([Fig. 37-1](#)). Although these mechanisms may initially increase cardiac output, they eventually have a damaging

FIG. 37-1 Left-sided heart failure from elevated systemic vascular resistance. Left heart failure leads to right heart failure. Systemic vascular resistance and preload are exacerbated by renal and adrenal mechanisms. *ADH*, Antidiuretic hormone; *LA*, left atrial; *LV*, left ventricular; *LVEDP*, left ventricular end-diastolic pressure; *RV*, right ventricular.

effect on pump function. Major compensatory mechanisms include:

- Sympathetic nervous system stimulation
- Renin-angiotensin system (RAS) activation
- Other chemical responses
- Myocardial hypertrophy

Stimulation of the Sympathetic Nervous System. In heart failure (HF), **stimulation of the sympathetic nervous system** (i.e., increasing catecholamines) as a result of tissue hypoxia represents the most immediate compensatory mechanism. Stimulation of the adrenergic receptors causes an increase in heart rate (beta adrenergic) and blood pressure from vasoconstriction (alpha adrenergic).

Because cardiac output (CO) is the product of heart rate (HR) and stroke volume (SV), an increase in HR results in

an immediate *increase in cardiac output*. The HR is limited, though, in its ability to compensate for decreased CO. If it becomes too rapid, diastolic filling time is limited and CO may start to decline. An increase in HR also significantly increases oxygen demand by the myocardium. If the heart is poorly perfused because of arteriosclerosis, HF may worsen.

Stroke volume (SV) is also *improved* by sympathetic stimulation. Sympathetic stimulation increases venous return to the heart, which further stretches the myocardial fibers causing dilation. According to Starling's law, increased myocardial stretch results in more forceful contraction. More forceful contractions increase SV and CO. After a critical point is reached within the cardiac muscle, further volume and stretch reduce the force of contraction and cardiac output.

Sympathetic stimulation also results in *arterial vasoconstriction*. Vasoconstriction has the benefit of maintaining blood pressure and improving tissue perfusion in low-output states. However, constriction of the arteries increases **afterload**, the resistance against which the heart must pump. Afterload is the major determinant of myocardial oxygen requirements. As it increases, the left ventricle requires more energy to eject its contents and SV may decline.

Renin-Angiotensin System Activation. Reduced blood flow to the kidneys, a common occurrence in low-output states, results in activation of the renin-angiotensin system (RAS). Vasoconstriction becomes more pronounced in response to angiotensin II, and aldosterone secretion causes sodium and water retention. Preload and afterload increase. Angiotensin II contributes to **ventricular remodeling** resulting in progressive myocyte (myocardial cell) contractile dysfunction over time (McCance et al., 2010).

Other Chemical Responses. In addition to the sympathetic nervous system and RAS responses, other mechanisms are activated when a patient experiences heart failure (HF). Most of these actions contribute to worsening of the condition.

For example, in those who have had an MI, heart muscle cell injury causes an *immune response*. Pro-inflammatory cytokines, such as tumor necrosis factor (TNF) and interleukins (IL-1 and IL-6), are released, especially with left-sided HF. These substances contribute to ventricular remodeling.

Natriuretic peptides are neurohormones that work to promote vasodilation and diuresis through sodium loss in the renal tubules. The **B-type natriuretic peptide (BNP)** is produced and released by the ventricles when the patient has fluid overload as a result of HF. It increases with age and has a greater concentration in women (Jessup et al., 2009). People who are obese have lower BNP levels compared with those who are not (Noveanu et al., 2009).

Low cardiac output (CO) causes decreased cerebral perfusion. As a result, the posterior pituitary gland secretes *vasopressin* (antidiuretic hormone [ADH]). The hormone causes vasoconstriction and fluid retention, which worsen HF.

Endothelin is secreted by endothelial cells when they are stretched. As the myocardial fibers are stretched in patients with HF, this potent vasoconstrictor is released, which increases peripheral resistance and hypertension. HF worsens as a result of these actions.

Myocardial Hypertrophy. **Myocardial hypertrophy** (enlargement of the myocardium), with or without chamber dilation, is another compensatory mechanism. The walls of the heart thicken to provide more muscle mass, which results in more forceful contractions, further increasing cardiac output. Cardiac muscle, however, may hypertrophy more rapidly than collateral circulation can provide adequate blood supply to the muscle. Often a hypertrophied heart is slightly oxygen deprived.

All the compensatory mechanisms contribute to an increase in the consumption of myocardial oxygen. When the demand for oxygen increases and the myocardial reserve has been exhausted, clinical manifestations of HF develop.

Etiology

Heart failure (HF) is caused by systemic hypertension in most cases. About a third of patients experiencing myocardial infarction (MI, “heart attack”) also develop HF. The next

TABLE 37-1 COMMON CAUSES AND RISK FACTORS FOR HEART FAILURE

• Hypertension • Coronary artery disease • Cardiomyopathy • Substance abuse (alcohol and illicit/prescribed drugs) • Valvular disease • Congenital defects • Cardiac infections and inflammations • Dysrhythmias	• Diabetes mellitus • Smoking/tobacco use • Family history • Obesity • Severe lung disease • Sleep apnea • Hyperkinetic conditions (e.g., hyperthyroidism)
---	--

most common cause is structural heart changes, such as valvular dysfunction, particularly pulmonic or aortic stenosis, which leads to pressure or volume overload on the heart. Common direct causes and risk factors for HF are listed in Table 37-1.

CONSIDERATIONS FOR OLDER ADULTS

Heart failure is a common problem among older adults. The use of certain drugs can contribute to the development or exacerbation of the problem in this population. For example, long-term use of NSAIDs for arthritis and other chronic pain can cause fluid and sodium retention. NSAIDs may also cause peripheral vasoconstriction and increase the toxicity of diuretics and angiotensin-converting enzyme inhibitors (ACEIs). Thiazolidinediones (TZDs) (e.g., pioglitazone [Actos]) used for diabetics also cause fluid and sodium retention. Rosiglitazone (Avandia), another TZD drug, has recently been found to cause acute myocardial infarction (AMI) in patients with type 2 diabetes. These drugs should be used with caution and restrictions in the older adult population.

Right-sided HF in the absence of left-sided HF is usually the result of pulmonary problems such as chronic obstructive pulmonary disease (COPD) or pulmonary hypertension. Acute respiratory distress syndrome (ARDS) may also cause right-sided HF. These problems are discussed elsewhere in the cardiac unit.

Incidence/Prevalence

Over five million people in the United States have HF, causing about 875,000 hospitalizations each year. HF is the most common reason for hospital admission for people over 65 years of age. African Americans are affected more often than Euro-Americans, probably because they have more risk factors that can lead to HF. The disease is a major cause of disability and death after MI, often due to nonadherence to the treatment plan and recommended lifestyle changes.

CONSIDERATIONS FOR OLDER ADULTS

Heart failure has been referred to as a U.S. epidemic, although it is a major problem worldwide (Joseph et al., 2009). One of the proposed U.S. *Healthy People 2020* objectives is to reduce the number of hospitalizations of older adults with HF as the principal diagnosis. Patient and family education can help meet this objective (Table 37-2). As the “baby boomer” population reaches 65 years of age, the numbers of hospital stays and deaths from HF are likely to increase dramatically.

TABLE 37-2 MEETING PROPOSED HEALTHY PEOPLE 2020 OBJECTIVES

Cardiac Disease

To reduce hospitalizations of older adults with heart failure as the principal diagnosis.

- For patients hospitalized for heart failure, collaborate with the case manager for discharge planning, including adequate support in the community.
- Provide a continuing plan of care for patients and their families or other caregivers when the patient is discharged from the hospital.
- If the patient is discharged to home, call to check that he or she has no impending signs and symptoms of heart failure (the case manager may make calls).
- Teach the patient and family or other caregiver about when to call the health care provider for health changes so the patient can be treated at home.
- Ensure that the interdisciplinary team provides the patient with follow-up care in the home or nursing home.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

When obtaining a history, keep in mind the many conditions that can lead to HF. Carefully question the patient about his or her medical history, including hypertension, angina (cardiac pain), MI, rheumatic heart disease, valvular disorders, endocarditis, and pericarditis. Ask about the patient's perception of his or her activity tolerance, breathing pattern, sleeping pattern, urinary pattern, and fluid volume status, as well as his or her knowledge about HF.

Left-Sided Heart Failure. With left ventricular systolic dysfunction, cardiac output (CO) is diminished, leading to impaired tissue perfusion, anaerobic metabolism, and unusual fatigue. Assess activity tolerance by asking whether the patient can perform normal ADLs or climb flights of stairs without *fatigue* or dyspnea. Many patients with heart failure (HF) experience weakness or fatigue with activity or have a feeling of heaviness in their arms or legs. Ask about their ability to perform simultaneous arm and leg work (e.g., walking while carrying a bag of groceries). Such activity may place an unacceptable demand on the failing heart. Ask the patient to identify his or her most strenuous activity in the past week. Many people unconsciously limit their activities in response to fatigue or dyspnea and may not realize how limited they have become.

Perfusion to the myocardium is often impaired as a result of left ventricular failure, especially with cardiac hypertrophy. The patient may report *chest discomfort* or may describe palpitations, skipped beats, or a fast heartbeat.

As the amount of blood ejected from the left ventricle diminishes, hydrostatic pressure builds in the pulmonary venous system and results in fluid-filled alveoli and pulmonary congestion, which results in a *cough*. The patient in early HF describes the cough as irritating, nocturnal (at night), and usually nonproductive. As HF becomes very severe, he or she may begin expectorating frothy, pink-tinged sputum—a sign of life-threatening pulmonary edema.

Dyspnea also results from increasing pulmonary venous pressure and pulmonary congestion. Carefully question about the presence of dyspnea and when and how it developed. The patient may refer to dyspnea as “trouble in catching my breath,” “breathlessness,” or “difficulty in breathing.”

As **exertional dyspnea** develops (also called *dyspnea upon or on exertion [DUE/DOE]*), the patient often stops previously tolerated levels of activity because of shortness of breath. Dyspnea at rest in the recumbent (lying flat) position is known as **orthopnea**. Ask how many pillows are used to sleep or whether the patient sleeps in an upright position in a bed, recliner, or other type of chair.

Patients who describe sudden awakening with a feeling of breathlessness 2 to 5 hours after falling asleep have **paroxysmal nocturnal dyspnea (PND)**. Sitting upright, dangling the feet, or walking usually relieves this condition.

Right-Sided Heart Failure. Signs of systemic congestion occur as the right ventricle fails, fluid is retained, and pressure builds in the venous system. Edema develops in the lower legs and may progress to the thighs and abdominal wall. Patients may notice that their shoes fit more tightly, or their shoes or socks may leave indentations on their swollen feet. They may have removed their rings because of swelling in their fingers and hands. Ask about weight gain. An adult may retain 4 to 7 liters of fluid (10 to 15 lb [4.5 to 6.8 kg]) before pitting edema occurs.

Reports of *nausea and anorexia* may be a direct consequence of liver engorgement (congestion) resulting from fluid retention. In *advanced* heart failure (HF), *ascites* and an increased abdominal girth may develop from severe liver congestion. Another common finding related to fluid retention is *diuresis at rest*. At rest, fluid in the peripheral tissue is mobilized and excreted and the patient describes frequent awakening at night to urinate.

Obtain a careful nutritional history, questioning about the use of salt and the types of food consumed. Ask about daily fluid intake. Patients with HF may experience increased thirst and drink excessive fluid (4000 to 5000 mL/day) because of sodium retention.

Physical Assessment/Clinical Manifestations

Manifestations of HF depend on the type of failure, the ventricle involved, and the underlying cause. Impaired tissue perfusion, pulmonary congestion, and edema are associated with *left* ventricular failure (**Chart 37-1**). Conversely, systemic venous congestion and peripheral edema are associated with *right* ventricular failure (**Chart 37-2**).

Left-Sided Heart Failure. Left ventricular failure is associated with decreased cardiac output and elevated pulmonary venous pressure. It may appear clinically as:

- Weakness
- Fatigue
- Dizziness
- Acute confusion
- Pulmonary congestion
- Breathlessness
- Oliguria (scant urine output)

Decreased blood flow to the major body organs can cause dysfunction, especially renal failure. Nocturia may occur when the patient is at rest.

The pulse may be tachycardic, or it may alternate in strength (**pulsus alternans**). Take the apical pulse for a full

CHART 37-1 KEY FEATURES

Left-Sided Heart Failure**DECREASED CARDIAC OUTPUT**

- Fatigue
- Weakness
- Oliguria during the day (nocturia at night)
- Angina
- Confusion, restlessness
- Dizziness
- Tachycardia, palpitations
- Pallor
- Weak peripheral pulses
- Cool extremities

PULMONARY CONGESTION

- Hacking cough, worse at night
- Dyspnea/shortness of breath
- Crackles or wheezes in lungs
- Frothy, pink-tinged sputum
- Tachypnea
- S₃/S₄ summation gallop

CHART 37-2 KEY FEATURES

Right-Sided Heart Failure**Systemic Congestion**

- Jugular (neck vein) distention
- Enlarged liver and spleen
- Anorexia and nausea
- Dependent edema (legs and sacrum)
- Distended abdomen
- Swollen hands and fingers
- Polyuria at night
- Weight gain
- Increased blood pressure (from excess volume) or decreased blood pressure (from failure)

minute, noting any irregularity in heart rhythm. *An irregular heart rhythm resulting from premature atrial contractions (PACs), premature ventricular contractions (PVCs), or atrial fibrillation (AF) is common in HF (see Chapter 36).* The sudden development of an irregular rhythm may further compromise CO. Carefully monitor the patient's respiratory rate, rhythm, and character, as well as oxygen saturation. The respiratory rate typically exceeds 20 breaths/min.

Assess whether the patient is oriented to person, place, and time. A short mental status examination may be used if there are concerns about orientation. Objective data are important because in daily conversation many people are skillful at covering up memory losses. Older adults are frequently disoriented or confused when the heart fails due to brain hypoxia (decreased oxygen).

Increased heart size is common with a displacement of the apical impulse to the left. A third heart sound, **S₃ gallop**, is an early diastolic filling sound indicating an increase in left ventricular pressure. This sound is often the first sign of HF. A fourth heart sound (S₄) also can occur; it is not a sign of failure but is a reflection of decreased ventricular compliance.

Auscultate for crackles and wheezes of the lungs. Late inspiratory crackles and fine profuse crackles that repeat themselves from breath to breath and do not diminish with coughing indicate HF. *Crackles are produced by intra-alveolar fluid and are often noted first in the bases of the lungs and spread upward as the condition worsens.* Wheezes indicate a narrowing of the bronchial lumen caused by engorged pulmonary vessels. Identify the precise location of crackles and wheezes and whether the wheezes are heard on inspiration, expiration, or both.

Right-Sided Heart Failure. Right ventricular failure is associated with increased systemic venous pressures and congestion. On inspection, assess the neck veins for distention and measure abdominal girth. Hepatomegaly (liver engorgement), hepatjugular reflux, and ascites may also be assessed. Abdominal fluid can reach volumes of more than 10 liters.

Assess for dependent edema. In ambulatory patients, edema commonly presents in the ankles and legs. When patients are restricted to bedrest, the sacrum is dependent and fluid accumulates there.

! NURSING SAFETY PRIORITY**Action Alert**

Edema is an extremely unreliable sign of HF. Be sure that accurate daily weights are taken every morning to document fluid retention. *Weight is the most reliable indicator of fluid gain and loss!*

? NCLEX EXAMINATION CHALLENGE**Physiological Integrity**

A client is diagnosed with right-sided heart failure. Which assessment findings will the nurse expect the client to have? **Select all that apply.**

- A. Peripheral edema
- B. Crackles in both lungs
- C. Breathlessness
- D. Ascites
- E. Lung congestion

Psychosocial Assessment

Chronic heart failure (HF) is typically a slow, debilitating disease. Anxiety and frustration are common. Symptoms such as dyspnea increase the patient's anxiety level.

Patients with HF, especially those with advanced disease, are at high risk for depression. It is not certain whether the functional impairments contribute to the depression or depression affects functional ability. Older hospitalized patients may be depressed, particularly those who have been readmitted for an acute episode of HF. Lifestyle changes and quality-of-life issues can also cause depression many months after the initial diagnosis of HF (Thomas et al., 2008).

Assess patients and their families for anxiety and depression. Ask them about their usual methods of coping, as well as any history of depression. If anxiety or depression is present, notify the health care provider for further assessment. Social workers, certified clinical chaplains, or psychologists may administer specific assessment tools to determine the extent of the problem. Some patients need drug therapy and nonpharmacologic modalities, such as cognitive behavior therapy, biofeedback, or relaxation training.

Hope is a major indicator of well-being for patients with HF. Those who are hopeful tend to feel better and are more socially involved. Ask patients about their daily activities and how often they interact with the significant people in their life to help determine patient and family coping strategies.

Laboratory Assessment

Electrolyte imbalance may occur from complications of HF or as side effects of drug therapy, especially diuretic therapy. Regular evaluations of a patient's *serum electrolytes*, including

sodium, potassium, magnesium, calcium, and chloride, are essential. Any impairment of renal function resulting from inadequate perfusion causes elevated blood urea nitrogen and serum creatinine and decreased creatinine clearance levels. *Hemoglobin* and *hematocrit* tests should be performed to identify HF resulting from anemia. If the patient has fluid volume excess, the hematocrit levels may be low as a result of hemodilution.

B-type natriuretic peptide (BNP) is used for diagnosing HF (in particular, diastolic HF) in patients with acute dyspnea. As discussed earlier, it is part of the body's response to decreased cardiac output from either left or right ventricular dysfunction. An increase in BNP, in conjunction with history and physical, best differentiates between the dyspnea of HF and that associated with lung dysfunction (Wexler et al., 2009). However, patients with renal disease may also have elevated BNP levels (Chen et al., 2010).

Urinalysis may reveal proteinuria and high specific gravity. *Microalbuminuria* is an early indicator of decreased compliance of the heart and occurs before the BNP rises. It serves as an "early warning detector" that lets the health care provider know that the heart is experiencing early signs of decreased compliance, long before symptoms occur.

CONSIDERATIONS FOR OLDER ADULTS

Thyroxine (T_4) and thyroid-stimulating hormone (TSH) levels should be assessed in patients who are older than 65 years, have atrial fibrillation, or have evidence of thyroid disease. Heart failure (HF) may be caused or aggravated by hypothyroidism or hyperthyroidism.

Arterial blood gas (ABG) values often reveal hypoxemia (low blood oxygen level) because oxygen does not diffuse easily through fluid-filled alveoli. Respiratory alkalosis may occur because of hyperventilation; respiratory acidosis may occur because of carbon dioxide retention. Metabolic acidosis may indicate an accumulation of lactic acid.

Imaging Assessment

Chest x-rays can be helpful in diagnosing left ventricular failure. Typically the heart is enlarged (cardiomegaly), representing hypertrophy or dilation. Pleural effusions develop less often and generally reflect biventricular failure. *Echocardiography is considered the best tool in diagnosing heart failure.* Cardiac valvular changes, pericardial effusion, chamber enlargement, and ventricular hypertrophy can be diagnosed using this noninvasive technique. The test can also be used to determine ejection fraction.

Radionuclide studies (thallium imaging or technetium pyrophosphate scanning) can also indicate the presence and cause of HF. Multigated angiographic (MUGA) scans provide information about left ventricular ejection fraction and velocity, which are typically low in patients with HF. These tests are discussed in [Chapter 35](#).

Other Diagnostic Assessment

An *electrocardiogram (ECG)* is also performed. It may show ventricular hypertrophy, dysrhythmias, and any degree of myocardial ischemia, injury, or infarction. It is *not* helpful in determining the presence or extent of HF.

Invasive hemodynamic monitoring allows the direct assessment of cardiac function and volume status in acutely ill

patients. These measurements can confirm the diagnosis and guide the management of HF. Right atrial pressure may be normal or elevated in left ventricular failure and is elevated in right ventricular failure. Pulmonary artery pressure (PAP) and pulmonary artery wedge pressure (PAWP) are elevated in left-sided HF because volumes and pressures are increased in the left ventricle. (See [Chapter 35](#) for a more detailed description of hemodynamic monitoring.)

ANALYSIS

The priority problems for patients with heart failure (HF) include:

1. Impaired Gas Exchange related to ventilation/perfusion imbalance
2. Decreased Cardiac Output related to altered contractility, preload, and afterload
3. Fatigue and weakness related to hypoxemia
4. Potential for pulmonary edema related to left-sided HF

PLANNING AND IMPLEMENTATION

The patient-centered collaborative care that patients with HF need depends on their disease stage and severity of signs and symptoms.

Improving Gas Exchange

Planning: Expected Outcomes. The expected outcome is that the patient will have an optimal spontaneous breathing pattern that increases oxygenation and maintains a serum carbon dioxide level that is within normal limits.

Interventions. The purpose of collaborative care is to help promote oxygenation and gas exchange. *Ventilation assistance* may be needed because the oxygen content of the blood is often decreased in patients who have pulmonary congestion. Monitor or have assistive personnel monitor the patient's respiratory rate, rhythm, and quality every 1 to 4 hours. Auscultate breath sounds every 4 to 8 hours.

NURSING SAFETY PRIORITY

Action Alert

Provide the necessary amount of supplemental oxygen within a range prescribed by the health care provider *to maintain oxygen saturation at 90% or greater.* If the patient has dyspnea, place him or her in a high Fowler's position with pillows under each arm to maximize chest expansion and improve oxygenation. Repositioning and performing coughing and deep-breathing exercises every 2 hours help improve oxygenation and prevent atelectasis. Collaborate with the respiratory therapist, if available, to plan the most effective methods for assisting with ventilation.

Improving Cardiac Output

Planning: Expected Outcomes. The expected outcome is that the patient will have increased cardiac output by improving stroke volume (SV) (determined by preload, afterload, and contractility) and heart rate (HR).

Interventions. Collaborative care begins with nonsurgical interventions, but the patient may need surgery if these are not successful in meeting optimal outcomes.

Nonsurgical Management. Nonsurgical management relies primarily on a variety of drugs ([Table 37-3](#)). If drug therapy is ineffective, other nonsurgical options are available.

TABLE 37-3 COMMONLY USED DRUG CLASSIFICATIONS FOR PATIENTS WITH SYSTOLIC HEART FAILURE

Angiotensin-converting enzyme (ACE) inhibitors or angiotensin-receptor blockers (ARBs)

Diuretics:

- High-ceiling
- Potassium-sparing

Human B-type natriuretic peptides

Nitrates

Inotropics:

- Beta-adrenergic agonists
- Phosphodiesterase inhibitors
- Calcium sensitizers
- Digoxin (Lanoxin)

Beta-adrenergic blockers

Drugs to improve stroke volume include those that reduce afterload, reduce preload, and improve cardiac muscle contractility. A major role of the nurse is to give medications as prescribed, monitor for their therapeutic and adverse effects, and teach the patient and family about drug therapy. A variety of classes of drugs that reduce afterload and preload are used to manage heart failure (see Table 37-3).

Drugs That Reduce Afterload. By relaxing the arterioles, arterial vasodilators can reduce the resistance to left ventricular ejection (afterload) and improve CO. These drugs do not cause excessive vasodilation but reverse some of the inappropriate or excessive vasoconstriction common in HF.

Angiotensin-Converting Enzyme Inhibitors (ACEIs) and Angiotensin-Receptor Blockers (ARBs). Patients with even mild heart failure (HF) resulting from left ventricular dysfunction are given a trial of ACE inhibitors or ARBs. Both ACE inhibitors (e.g., enalapril [Vasotec] and fosinopril [Monopril]) and ARBs (e.g., valsartan [Diovan], irbesartan [Avapro], and losartan [Cozaar]) improve function and quality of life for patients with HF. ACE inhibitors are the first-line drug of choice, but some health care providers prefer to start the patient on an ARB because ACE inhibitors can cause a nagging, dry cough. For patients with *acute* HF, the health care provider may prescribe an IV-push ACE inhibitor such as Vasotec IV.

The ACE inhibitors and ARBs suppress the renin-angiotensin system (RAS), which is activated in response to decreased renal blood flow. ACE inhibitors prevent conversion of angiotensin I to angiotensin II, resulting in arterial dilation and increased stroke volume. ARBs block the effect

of angiotensin II receptors and thus decrease arterial resistance and arterial dilation. In addition, these drugs block aldosterone, which prevents sodium and water retention, thus decreasing fluid overload. *Both ACEIs and ARBs work more effectively for Euro-Americans than for African-American populations.* Volume-depleted patients should receive a low starting dose, or the fluid volume should be restored before beginning the prescribed drug. Monitor for hyperkalemia, a potential adverse drug effect in patients who have renal dysfunction.

Assess for orthostatic hypotension, acute confusion, poor peripheral perfusion, and reduced urine output in patients with low systolic blood pressure. Monitor serum potassium and creatinine levels to determine renal dysfunction. Additional nursing implications for selected ACE inhibitor/ARB drugs are described in Chapter 38 on p. 783 in the Drug Therapy section.

Human B-type Natriuretic Peptides. Human B-type natriuretic peptides (hBNPs) such as nesiritide (Natrecor) are often used to treat *acute* HF. Endogenous BNP is released in response to decreased CO and causes *natriuresis*, or loss of sodium in the renal tubules, as well as vasodilation. Natrecor lowers pulmonary capillary wedge pressure (PCWP) and improves renal glomerular filtration. It is given as an IV bolus over 60 seconds followed with a continuous infusion for up to 48 hours.

! NURSING SAFETY PRIORITY

Drug Alert

When giving Natrecor, monitor BP and pulse carefully because significant decreases in BP may occur. Although the patient's systolic BP may be between 90 and 100 mm Hg, he or she is usually asymptomatic. *Give Natrecor through a separate infusion line because it is incompatible with heparin and most other parenteral medications.* Expect an increase in the serum BNP after drug administration.

Interventions That Reduce Preload. Ventricular fibers contract less forcefully when they are overstretched, such as in a failing heart. Interventions aimed at reducing preload attempt to decrease volume and pressure in the left ventricle, increasing ventricular muscle stretch and contraction. Preload reduction is appropriate for HF accompanied by congestion with total body sodium and water overload.

Nutrition Therapy. In HF, nutrition therapy is aimed at reducing sodium and water retention to decrease the workload of the heart. The health care provider may restrict sodium intake in an attempt to decrease fluid retention. Many patients need to omit table salt (no added salt) from their diet, thus reducing sodium intake to about 3 g daily.

If salt intake must be reduced further, the patient may need to eliminate all salt in cooking and high-sodium foods (e.g., ham, bacon, pickles), thus reducing sodium intake to 2 g daily. If needed, collaborate with the dietitian to help the patient select foods that meet such a restricted therapeutic diet.

Few patients are placed on severe fluid restrictions. However, patients with excessive aldosterone secretion may experience thirst and drink 3 to 5 liters of fluid each day. As a result, their fluid intake may be limited to a more normal 2 liters daily. *Supervise unlicensed assistive personnel (UAP) to ensure that they limit the prescribed intake and accurately record intake and output.*

! NURSING SAFETY PRIORITY

Drug Alert

ACEIs and ARBs are started slowly and cautiously. The first dose may be associated with a rapid drop in blood pressure (BP). Patients at risk for hypotension usually have an initial systolic BP less than 100 mm Hg, are older than 75 years, have a serum sodium level less than 135 mEq/L, or are volume depleted. Monitor BP every hour for several hours after the initial dose and each time the dose is increased. Immediately report to the health care provider and document a systolic blood pressure of less than 90 mm Hg (or designated protocol level). If this problem occurs, place the patient flat to increase cerebral perfusion.

Weigh the patient daily, or delegate this activity to UAP and supervise that it is done. Keep in mind that *1 kg of weight gain or loss equals 1 liter of retained or lost fluid*. The same scale should be used every morning before breakfast for the most accurate assessment of weight. Monitor for an expected decrease in weight because excess fluid is excreted from the body.

Drug Therapy. Common drugs prescribed to reduce preload are diuretics and venous vasodilators. *Morphine sulfate* is also given for patients in *acute* heart failure (HF) to reduce anxiety, decrease preload and afterload, slow respirations, and reduce the pain associated with a myocardial infarction (MI).

The health care provider adds *diuretics* to the regimen when diet and fluid restrictions have not been effective in managing the symptoms of HF. Diuretics are the first-line drug of choice in older adults with HF and fluid overload (Joseph et al., 2009). These drugs enhance the renal excretion of sodium and water by reducing circulating blood volume, decreasing preload, and reducing systemic and pulmonary congestion.

The type and dosage of diuretic prescribed depend on the severity of HF and renal function. High-ceiling (loop) diuretics, such as furosemide (Lasix, Furoside ♣, Novosemide ♣), torsemide (Demadex), and bumetanide (Bumex), are most effective for treating fluid volume overload.

CONSIDERATIONS FOR OLDER ADULTS

Loop diuretics continue to work even after excess fluid is removed. As a result, some patients, especially older adults, can become dehydrated. Observe for manifestations of dehydration in the older adult, especially acute confusion, decreased urinary output, and dizziness. Provide evidence-based interventions to reduce the risk of falls, as discussed in Chapter 3.

For those patients with *acute* HF, Lasix or Bumex can be administered by IV push (IVP). Lasix can be given in doses of 20 to 40 mg IV and increased by 20 mg every 2 hours until the desired diuresis is obtained. The usual IV initial dose for Bumex is 1 to 2 mg once or twice daily, but it is more often given in a continuous infusion of 10 mg over 24 hours.

The practitioner may initially use a thiazide diuretic, such as hydrochlorothiazide (HCTZ) (HydroDIURIL, Urozide ♣) and metolazone (Zaroxolyn), for *older adults* with *mild* volume overload. Zaroxolyn is a long-acting agent and is therefore often given every second, third, or fourth day, depending on patient need and tolerance.

Unlike loop diuretics, the action of thiazides is self-limiting (i.e., diuresis decreases after edema fluid is lost). Therefore the dehydration that may occur with loop diuretics is not common with these drugs. Patients also prefer thiazides because of the gradual onset of diuresis.

As HF progresses, many patients develop diuretic resistance with refractory edema. The health care provider may choose to manage this problem by prescribing both types of diuretics.

Monitor for and prevent potassium deficiency (hypokalemia) from diuretic therapy. The primary signs of hypokalemia are nonspecific neurologic and muscular symptoms, such as generalized weakness, depressed reflexes, and irregular heart rate. A potassium supplement may be prescribed for some patients. Other practitioners prescribe a

potassium-sparing diuretic, such as spironolactone (Aldactone), for patients at risk for dysrhythmias from hypokalemia. Although not as effective as other diuretics, Aldactone helps retain potassium and thus decrease the risk of ventricular dysrhythmias.

Patients being managed with ACE inhibitors or ARBs and diuretics at the same time may not experience hypokalemia. However, if their kidneys are not functioning well, they may develop hyperkalemia (elevated serum potassium level). Review the patient's serum creatinine level. *If the creatinine is greater than 1.8 mg/dL, notify the health care provider before administering supplemental potassium.*

The health care provider may prescribe *venous vasodilators* (e.g., nitrates) for the patient with HF who has persistent dyspnea. Significant constriction of venous and arterial blood vessels occurs to compensate for reduced CO. Constriction reduces the volume of fluid that the vascular bed can hold and increases preload. Venous vasodilators may benefit by:

- Returning venous vasculature to a more normal capacity
- Decreasing the volume of blood returning to the heart
- Improving left ventricular function

Nitrates may be administered IV, orally, or topically. IV nitrates are used most often for *acute* HF. These drugs cause primarily venous vasodilation but also a significant amount of arteriolar vasodilation. Monitor the patient's blood pressure when starting nitrate therapy or increasing the dosage. Patients may initially report headache, but assure them that they will develop a tolerance to this effect and that the headache will cease or diminish. Acetaminophen (Tylenol, Exdol ♣) can be given to help relieve discomfort.

Unfortunately, tolerance to the vasodilating effects develops when nitrates are given around-the-clock. To prevent this tolerance, the health care provider may prescribe at least one 12-hour nitrate-free period out of every 24 hours (usually overnight). Nitrates such as isosorbide (Imdur, ISMO) are prescribed to provide nitrate-free periods and reduce the problem of tolerance. Chapter 40 discusses nitrates in more detail.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client has been taking furosemide (Lasix) for the past 3 years. The hospital laboratory notifies the nurse that the client's serum potassium level is 2.9 mEq/L. What is the nurse's best action at this time?

- Notify the health care provider.
- Ask the lab to retest the potassium level.
- Give potassium as an IV infusion.
- Withhold this morning's Lasix dose.

Drugs That Enhance Contractility. Contractility of the heart can also be enhanced with drug therapy. Positive inotropic drugs are most commonly used, but vasodilators and beta-adrenergic blockers may also be administered. For *chronic* HF, low-dose beta blockers are most commonly used. Digoxin (Lanoxin) may be prescribed to improve symptoms, thereby decreasing dyspnea and improving functional activity. This older and long-used drug is not expensive. In some settings, nesiritide (Natrecor) may be administered for end-stage HF, although this drug is very expensive (see discussion of Natrecor for acute HF on p. 751).

Digoxin. Although not as commonly used today, digoxin (Lanoxin, Novodigoxin ) a cardiac glycoside, has been demonstrated to provide symptomatic benefits for patients in *chronic* heart failure (HF) with sinus rhythm and atrial fibrillation. Digoxin (sometimes called “dig”) therapy reduces exacerbations of HF and hospitalizations when added to a regimen of ACE inhibitors or ARBs, beta blockers, and diuretics. However, it may increase mortality due to drug toxicity, especially in older adults.

The potential benefits of digoxin include:

- Increased contractility
- Reduced heart rate (HR)
- Slowing of conduction through the atrioventricular node
- Inhibition of sympathetic activity while enhancing parasympathetic activity

Digoxin is erratically absorbed from the GI tract. Many drugs, especially antacids, interfere with its absorption. It is eliminated primarily by renal excretion. Older patients should be maintained on lower doses of the drug than younger patients.

! NURSING SAFETY PRIORITY

Drug Alert

Increased cardiac automaticity occurs with toxic digoxin levels or in the presence of hypokalemia, resulting in ectopic beats (e.g., premature ventricular contractions [PVCs]). Changes in potassium level, especially a decrease, causes patients to be more sensitive to the drug and cause toxicity.

The clinical manifestations of **digoxin toxicity** are often vague and nonspecific and include anorexia, fatigue, blurred vision, and changes in mental status, especially in older adults. Toxicity may cause nearly any dysrhythmia, but PVCs are most commonly noted. Assess for early signs of toxicity such as bradycardia and loss of the P wave on the ECG. Carefully monitor the apical pulse rate and heart rhythm of patients receiving digoxin.

The health care provider determines the desirable heart rate (HR) to achieve. Some health care providers prefer a rate less than 60 beats per minute. Report the development of either an irregular rhythm in a patient with a previously regular rhythm or a regular rhythm in a patient with a previously irregular one. Monitor serum digoxin and potassium levels (hypokalemia potentiates digoxin toxicity) to identify toxicity. Older adults are more likely than other patients to become toxic because of decreased renal excretion.

Any drug that increases the workload of the failing heart also increases its oxygen requirement. Be alert for the possibility that the patient may experience angina (chest pain) in response to digoxin.

Other Inotropic Drugs. Patients experiencing *acute* heart failure (HF) are candidates for IV drugs that increase contractility. For example, *beta-adrenergic agonists*, such as dobutamine (Dobutrex), are used for short-term treatment of *acute* episodes of HF. Dobutamine improves cardiac contractility and thus cardiac output and myocardial-systemic perfusion.

A more potent drug used for *acute* HF, milrinone (Primacor), functions as a vasodilator/inotropic medication with phosphodiesterase activity. Also known as a *phosphodiesterase inhibitor*, this drug increases cyclic adenosine monophosphate (cAMP), which enhances the entry of calcium into myocardial cells to increase contractile function. Like the beta-adrenergic agonists, Primacor is given IV.

Levosimendan (Simdax) is a calcium-sensitizing medication and a positive inotropic drug. It appears to bind to

troponin C in the heart muscle and therefore increases the contraction of the heart. Simdax is used most often in patients who have had or are at high risk for myocardial infarction.

Chapter 40 discusses inotropic drugs in more detail.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

An older adult taking digoxin and furosemide (Lasix) for chronic heart failure is admitted to the emergency department (ED) with an apical pulse of 52. A family member states that the client has fallen four times this week. What is the nurse's first action?

- Call the ED physician immediately.
- Draw a serum digoxin level.
- Assess for signs of hypokalemia.
- Establish the client's airway.

Beta-Adrenergic Blockers. Beta-adrenergic blockers (commonly referred to as “beta blockers”) improve the condition of some patients in HF. Prolonged exposure to increased levels of sympathetic stimulation and catecholamines worsens cardiac function. Beta-adrenergic blockade reverses this effect, improving morbidity, mortality, and quality of life for patients in HF.

Beta blockers must be started slowly for HF. *Patients in acute HF should not be started on these drugs.* Carvedilol (Coreg), metoprolol (Lopressor, Betaloc ) and bisoprolol (Zebeta) are approved for treatment of *chronic* HF. The first dose is extremely low. Monitor the patient either in the hospital or in the health care provider's office to assess for bradycardia or hypotension after the first dose is given.

Instruct the patient to weigh daily and to report any signs of worsening HF immediately. The health care provider gradually increases the drug dose if HF worsens. The patient is evaluated at least weekly for changes in BP, pulse, activity tolerance, and orthopnea. A modest drop in BP is acceptable if he or she remains asymptomatic and can stand without experiencing dizziness or a further drop in BP. The resting heart rate (HR) should remain between 55 and 60 and increase slightly with exercise. Activity tolerance improves, and less orthopnea is experienced. Most patients with mild and moderate HF demonstrate improved ejection fraction, decreased hospital admissions, and improvement in symptoms when beta blockers are added to their treatment regimens. The benefits of this therapy are seen over a long period rather than immediately.

For patients with *diastolic* HF, drug therapy has not been as effective. Calcium channel blockers, ACE inhibitors, and beta blockers have been used with various degrees of success.

Other Nonsurgical Options. In addition to drug therapy, other nonsurgical options, both noninvasive and invasive, may be used and include:

- Continuous positive airway pressure (CPAP)
- Cardiac resynchronization therapy (CRT)
- Investigative gene therapy

Continuous positive airway pressure (CPAP) is a respiratory treatment that improves obstructive sleep apnea in patients with HF. It also improves cardiac output (CO) and ejection fraction (EF) by decreasing afterload and preload, blood pressure (BP), and dysrhythmias. Sleep apnea is directly correlated with coronary artery disease as a result of diminished

oxygen supply to the heart during apneic episodes. This respiratory problem is discussed in detail in [Chapter 31](#).

Cardiac resynchronization therapy (CRT), also called *biventricular pacing*, uses a permanent pacemaker alone or is combined with an implantable cardioverter/defibrillator. Electrical stimulation causes more synchronous ventricular contractions to improve EF, CO, and mean arterial pressure. This modality is indicated for patients with class III or IV HF and an EF of less than 35%. CRT improves the patient's ability to perform ADLs. [Chapter 36](#) discusses pacing in more detail.

Gene therapy may be indicated for patients in end-stage HF who are not candidates for heart transplantation. This therapy replaces damaged genes with normal or modified genes by a series of injections of growth factor into the left ventricle. Although still investigative, this therapy may result in improved exercise tolerance and regrowth of cardiac cells.

Surgical Management. Heart transplantation is still the ultimate choice for end-stage HF (see discussion on p. 768). Several surgical procedures are available to improve CO in patients who are *not* candidates for a transplant or are awaiting transplant.

Ventricular Assist Devices. Patients with debilitating end-stage heart failure are often sent home on drug therapy and referred to hospice. However, ventricular assist devices (VADs) can dramatically improve the lives of many patients (Osaki et al., 2008). In this procedure, a mechanical pump is implanted to work with the patient's own heart ([Fig. 37-2](#)). Both left and right VADs are available, depending on the type of heart failure the patient has. Those with end-stage kidney disease, severe chronic lung disease, clotting disorders, and infections that do not respond to antibiotics are not candidates for this surgery. Postoperative complications include bleeding, infective endocarditis, ventricular dysrhythmias, and stroke. Nursing care is similar to that described for cardiac surgery in [Chapter 40](#).

Ventricular assist devices can be used short-term while awaiting heart transplantation (a "bridge-to-transplant" procedure) or long-term (destination therapy). Most patients survive with a VAD until a transplant is available. The evidence shows that patients who have long-term devices live

longer and have an improved quality of life (Rogers et al., 2010).

Other Surgical Therapies. Heart failure causes ventricular remodeling, or dilation, which worsens as the disease progresses. Several new therapies are used to reshape the left ventricle in patients with HF. Perioperative care is similar to that for the patient having a coronary artery bypass graft (CABG) (see [Chapter 40](#)). The most common ventricular reconstructive procedures include:

- Partial left ventriculectomy (PLV)
- Endoventricular circular patch cardioplasty
- Acorn cardiac support device
- Myosplint

Also known as **heart reduction surgery**, PLV (sometimes referred to as the *Batista procedure*) involves removing a triangle-shaped section of the weakened heart in the left lateral ventricle to reduce the ventricle's diameter and decrease wall tension. In **endoventricular circular patch cardioplasty**, the surgeon removes portions of the cardiac septum and left ventricular wall and grafts a circular patch (synthetic or autologous) into the opening. This procedure provides a more normal shape to the left ventricle to improve the heart's ejection fraction (EF) and cardiac output (CO).

The **Acorn cardiac support device** is a polyester mesh jacket that is placed over the ventricles to provide support and to avoid overstretching the myocardial muscle. The material for the jacket has been used for other procedures, such as vascular grafts. The jacket appears to reduce hypertrophy of the heart muscle and assists with improvement of the EF.

The **myosplint** has recently been approved for use in the United States. Electrical stimulation of several tension pads (splints) on the outside of the ventricle changes it to a more normal shape to improve function.

Decreasing Fatigue and Weakness

Planning: Expected Outcomes. The expected outcome is that the patient will have decreased fatigue and weakness and will gain energy as heart failure improves.

Interventions. The patient in severe heart failure (HF) initially requires physical and emotional rest for *energy management*. On the first day of hospitalization, he or she may sit up in a chair for meals and perform basic leg exercises while out of bed. Organize nursing care to allow periods of rest. Collaborate with the interdisciplinary team to observe and document the patient's physiologic response to activity.

As the patient's condition improves, the physical therapist (PT) starts ambulation, usually on hospital day 2. The PT or nurse checks the BP, pulse, and oxygen saturation before and after the activity. A BP change of more than 20 mm Hg or a pulse increase of more than 20 beats per minute may indicate that the activity is too stressful. Other indications of activity intolerance include dyspnea, fatigue, and chest pain. Ask a patient having any of these symptoms to rate how hard he or she has been working on a scale of 1 to 20, with 20 being the maximum perceived exertion. If the patient rates the exertion more than 12, remind him or her to slow down. If activity is tolerated, the PT steadily increases the activity level until the patient is ambulating 200 to 400 feet several times per day.

If the patient is able, the PT (or assistive nursing or PT personnel) might time him or her for 6 minutes while walking at a comfortable pace. The distance the patient can walk can

FIG. 37-2 The AbioCor Implantable Replacement Heart has four main parts that are placed inside the body. TET, Trans-telephonic electrocardiographic transmission device.

be used to determine his or her functional level and activity plan.

Preventing or Managing Pulmonary Edema

Planning: Expected Outcomes. The most desirable outcome is that the patient will not develop pulmonary edema as a result of heart failure (HF). However, if the patient progresses to pulmonary edema, the expected outcome is that he or she will recover from this complication without other complications.

Interventions. Monitor for manifestations of acute pulmonary edema, a life-threatening event that can result from severe HF (with fluid overload), acute myocardial infarction (MI), mitral valve disease, and possibly dysrhythmias. In pulmonary edema, the left ventricle fails to eject sufficient blood and pressure increases in the lungs as a result. The increased pressure causes fluid to leak across the pulmonary capillaries and into the lung airways and tissues.

! NURSING SAFETY PRIORITY

Critical Rescue

Assess for and report early manifestations, such as crackles in the lung bases, dyspnea at rest, disorientation, and confusion, especially in older patients. Document the precise location of the crackles because the level of the fluid progresses from the bases to higher levels in the lungs when the condition worsens. The patient in acute pulmonary edema is also typically extremely anxious, tachycardic, and struggling for air. As pulmonary edema becomes more severe, he or she may have a moist cough productive of frothy, blood-tinged sputum and his or her skin may be cold, clammy, or cyanotic. *Chart 37-3* lists the major clinical manifestations of this complication.

The patient diagnosed with pulmonary edema is admitted to the acute care hospital, often in a critical care unit. Reassure the patient and family that his or her distress will decrease with proper management.

! NURSING SAFETY PRIORITY

Critical Rescue

If the patient is not hypotensive, place him or her in a sitting (high Fowler's) position with his or her legs down to decrease venous return to the heart. The *priority nursing action* is to administer high-flow oxygen therapy at 5 to 6 L/min by facemask or at 10 to 15 L/min by non-rebreather mask with reservoir. Apply a pulse oximeter and titrate the oxygen flow to keep the patient's oxygen saturation above 90%. If supplemental oxygen does not resolve the patient's respiratory distress, collaborate with the respiratory therapist, if available, for more aggressive therapy, such as continuous positive airway pressure (CPAP) or bi-level positive airway pressure (BIPAP) ventilation. Intubation and mechanical ventilation may be needed for some patients.

If the patient's systolic blood pressure is above 100, give sublingual nitroglycerin (NTG) to decrease afterload and preload every 5 minutes for three doses while establishing IV access for additional drug therapy (Donlan et al., 2009). The health care provider prescribes rapid-acting diuretics, such as Lasix or Bumex. Give Lasix IV push (IVP) over 1 to 2 minutes, usually at a starting dose of 20 to 40 mg for diuretic-naïve patients, and another 40 mg if needed in 30 minutes. Patients already on oral diuretic therapy should be given an amount

CHART 37-3 KEY FEATURES

Pulmonary Edema

- Crackles
- Dyspnea at rest
- Disorientation or acute confusion (especially in older adults as early symptom)
- Tachycardia
- Hypertension or hypotension
- Reduced urinary output
- Cough with frothy, pink-tinged sputum
- Premature ventricular contractions and other dysrhythmias
- Anxiety
- Restlessness
- Lethargy

that is the same or doubled in milligrams as initial IV diuretic therapy. Administer each increment of 40 mg of Lasix over 1 to 2 minutes to avoid ototoxicity. Bumex may be administered 1 to 2 mg IVP or as a continuous infusion to provide consistent fluid removal over 24 hours. Monitor vital signs frequently, at least every 30 to 60 minutes.

If the patient's blood pressure is adequate, IV morphine sulfate may be prescribed, 1 to 2 mg at a time, to reduce venous return (preload), decrease anxiety, and reduce the work of breathing. Monitor respiratory rate and BP closely. Other drugs, such as IV NTG and drugs to treat HF, may be administered. Monitor the patient's vital signs closely (especially BP) while these drugs are being given.

In severe cases of fluid overload and renal dysfunction or diuretic resistance, ultrafiltration may be used. The benefits of ultrafiltration include:

- Decrease in filling pressures
- Decrease in pulmonary arterial pressure
- Increase in cardiac index
- Reduction in norepinephrine, rennin, and aldosterone

Ultrafiltration can remove up to 500 mL/hr and uses a blood flow rate of 10 to 40 mL/hr. Peripheral lines are used for IV access. See *Chapter 71* for discussion of this procedure and nursing implications.

? DECISION-MAKING CHALLENGE

Safety; Patient-Centered Care; Evidence-Based Practice; Informatics

A 64-year-old man is admitted to the telemetry unit with left-sided heart failure, type 2 diabetes mellitus, and hypertension. He is married with two grown children who live out of state. During your evening assessment, you observe that his color is slightly pale and he is having problems breathing. Upon further assessment, you note that he seems a little confused and is oriented only to person.

1. What evidence-based actions will you plan to implement at this time based on your observations? What is the source of the evidence?
2. The patient's physician prescribes an initial dose of furosemide (Lasix) 40 mg IVP. What assessments will you perform to determine if the drug was effective?
3. What will you tell the patient's wife about his condition at this time? Should the patient's wife be present during his emergency treatment? Why or why not?
4. After two doses of Lasix, the patient's condition improves. What data will you document in the electronic medical record (EMR)?

Community-Based Care

Patients who are not adequately prepared for discharge or do not have adequate community support and follow-up for self-management are at high risk for repeated hospital admissions for heart failure (HF). Collaborate with the case manager or care coordinator to assess the patient's needs for health care resources.

The Heart Failure Core Measure Set must be determined for hospitals accredited by The Joint Commission. These measures include that the patient with heart failure have:

- Discharge instructions
- Evaluation of left ventricular systolic function
- An ACEI or ARB for left ventricular systolic dysfunction
- Adult smoking cessation advice/counseling (if appropriate)

An inability to obtain help in activities such as food shopping and obtaining medications is a major contributor to hospital readmission. If home support is available, the patient may be discharged home in the care of a family member or other caregiver. Home care nurses may direct the care and assess for adherence to the discharge plan; home health aides may provide assistance with ADLs for a short time. If the patient has multiple health problems or has been severely compromised by heart disease, he or she may require admission to a skilled unit for either transitional or long-term care.

Home Care Management

The focus of the home care nurse's interventions is assessment and health teaching, which are reimbursable by Medicare and other third-party payers. [Chart 37-4](#) lists the major areas of home health assessment.

Patients with chronic HF need to make many adjustments in their lifestyles. They must adhere to the collaborative plan of care that includes dietary restrictions, activity prescriptions, and drug therapy. They need careful, concise explanations of the self-management plan. The community-based nurse in any setting encourages the patient to verbalize fears and concerns about his or her illness and assists in exploring coping skills. Patient participation in self-management can help alleviate and control symptoms.

Teaching for Self-Management

Health teaching is essential for promoting self-management (also called *self-care*). Many patients are readmitted to hospitals because they do not maintain their prescribed treatment plan, including lifestyle changes. Because of the need for extensive discharge instructions, most hospitals are using teaching packets with videos, CDs, and easy-to-read information about the importance of adhering to specific self-management strategies at home. One standardized and commonly used self-management plan called MAWDS is outlined in [Table 37-4](#). Medication reconciliation is also important to be sure that similar drugs are not being prescribed and that patients meet the Core Measure requirements for HF.

Ambulatory care clinics for heart failure patients are also becoming increasingly common. Their purpose is to offer assessments, drug therapy, and health teaching. Some nurses specialize in caring for patients with health failure.

Activity Schedule. Encourage patients with heart failure (HF) to stay as active as possible and to develop a regular

exercise regimen (e.g., home walking program). However, teach the patient not to overdo it. Medicare and third-party payers typically do not reimburse for cardiac rehabilitation for HF. Paying for a cardiac rehabilitation program out of pocket is expensive.

CHART 37-4 HOME CARE ASSESSMENT

The Patient with Heart Failure

Assess for signs of heart failure, including:

- Changes in vital signs (heart rate >100 beats/min at rest, new atrial fibrillation, blood pressure <90 or >150 systolic)
- Indications of poor tissue perfusion:
 - Fatigue
 - Angina
 - Activity intolerance
 - Changes in mental status
 - Pallor or cyanosis
 - Cool extremities
- Indications of congestion:
 - Presence of cough or dyspnea
 - Weight gain
 - Jugular venous distention and peripheral edema

Assess functional ability, including:

- Performance of ADLs
- Mobility and ambulation (review frequency and duration of walking, development of symptoms, and pulse rate)
- Cognitive ability

Assess nutritional status, including:

- Food and fluid intake
- Intake of sodium-rich foods
- Alcohol consumption
- Skin turgor

Assess home environment, including:

- Safety hazards, especially related to oxygen therapy
- Structural barriers affecting functional ability
- Social support (family, home health services)

Assess the patient's adherence and understanding of illness and its treatment, including:

- Signs and symptoms to report to health care provider
- Dosages, effects, and side or toxic effects of medications
- When to report for laboratory and health care provider visits
- Ability to accurately weigh self on scale
- Presence of advance directive
- Use of home oxygen, if appropriate

Assess patient and caregiver coping skills

TABLE 37-4 HEART FAILURE SELF-MANAGEMENT HEALTH TEACHING (MAWDS)

Medications:

- Take medications as prescribed, and do not run out.
- Know the purpose and side effects of each drug.
- Avoid NSAIDs to prevent sodium and fluid retention.

Activity:

- Stay as active as possible, but don't overdo it.
- Know your limits.
- Be able to carry on a conversation while exercising.

Weight:

- Weigh each day at the same time on the same scale to monitor for fluid retention.

Diet:

- Limit daily sodium intake to 2 to 3 grams as prescribed.
- Limit daily fluid intake to 2 liters.

Symptoms:

- Note any new or worsening symptoms, and notify the health care provider immediately.

Remind patients with persistent crackles and uncontrolled edema to begin exercise after their condition stabilizes. When exercise is indicated, teach the patient to begin walking 200 to 400 feet per day. At home the patient should try to walk at least three times a week and should slowly increase the amount of time walked over several months. If chest pain or severe dyspnea occurs while exercising or the patient has fatigue the next day, he or she is probably advancing the activity too quickly and should slow down. Encourage him or her to keep a diary that documents the time and duration of each exercise session, as well as HR and any symptoms that occur with exercise.

Indications of Worsening or Recurrent Heart Failure.

Many patients who are readmitted to hospitals for treatment of HF fail to seek medical attention promptly when symptoms recur.

! NURSING SAFETY PRIORITY

Action Alert

Per the HF Core Measure for discharge instructions, teach the patient and caregiver to immediately report to the health care provider the occurrence of *any* of these symptoms, which could indicate worsening or recurrent heart failure:

- Rapid weight gain (3 lb in a week or 1 to 2 lb overnight)
- Decrease in exercise tolerance lasting 2 to 3 days
- Cold symptoms (cough) lasting more than 3 to 5 days
- Excessive awakening at night to urinate
- Development of dyspnea or angina at rest or worsening angina
- Increased swelling in the feet, ankles, or hands

Drug Therapy. Provide oral, written, and video instructions about the drug regimen. Teach the caregiver and patient how to count a pulse rate, especially if the patient is on digoxin or beta blockers. [Chart 37-5](#) lists instructions for the patient taking either of these drugs at home.

Advise the patient taking diuretics to take them in the morning to avoid waking during the night for voiding. After determining whether he or she has a weight scale and can use it, emphasize the importance of weighing each morning at

the same time. Daily weights indicate whether the patient is losing or retaining fluid. Some patients are taught to use a sliding scale to adjust their daily diuretic dose depending on their daily weight, similar to the way a diabetic patient adjusts an insulin dose based on the capillary glucose level.

Teach patients taking ACEIs or ARBs to move slowly when changing positions, especially from a lying to a sitting position. Remind them to report dizziness, light-headedness, and cough to the health care provider.

Serum potassium level and renal function are monitored at least every few months for patients taking diuretics and ACE inhibitors or ARBs. Diuretics, especially loop diuretics such as Lasix and Bumex, deplete potassium and often cause hypokalemia. Conversely, ACE inhibitors, ARBs, or potassium-sparing diuretics may result in potassium retention. If serum potassium levels drop below 4.0 mEq/L, the health care provider may prescribe potassium supplements or add a potassium-sparing diuretic such as spironolactone (Aldactone). Provide information about potassium-rich foods to include in the diet for patients at risk for hypokalemia (see [Chapter 13](#)).

Nutrition Therapy. Remind patients with chronic HF to restrict their dietary sodium. In collaboration with the home care nurse or dietitian, provide written instructions on low- or restricted-sodium diets. A 3-g sodium diet is recommended for *mild to moderate* disease. Remind the patient to avoid salty foods and table salt. Patients usually find this diet acceptable and fairly easy to follow.

A 2-g sodium diet may be needed for patients with *severe* HF. They should not add salt during or after meal preparation, avoid milk and milk products, use few canned or prepared foods, and read food labels to determine sodium content. This diet is not easily tolerated for many patients, and the cost of low-sodium foods can be a financial burden.

Commercial salt substitutes typically contain potassium. Teach patients that their renal status and serum potassium level must be evaluated using these products. Suggest that patients try lemon, spices, and herbs to enhance the flavor of low-salt foods.

Advance Directives. About 50% of deaths from HF are sudden—many without any warning or worsening of symptoms. Assess whether the patient has written advance directives. If not, provide information about them during his or her hospital stay. Because most of these deaths occur at home, it is important for the health care provider or home care nurse to discuss advance directives with the patient and family. The family should be prepared to act in agreement with the patient's wishes in the event of cardiac arrest. If resuscitation is desired, be sure that the family knows how to activate the emergency medical system (EMS) and how to provide cardiopulmonary resuscitation (CPR) until an ambulance arrives. If CPR is not desired, the patient, family, and nurse plan how the family will respond. For some patients with end-stage disease, hospice care is an option. [Chapter 9](#) discusses hospice and end-of-life care in detail.

Health Care Resources

A home care nurse, ambulatory care clinic, or nurse-led follow-up program may be needed to assess the patient's adherence to drug and nutrition therapy and to monitor for worsening or recurrent HF. Many large hospitals use follow-up telephone calls or teleconferencing/videoconferencing devices

CHART 37-5 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Beta Blocker/Digoxin Therapy

- Establish same time of day to take this medication every day.
- Continue taking this medication unless your health care provider tells you to stop.
- Do not take digoxin at the same time as antacids or cathartics (laxatives).
- Take your pulse rate before taking each dose of digoxin. Notify your health care provider of a change in pulse rate (60 to 100 beats/min is normal) or rhythm, as well as increasing fatigue, muscle weakness, confusion, or loss of appetite (signs of digoxin toxicity).
- If you forget to take a dose, it may be delayed a few hours. However, if you do not remember it until the next day, you should take only your usual daily dose.
- Report for scheduled laboratory tests (e.g., potassium and digoxin levels).
- If potassium supplements are prescribed, continue the dose until told to stop by your health care provider.

EVIDENCE-BASED PRACTICE

Does Utilizing Telephone Visits in Addition to Home Health Care Visits Improve the Quality of Life in Stage III/IV Heart Failure Patients?

Duffy, J., Hoskins, L., & Dudley-Brown, S. (2009). Improving outcomes for older adults with heart failure: A randomized trial using a theory-guided nursing intervention. *Journal of Nursing Care Quality*, 25(1), 56-64.

The purposes of this randomized-controlled research to study the effectiveness of follow-up phone visits for patients with heart failure were to:

1. Determine the patient population.
2. Assess the study methods.
3. Evaluate the results of the intervention on intended patient outcomes.
4. Examine the resources required to implement the intervention.
5. Identify unanticipated problems or operational difficulties.

The sample consisted of 32 patients with stage III/IV heart failure: 15 enrolled in the intervention group and 17 in the control. Patients in the intervention group were assigned to one of seven intervention nurses. The intervention nurse followed the same patient throughout the study to monitor symptoms and provide education and emotional support via telephone. In addition, the intervention group received standard home health visits. The control group was assigned to a home health nurse and received standard care. Every patient completed the *Living with Heart Failure* questionnaire and *Home Care Client Satisfaction Instrument-Revised* on enrollment and at day 60.

The results showed that two patients from the control group were readmitted and one was transferred to a skilled nursing facility as compared with the intervention group, in which one patient was readmitted. The quality-of-life scores at 60 days revealed the control group at 48 (SD = 30.8) and the intervention group at 44.3 (SD = 26.8). Although this was an improvement of 8.6%, it did not have statistical significance. The intervention group reported greater satisfaction with care (M = 55.27, SD = 5.55) at 60 days as compared with the control (M = 51.44, SD = 6.63).

Level of Evidence: 1

Although the sample size was small, the study was a randomized-controlled study from which conclusions about practice can be drawn.

Commentary: Implications for Practice and Research

One limitation to this study is that only patients who were eligible for home care services were included in the study. There is a large population of stage III/IV heart failure patients discharged from hospitals who may benefit from services but do not have a high quality of life. This study begins to look at different models of posthospital care of the heart failure patient. As this population expands, the desired outcomes for care continue to be prevention of readmission and increased quality of care at home. Nurses are in a prime position to research the best way to provide this care. Additional studies in this area are needed.

to monitor patients at home. Teleconferencing can also assess the patient's heart and lung sounds. These follow-up processes have been very successful in decreasing repeated hospital stays for chronic HF patients (see the Evidence-Based box above).

In addition to home care support, other resources are available for patient education and family support. The American Heart Association is an excellent community resource for print and electronic pamphlets, books, newsletters, and videotapes or DVDs related to HF and heart disease. The organization also provides referrals to various local support groups for patients and their caregivers.

For equipment needs (e.g., home oxygen therapy, hospital bed), medical supply companies provide setup and maintenance services. [Chapter 30](#) provides a detailed description of home oxygen therapy.

DECISION-MAKING CHALLENGE

Quality Improvement; Informatics

At a recent staff meeting, the telemetry nurse manager reports that the rate of repeated hospitalizations for patients with chronic heart failure has increased 75% in the past 6 months. As a staff nurse, you agree to be part of the unit care improvement (CI) team to examine the cause(s) of the increase and make evidence-based recommendations for improving the outcomes for this patient population. Specific patient data and summaries are available for the CI team to review as needed.

1. Where will your team begin with this process during the first meeting of the team?
2. Formulate a PICOT clinical question using the format described in [Chapter 7](#).
3. What Internet sites will your team use to determine best practices for decreasing repeated hospital stays and why?
4. How will your team interpret and use the evidence that you obtain? (See [Chapter 7](#) for help.)
5. After your team assembles and analyzes the evidence to determine best practices, what will be done with the information?
6. How will you know if the plan of action to improve care was effective?

EVALUATION: OUTCOMES

Evaluate the care of the patient with HF on the basis of the identified patient problems. The expected outcomes include that the patient will:

- Have adequate pulmonary tissue perfusion
- Have increased cardiac pump effectiveness
- Take actions to manage energy
- Be free of pulmonary edema

VALVULAR HEART DISEASE

Pathophysiology

Acquired valvular dysfunctions include mitral stenosis, mitral regurgitation, mitral valve prolapse, aortic stenosis, and aortic regurgitation ([Chart 37-6](#)). The tricuspid valve is not affected often and may occur following endocarditis in IV drug abusers.

Mitral Stenosis

Mitral stenosis usually results from rheumatic carditis, which can cause valve thickening by fibrosis and calcification. Rheumatic fever is the most common cause of the problem. In industrialized nations, congenital anomalies affect the majority of patients with mitral stenosis ([Ray, 2010](#)).

In mitral stenosis, the valve leaflets fuse and become stiff and the chordae tendineae contract and shorten. The valve opening narrows, preventing normal blood flow from the left atrium to the left ventricle. As a result of these changes, left atrial pressure rises, the left atrium dilates, pulmonary artery pressures increase, and the right ventricle hypertrophies.

Pulmonary congestion and right-sided heart failure (HF) occur first. Later, when the left ventricle receives insufficient blood volume, preload is decreased and cardiac output (CO) falls.

CHART 37-6 KEY FEATURES

Valvular Heart Disease

MITRAL STENOSIS	MITRAL REGURGITATION	MITRAL VALVE PROLAPSE	AORTIC STENOSIS	AORTIC REGURGITATION
Fatigue Dyspnea on exertion Orthopnea Paroxysmal nocturnal dyspnea Hemoptysis Hepatomegaly Neck vein distention Pitting edema Atrial fibrillation Rumbling, apical diastolic murmur	Fatigue Dyspnea on exertion Orthopnea Palpitations Atrial fibrillation Neck vein distention Pitting edema High-pitched holosystolic murmur	Atypical chest pain Dizziness, syncope Palpitations Atrial tachycardia Ventricular tachycardia Systolic click	Dyspnea on exertion Angina Syncope on exertion Fatigue Orthopnea Paroxysmal nocturnal dyspnea Harsh, systolic crescendo-decrescendo murmur	Palpitations Dyspnea Orthopnea Paroxysmal nocturnal dyspnea Fatigue Angina Sinus tachycardia Blowing, decrescendo diastolic murmur
 S ₁ S ₂ S ₁ S ₂ S ₁	 S ₁ S ₂ S ₃ S ₁ S ₂ S ₃	 S ₁ S ₂ S ₁ S ₂	 S ₁ S ₂ S ₁ S ₂	 S ₁ S ₂ S ₁ S ₂ S ₁

People with mild mitral stenosis are usually asymptomatic. As the valvular orifice narrows and pressure in the lungs increases, the patient experiences dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea (sudden dyspnea at night), palpitations, and dry cough. Hemoptysis (coughing up blood) and pulmonary edema occur as pulmonary hypertension and congestion progress. Right-sided HF can cause hepatomegaly (enlarged liver), neck vein distention, and pitting dependent edema late in the disorder.

On palpation, the pulse may be normal, rapid, or irregularly irregular (as in atrial fibrillation). Because the development of atrial fibrillation indicates that the patient may decompensate, the physician should be notified immediately of the development of an irregularly irregular rhythm. A rumbling, apical diastolic murmur is noted on auscultation.

Mitral Regurgitation (Insufficiency)

The fibrotic and calcific changes occurring in **mitral regurgitation** (insufficiency) prevent the mitral valve from closing completely during *systole*. Incomplete closure of the valve allows the backflow of blood into the left atrium when the left ventricle contracts (Ray, 2010). During *diastole*, regurgitant output again flows from the left atrium to the left ventricle along with the normal blood flow. The increased volume must be ejected during the next systole. To compensate for the increased volume and pressure, the left atrium and ventricle dilate and hypertrophy.

The primary causes of mitral regurgitation are “degenerative” due to aging and infective endocarditis (Ray, 2010). Other causes include papillary muscle dysfunction or rupture resulting from ischemic heart disease or congenital anomalies. Rheumatic heart disease is the number-one cause in developing nations. When it results from rheumatic heart disease, it usually coexists with some degree of mitral stenosis; it affects women more often than men.

Mitral regurgitation usually progresses slowly; patients may remain symptom-free for decades. Symptoms begin to occur when the left ventricle fails in response to chronic blood volume overload. They include fatigue and chronic weakness as a result of reduced cardiac output (CO). Dyspnea on exertion and orthopnea develop later. A significant number

of patients report anxiety, atypical chest pains, and palpitations. Assessment may reveal normal BP, atrial fibrillation, or changes in respirations characteristic of left ventricular failure.

When right-sided HF develops, the neck veins become distended, the liver enlarges (hepatomegaly), and pitting edema develops. A high-pitched systolic murmur at the apex, with radiation to the left axilla, is heard on auscultation. Severe regurgitation often exhibits a third heart sound (S₃).

Mitral Valve Prolapse

Mitral valve prolapse (MVP) occurs because the valvular leaflets enlarge and prolapse into the left atrium during systole. This abnormality is usually benign but may progress to pronounced mitral regurgitation.

The etiology of MVP is variable and has been associated with conditions such as Marfan syndrome and other congenital cardiac defects (see Chapter 20 for a brief discussion of Marfan syndrome). MVP also has a familial tendency. Usually, however, no other cardiac abnormality is found.

Most patients with MVP are asymptomatic. However, some may report chest pain, palpitations, or exercise intolerance. Chest pain is usually atypical with patients describing a sharp pain localized to the left side of the chest. Dizziness, **syncope** (“blackouts”), and palpitations may be associated with atrial or ventricular dysrhythmias.

A normal heart rate and BP are usually found on physical examination. A midsystolic click and a late systolic murmur may be heard at the apex of the heart. The intensity of the murmur is not related to the severity of the prolapse.

Aortic Stenosis

Aortic stenosis is the most common cardiac valve dysfunction in the United States and is often considered a disease of “wear and tear.” In **aortic stenosis**, the aortic valve orifice narrows and obstructs left ventricular outflow during systole. This increased resistance to ejection or afterload results in ventricular hypertrophy. As stenosis worsens, cardiac output becomes fixed and cannot increase to meet the demands of the body during exertion. Symptoms then develop. Eventually the left ventricle fails, blood backs up in the left atrium, and

the pulmonary system becomes congested. Right-sided HF can occur late in the disease. *When the surface area of the valve becomes 1 cm or less, surgery is indicated on an urgent basis!*

Congenital bicuspid or unicuspid aortic valves are the primary causes for aortic stenosis in many patients. Rheumatic aortic stenosis occurs with rheumatic disease of the mitral valve and develops in young and middle-aged adults. Atherosclerosis and degenerative calcification of the aortic valve are the major causative factors in older adults. *Aortic stenosis has become the most common valvular disorder in all countries with aging populations.*

The classic symptoms of aortic stenosis result from fixed cardiac output: dyspnea, angina, and syncope occurring on exertion. When cardiac output falls in the late stages of the disease, the patient experiences marked fatigue, debilitation, and peripheral cyanosis. A narrow pulse pressure is noted when the BP is measured. A diamond-shaped, systolic crescendo-decrescendo murmur is usually noted on auscultation.

Aortic Regurgitation (Insufficiency)

In patients with **aortic regurgitation**, the aortic valve leaflets do not close properly during diastole and the *annulus* (the valve ring that attaches to the leaflets) may be dilated, loose, or deformed. This allows flow of blood from the aorta back into the left ventricle during diastole. The left ventricle, in compensation, dilates to accommodate the greater blood volume and eventually hypertrophies.

Aortic insufficiency usually results from nonrheumatic conditions such as infective endocarditis, congenital anatomic aortic valvular abnormalities, hypertension, and Marfan syndrome (a rare, generalized, systemic disease of connective tissue).

Patients with aortic regurgitation remain asymptomatic for many years because of the compensatory mechanisms of the left ventricle. As the disease progresses and left ventricular failure occurs, the major symptoms are exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea. Palpitations may be noted with severe disease, especially when the patient lies on the left side. Nocturnal angina with diaphoresis often occurs.

On palpation, the nurse notes a “bounding” arterial pulse. The pulse pressure is usually widened, with an elevated systolic pressure and diminished diastolic pressure. The classic auscultatory finding is a high-pitched, blowing, decrescendo diastolic murmur.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

A patient with valvular disease may suddenly become ill or slowly develop symptoms over many years. Collect information about the patient’s family health history, including valvular or other forms of heart disease to which he or she may be genetically predisposed. Question about attacks of rheumatic fever and infective endocarditis, the specific dates when these occurred, and the use of antibiotics to prevent recurrence of these diseases. Also question the patient about a history of IV drug abuse, a common cause of infective endocarditis. Discuss the patient’s fatigue level and tolerated

activity level, the presence of angina or dyspnea, and the occurrence of palpitations, if present.

As part of the physical assessment, obtain vital signs, inspect for signs of edema, palpate and auscultate the heart and lungs, and palpate the peripheral pulses. Assessment findings are summarized in [Chart 37-6](#).

Echocardiography is the noninvasive diagnostic procedure of choice to visualize the structure and movement of the heart. The more invasive transesophageal echocardiography (TEE) or transthoracic echocardiography (TTE) is also performed to assess most valve problems. Exercise tolerance testing (ETT) and stress echocardiography are sometimes done to evaluate symptomatic response and assess functional capacity. With either mitral or aortic stenosis, cardiac catheterization may be indicated to assess the severity of the stenosis and its other effects on the heart.

In patients with mitral stenosis, the chest x-ray shows left atrial enlargement, prominent pulmonary arteries, and an enlarged right ventricle. In those with mitral regurgitation (insufficiency), the chest x-ray reveals an increased cardiac shadow, indicating left ventricular and left atrial enlargement.

In the later stages of aortic stenosis, the chest x-ray may show left ventricular enlargement and pulmonary congestion. Left atrial and left ventricular dilation appear on the chest x-ray of patients with aortic regurgitation (insufficiency). If HF is present, pulmonary venous congestion is also evident.

The health care provider also requests an ECG to assess abnormalities such as left ventricular hypertrophy, as seen with mitral regurgitation and aortic regurgitation, or right ventricular hypertrophy, as seen in severe mitral stenosis. Atrial fibrillation is a common finding in both mitral stenosis and mitral regurgitation and may develop in aortic stenosis because of left atrial dilation.

INTERVENTIONS

Management of valvular heart disease depends on which valve is affected and the degree of valve impairment. Some patients can be managed with yearly monitoring and drug therapy, whereas others require invasive procedures or heart surgery.

Nonsurgical Management

Nonsurgical management focuses on drug therapy and rest. During the course of valvular disease, left ventricular failure with pulmonary or systemic congestion may develop.

Drug Therapy. Diuretics, beta blockers, digoxin, and oxygen are often administered to improve the symptoms of heart failure (HF). Nitrates are administered cautiously to patients with aortic stenosis because of the potential for syncope associated with a reduction in left ventricular volume (preload). Vasodilators such as calcium channel blockers may

! NURSING SAFETY PRIORITY

Drug Alert

Teach patients with valve disease the importance of prophylactic antibiotic therapy before any invasive procedure. Examples of these procedures include bronchoscopy, upper GI endoscopy, colonoscopy, genitourinary instrumentation, surgery, and dental procedures of any type.

be used to reduce the regurgitant flow for patients with aortic or mitral stenosis.

A major concern in valvular heart disease is maintaining cardiac output if atrial fibrillation develops. With mitral valvular disease, left ventricular filling is especially dependent on atrial contraction. When atrial fibrillation develops, there is no longer a single coordinated atrial contraction. Cardiac output can decrease, and HF may occur. Ineffective atrial contraction may also lead to the stasis of blood and thrombi in the left atrium. Monitor the patient for the development of an irregular rhythm, and notify the primary care provider if it develops. (See Chapter 36 for a detailed explanation of atrial fibrillation.)

The primary care provider usually starts drug therapy first to control the heart rate and maintain cardiac output (<100 is considered a controlled ventricular response). After those outcomes are met, drugs are used in an attempt to restore normal sinus rhythm (NSR). In some cases, the provider elects to convert a patient from atrial fibrillation to sinus rhythm using IV diltiazem (Cardizem, Apo-Diltiaz ) or amiodarone (Cordarone, Pacerone). Monitor the patient on a unit where both cardiac rhythm and BP can be closely watched. Synchronized countershock (cardioversion) may be attempted if atrial fibrillation is rapid, the patient's condition worsens, and the rhythm is unresponsive to medical treatment (see Chapter 36).

If the patient remains in atrial fibrillation, low-dose amiodarone (Cordarone) is often prescribed to slow ventricular rate. Procainamide hydrochloride (Pronestyl hydrochloride, Procanbid) may be added to the regimen. A beta-blocking agent (e.g., metoprolol) may also be considered to slow the ventricular response.

For valvular heart disease and chronic atrial fibrillation, anticoagulation with sodium warfarin (Coumadin, Warfilone ) is usually a part of the plan of care to prevent thrombus formation. Thrombi may form in the atria or on defective valve segments, resulting in systemic emboli. If a portion breaks off and travels to the brain, one or more strokes may occur. Assess the patient's baseline neurologic status, and monitor for changes. A transesophageal echocardiography (TEE) is often done before synchronized cardioversion to ensure that thrombi are not present that could embolize when this therapy is administered.

Rest is often an important part of treatment. Activity may be limited because cardiac output (CO) cannot meet increased metabolic demands and angina or HF can result. A balance of rest and exercise is needed to prevent skeletal muscle atrophy and fatigue.

Noninvasive Heart Valve Reparative Procedures. Reparative procedures are becoming more popular because of continuing problems with thrombi, endocarditis, and left ventricular dysfunction after valve replacement. Reparative procedures do not result in a normal valve, but they usually “turn back the clock,” resulting in a more functional valve and an improvement in cardiac output. Turbulent blood flow through the valve may persist, and degeneration of the repaired valve is possible.

Balloon valvuloplasty, an invasive nonsurgical procedure, is possible for stenotic mitral and aortic valves; however, careful selection of patients is needed. It may be the initial treatment of choice for people with noncalcified, mobile mitral valves. Patients selected for *aortic* valvuloplasty are

usually older and are at high risk for surgical complications or have refused operative treatment. The benefits of this procedure for aortic stenosis tend to be short lived, rarely lasting longer than 6 months.

When performing *mitral* valvuloplasty, the physician passes a balloon catheter from the femoral vein, through the atrial septum, and to the mitral valve. The balloon is inflated to enlarge the mitral orifice. For *aortic* valvuloplasty, the physician inserts the catheter through the femoral artery and advances it to the aortic valve, where it is inflated to enlarge the orifice. The procedure usually offers immediate relief of symptoms because the balloon has dilated the orifice and improved leaflet mobility. The results are comparable with those of surgical commissurotomy for appropriately selected patients.

! NURSING SAFETY PRIORITY

Action Alert

After valvuloplasty, observe the patient closely for bleeding from the catheter insertion site and institute post-angiogram precautions. Bleeding is likely because of the large size of the catheter. Assess for signs of a regurgitant valve by closely monitoring heart sounds, CO, and heart rhythm. Because vegetations (thrombi) may have been dislodged from the valve, observe for any indication of systemic emboli (see the *Infective Endocarditis* section, p. 763).

Surgical Management

Surgeries for patients with valvular heart disease include invasive reparative procedures and replacement. These procedures are performed after symptoms of left ventricular failure have developed but before irreversible dysfunction occurs. Surgical therapy is the *only* definitive treatment of *aortic stenosis* and is recommended when angina, syncope, or dyspnea on exertion develops.

Invasive Heart Valve Reparative Procedures. *Direct (open) commissurotomy* is accomplished with cardiopulmonary bypass during open heart surgery. The surgeon visualizes the valve, removes thrombi from the atria, incises the fused commissures (leaflets), and débrides calcium from the leaflets, widening the orifice.

Mitral valve annuloplasty (reconstruction) is the reparative procedure of choice for most patients with acquired mitral insufficiency. To make the annulus (the valve ring that attaches to and supports the leaflets) smaller, the surgeon may suture the leaflets to an annuloplasty ring or take tucks in the patient's annulus. Leaflet repair is often performed at the same time. Elongated leaflets may be shortened, and shortened leaflets may be repaired by lengthening the chordae that bind them in place. Perforated leaflets may be patched with synthetic grafts.

Annuloplasty and leaflet repair result in an annulus of the appropriate size and in leaflets that can close completely. Thus regurgitation is eliminated or markedly reduced.

Heart Valve Replacement Procedures. The development of a wide variety of *prosthetic* (synthetic) and *biologic* (tissue) valves has improved the surgical therapy and prognosis of valvular heart disease. Each type has advantages and disadvantages. An aortic valve can be replaced only with a prosthetic valve for symptomatic adults with aortic stenosis and aortic insufficiency. A biologic valve cannot be used because of the high pressure within the aorta.

FIG. 37-3 Examples of biologic (tissue) heart valves. **A**, Freestyle, a stentless pig valve with no frame. **B**, Hancock II, a stented pig valve. **C**, Carpentier-Edwards pericardial bioprosthesis.

Biologic valve replacements may be **xenograft** (from other species), such as a porcine valve (from a pig) (Fig. 37-3) or a bovine valve (from a cow). Because tissue valves are associated with little risk for clot formation, long-term anticoagulation is *not* indicated. Xenografts are not as durable as prosthetic valves and usually must be replaced every 7 to 10 years. The durability of the graft is related to the age of the recipient. Calcium in the blood, which is present in larger quantities in younger patients, breaks down the valves. The older the patient, the longer the xenograft will last. Valves donated from human cadavers and **pulmonary autografts** (relocation of the patient's own pulmonary valve to the aortic position [Ross procedure]) are also being used for valve replacement.

Patients having a valve replacement have open heart surgery similar to the procedure for a coronary artery bypass graft (CABG) (see Chapter 40). Ideally, surgery is an elective and planned procedure. Inform the patient and family about the management of postoperative pain, incision care, and strategies to prevent respiratory complications (see Chapters 16 and 18). Teach patients receiving oral anticoagulants to stop taking them before surgery, usually at least 72 hours before the procedure. Patients also need to have a preoperative dental examination. If dental caries or periodontal disease is present, these problems must be resolved before valve replacement.

Postoperative nursing interventions for patients with valve replacement are similar to those for a CABG (see Chapter 40).

! NURSING SAFETY PRIORITY

Critical Rescue

Patients with mitral stenosis often have pulmonary hypertension and stiff lungs. Therefore monitor respiratory status closely during weaning from the ventilator. Be especially alert for bleeding in those with aortic valve replacements because of a higher risk for postoperative hemorrhage. If heart rate or blood pressure decreases, call the Rapid Response Team or other health care provider immediately!

Patients with valve replacements are also more likely to have significant reductions in cardiac output (CO) after surgery, especially those with aortic stenosis or left ventricular failure from mitral valve disease. Carefully monitor cardiac output (CO) and assess for indications of heart failure (HF). Report any manifestations of HF to the surgeon immediately

and prepare for collaborative management (see earlier discussion on **heart failure** in this chapter).

Community-Based Care

The patient with valvular heart disease may be discharged home on medical therapy or postoperatively after valve repair or replacement. Because fatigue is a common problem, ensure that the home environment can provide rest while moving the patient toward increased activity levels. Some older adults with aortic stenosis live in long-term care settings.

Home Care Management

A home care nurse may be needed to help the patient adhere to drug therapy and activity schedules and to detect any problems, particularly with anticoagulant therapy. Patients who have undergone surgery may require a nurse for assistance with incision care. A home care aide may assist with ADLs if the patient lives alone or is older.

Teaching for Self-Management

The teaching plan for the patient with valvular heart disease includes:

- The disease process and the possibility of heart failure
- Drug therapy, including diuretics, vasodilators, beta blockers, calcium channel blockers, antibiotics, and anticoagulants
- The prophylactic use of antibiotics
- A plan of activity and rest to conserve energy

Because patients with defective or repaired valves are at risk for infective endocarditis, teach them to adhere to the precautions described for endocarditis. *Remind them to inform all health care providers of the valvular heart disease history. Tell providers that they require antibiotic administration before all invasive procedures and tests.* Health teaching for the patient is summarized in Chart 37-7.

Patients who have had valve replacements with prosthetic valves require lifetime prophylactic anticoagulation therapy to prevent thrombus formation. Teach patients taking anticoagulants how to manage their drug therapy successfully, including nutritional considerations (if taking warfarin) and the prevention of bleeding. For example, the patient should be taught to avoid foods high in vitamin K, especially dark green leafy vegetables, and to use an electric razor to avoid skin cuts. In addition, teach him or her to report any bleeding or excessive bruising to the health care provider. Patients who

CHART 37-7 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Valvular Heart Disease

- Notify all your health care providers that you have a defective heart valve.
- Remind the health care provider of your valvular problem when you have any dental work (cleaning, filling, extraction), any examination by instrument (cystoscopy, endoscopy, sigmoidoscopy), or any other invasive procedure (arteriogram, surgery).
- Request antibiotic prophylaxis before and after these procedures if the health care provider does not offer it.
- Clean all wounds and apply antibiotic ointment to prevent infection.
- Notify your health care provider immediately if you experience fever, petechiae (pinpoint red dots on your skin), or shortness of breath.

have had prosthetic valve replacement need to take anticoagulants for the rest of their lives.

For patients who have surgery, reinforce how to care for the sternal incision and instruct them to watch for and report any fever, drainage, or redness at the site. Most patients can usually return to normal activity after 6 weeks but should avoid heavy physical activity involving their upper extremities for 3 to 6 months to allow the incision to heal. Those who have had valvular surgery should also avoid invasive dental procedures for 6 months because of the potential for endocarditis. Those with prosthetic valves need to avoid any procedure using magnetic resonance unless the newest technology is available. Remind patients to obtain a medical alert bracelet, card, or necklace to indicate they have a valve replacement and are taking anticoagulants.

Patients with valvular heart disease may have complicated medication schedules that can potentially lead to inadequate self-management. Provide clear, concise instructions about drug therapy, and discuss the risks associated with nonadherence. Patients with a failed valve or those who do not follow the treatment plan are at high risk for heart failure. Teach them to report any changes in cardiovascular status, such as dyspnea, syncope, dizziness, edema, and palpitations.

The psychological response to valve surgery is similar to that after coronary artery bypass surgery. Patients may experience an altered self-image as a result of the required lifestyle changes or the visible medial sternotomy incision. In addition, those with prosthetic valves may need to adjust to a soft but audible clicking sound of the prosthetic valve. Encourage patients to verbalize their feelings about the prosthetic heart valve. Patients may display a variety of emotions postoperatively, especially after hospital discharge.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client who recently had a heart valve replacement is taking warfarin (Coumadin) as prescribed. What health teaching will the nurse include before the client is discharged?

- “Take your pulse every day, and call your doctor if it is below 60.”
- “Weigh yourself every day in the morning using the same scale.”
- “Purchase a home kit to monitor your blood pressure every day.”
- “Avoid foods that are high in vitamin K, such as kale and spinach.”

Health Care Resources

The American Heart Association's Mended Hearts, Inc. (www.mendedhearts.org) is a community resource that provides information about valvular heart disease. A wallet-sized card can be obtained to identify the patient as needing prophylactic antibiotics. An identification bracelet or necklace that states the name of the drugs the patient is taking should also be worn.

INFLAMMATIONS AND INFECTIONS

INFECTIVE ENDOCARDITIS

Pathophysiology

Infective endocarditis (previously called *bacterial endocarditis*) is a microbial infection (e.g., viruses, bacteria, fungi) of the endocardium. The most common infective organism is *Streptococcus viridans* or *Staphylococcus aureus*.

Infective endocarditis occurs primarily in patients who abuse IV drugs, have had valve replacements, have experienced systemic infection, or have structural cardiac defects. With a cardiac defect, blood may flow rapidly from a high-pressure area to a low-pressure zone, eroding a section of endocardium. Platelets and fibrin adhere to the denuded endocardium, forming a vegetative lesion. During bacteremia, bacteria become trapped in the low-pressure “sinkhole” and are deposited in the vegetation. Additional platelets and fibrin are deposited, which causes the vegetative lesion to grow. The endocardium and valve are destroyed. Valvular insufficiency may result when the lesion interferes with normal alignment of the valve. If vegetations become so large that blood flow through the valve is obstructed, the valve appears stenotic and then is very likely to *embolize* (i.e., cause emboli to be released into the systemic circulation) (McCance et al., 2010).

Possible ports of entry for infecting organisms include:

- The oral cavity (especially if dental procedures have been performed)
- Skin rashes, lesions, or abscesses
- Infections (cutaneous, genitourinary, GI, systemic)
- Surgery or invasive procedures, including IV line placement

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Because the mortality rate remains high, early detection of infective endocarditis is essential. Unfortunately, many patients (especially older adults) are misdiagnosed. Clinical manifestations typically occur within 2 weeks of a bacteremia (Chart 37-8).

Most patients have recurrent fevers from 99° to 103° F (37.2° to 39.4° C). As a result of physiologic changes associated with aging, however, older adults may be afebrile. The severity of symptoms may depend on the virulence of the infecting organism.

Physical Assessment/Clinical Manifestations

Assess the patient's *cardiovascular status*. Almost all patients with infective endocarditis develop murmurs. Carefully auscultate the precordium, noting and documenting any new

CHART 37-8 KEY FEATURES

Infective Endocarditis

- Fever associated with chills, night sweats, malaise, and fatigue
- Anorexia and weight loss
- Cardiac murmur (newly developed or change in existing)
- Development of heart failure
- Evidence of systemic embolization
- Petechiae
- Splinter hemorrhages
- Osler's nodes (on palms of hands and soles of feet)
- Janeway's lesions (flat, reddened maculae on hands and feet)
- Positive blood cultures

murmurs (usually regurgitant in nature) or any changes in the intensity or quality of an old murmur. An S_3 or S_4 heart sound also may be heard.

Heart failure (HF) is the most common complication of infective endocarditis. Assess for right-sided HF (as evidenced by peripheral edema, weight gain, and anorexia) and left-sided HF (as evidenced by fatigue, shortness of breath, and crackles on auscultation of breath sounds). See discussion of HF earlier in this chapter.

Arterial embolization is a major complication in up to half of patients with infective endocarditis. Fragments of vegetation break loose and travel randomly through the circulation. When the left side of the heart is involved, vegetation fragments are carried to the spleen, kidneys, GI tract, brain, and extremities. When the right side of the heart is involved, emboli enter the pulmonary circulation.

Splenic infarction with sudden abdominal pain and radiation to the left shoulder can also occur. When performing an *abdominal assessment*, note rebound tenderness on palpation. The classic pain described with renal infarction is flank pain that radiates to the groin and is accompanied by hematuria (red blood cells in the urine) or pyuria (white blood cells in the urine). Mesenteric emboli cause diffuse abdominal pain, often after eating, and abdominal distention.

About a third of patients have *neurologic changes*, others have signs and symptoms of pulmonary problems. Emboli to the central nervous system cause either transient ischemic attacks (TIAs) or a stroke. Confusion, reduced concentration, and aphasia or dysphagia may occur. Pleuritic chest pain, dyspnea, and cough are symptoms of pulmonary infarction related to embolization.

Petechiae (pinpoint red spots) occur in many patients with endocarditis. Examine the mucous membranes, the palate, the conjunctivae, and the skin above the clavicles for small, red, flat lesions. Assess the distal third of the nail bed for **splinter hemorrhages**, which appear as black longitudinal lines or small red streaks.

Diagnostic Assessment

The most reliable criteria for diagnosing endocarditis include positive blood cultures, a new regurgitant murmur, and evidence of endocardial involvement by echocardiography.

A positive *blood culture* is a prime diagnostic test. Both aerobic and anaerobic specimens are obtained for culture. Some slow-growing organisms may take 3 weeks and require a specialized medium to isolate. Low hemoglobin and hematocrit levels may also be present.

Echocardiography has improved the ability to diagnose infective endocarditis accurately. Transesophageal echocardiography (TEE) allows visualization of cardiac structures that are difficult to see with transthoracic echocardiography (TTE; see Chapter 35).

INTERVENTIONS

Care of the patient with endocarditis usually includes antimicrobials, rest balanced with activity, and supportive therapy for HF. If these interventions are successful, surgery is usually not required.

Nonsurgical Management

The major component of treatment for endocarditis is drug therapy. Other interventions help prevent the life-threatening complications of the disease.

Antimicrobials are the main treatment, with the choice of drug depending on the specific organism involved. Because vegetations surround and protect the offending microorganism, an appropriate drug must be given in a sufficiently high dose to ensure its destruction. Antimicrobials are usually given IV, with the course of treatment lasting 4 to 6 weeks. For most bacterial cases, the ideal antibiotic is one of the penicillins or cephalosporins.

Patients may be hospitalized for several days to institute IV therapy and then are discharged for continued IV therapy at home. After hospitalization, most patients who respond to therapy may continue it at home when they become afebrile, have negative blood cultures, and have no signs of HF or embolization.

Anticoagulants do not prevent embolization from vegetations. Because they may result in bleeding, these drugs are avoided unless they are required to prevent thrombus formation on a prosthetic valve.

The patient's activities are balanced with *adequate rest*. Consistently use appropriate aseptic technique to protect the patient from contact with potentially infective organisms. Continue to assess for signs of HF (e.g., rapid pulse, fatigue, cough, dyspnea) throughout the antimicrobial regimen and report significant changes.

Surgical Management

The cardiac surgeon may be consulted if antibiotic therapy is ineffective in sterilizing a valve, if refractory HF develops secondary to a defective valve, if large valvular vegetations are present, or if multiple embolic events occur. Current surgical interventions for infective endocarditis include:

- Removing the infected valve (either biologic or prosthetic)
- Repairing or removing congenital shunts
- Repairing injured valves and chordae tendineae
- Draining abscesses in the heart

Preoperative and postoperative care of patients having surgery involving the valves is similar to that described earlier for valve replacement (pp. 761-762).

Community-Based Care

Community-based care for patients with infective endocarditis is essential to resolve the problem, prevent relapse, and avoid complications. Patients and families need to be willing and have the knowledge, physical ability, and resources to administer IV antibiotics at home. Collaborate with the

home care nurse to complete health teaching started in the hospital and to monitor patient adherence and health status as directed by The Joint Commission's National Patient Safety Goals.

In collaboration with the case manager, the home care nurse and pharmacist arrange for appropriate supplies to be available to the patient at home. Supplies include the prepared antibiotic, IV pump with tubing, alcohol wipes, IV access device, normal saline solution, and a saline flush solution drawn up in syringes. A saline lock, peripherally inserted central catheter (PICC) line, or central catheter is positioned at a venous site that is easily accessible to the patient or a family member.

Teach the patient and family how to administer the antibiotic and care for the infusion site while maintaining aseptic technique. The patient or family member should demonstrate this technique before the patient is discharged from the hospital. Emphasize the importance of maintaining a blood level of the antibiotic by administering the antibiotics as scheduled. After stabilization at home, the case manager or other nurse contacts the patient every week to determine whether he or she is adhering to the antibiotic therapy and whether any problems have been encountered.

Encourage proper oral hygiene. Advise patients to use a soft toothbrush, to brush their teeth at least twice per day, and to rinse the mouth with water after brushing. They should not use irrigation devices or floss the teeth because bacteremia may result. Teach them to clean any open skin areas well and apply an antibiotic ointment.

! NURSING SAFETY PRIORITY

Action Alert

Patients must remind health care providers (including their dentists) of their endocarditis. Teach patients to request prophylactic antibiotics for every invasive procedure, especially dental care.

Instruct patients to note any indications of recurring endocarditis such as fever. Remind them to monitor and record their temperature daily for up to 6 weeks. Teach them to report fever, chills, malaise, weight loss, increased fatigue, sudden weight gain, or dyspnea to their primary care provider.

PERICARDITIS

Pathophysiology

Acute pericarditis is an inflammation or alteration of the pericardium (the membranous sac that encloses the heart). The problem may be fibrous, serous, hemorrhagic, purulent, or neoplastic. Acute pericarditis is most commonly associated with:

- Infective organisms (bacteria, viruses, or fungi) (usually respiratory)
- Post–myocardial infarction (MI) syndrome (Dressler's syndrome)
- Post-pericardiotomy syndrome
- Acute exacerbations of systemic connective tissue disease

Chronic constrictive pericarditis occurs when chronic pericardial inflammation causes a fibrous thickening of the pericardium. It is caused by tuberculosis, radiation therapy, trauma, renal failure, or metastatic cancer. In chronic constrictive pericarditis, the pericardium becomes rigid,

preventing adequate filling of the ventricles and eventually resulting in cardiac failure.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Assessment findings for patients with *acute pericarditis* include substernal precordial pain that radiates to the left side of the neck, the shoulder, or the back. Pain is classically grating and oppressive and is aggravated by breathing (mainly on inspiration), coughing, and swallowing. The pain is worse when the patient is in the supine position and may be relieved by sitting up and leaning forward. Ask specific questions to evaluate chest discomfort to differentiate it from the pain associated with an acute MI (see [Chapter 40](#)).

A pericardial friction rub may be heard with the diaphragm of the stethoscope positioned at the left lower sternal border. This scratchy, high-pitched sound is produced when the inflamed, roughened pericardial layers create friction as their surfaces rub together.

Patients with acute pericarditis may have an elevated white blood cell count and usually have a fever. Therefore blood culture and sensitivity may be analyzed in the laboratory. The ECG usually shows ST-T spiking with the onset of inflammation, which returns to baseline with treatment. Atrial fibrillation is also common. Echocardiograms may be used to determine a pericardial effusion.

Patients with *chronic constrictive pericarditis* have signs of right-sided HF, elevated systemic venous pressure with jugular distention, hepatic engorgement, and dependent edema. Exertional fatigue and dyspnea are common complications. Thickening of the pericardium is seen on echocardiography or a computed tomography (CT) scan.

INTERVENTIONS

The focus of collaborative management is to relieve pain and treat the cause of pericarditis before severe complications occur.

Pain Management

The health care provider usually prescribes NSAIDs for pain associated with pericarditis. Patients who do not obtain pain relief and who do not have bacterial pericarditis may receive corticosteroid therapy. Assist the patient to assume positions of comfort—usually sitting upright and leaning slightly forward. If the pain is not relieved within 24 to 48 hours, notify the primary care provider.

The various causes of pericarditis require specific therapies. For example, bacterial pericarditis (acute) usually requires antibiotics and pericardial drainage. The usual clinical course of acute pericarditis is short term (2 to 6 weeks), but episodes may recur. Chronic pericarditis caused by malignant disease may be treated with radiation or chemotherapy, whereas uremic pericarditis is treated by hemodialysis. The definitive treatment for chronic constrictive pericarditis is surgical excision of the pericardium (**pericardiectomy**).

- Monitor all patients for **pericardial effusion**, which occurs when the space between the parietal and visceral layers of the pericardium fills with fluid. This

complication puts the patient at risk for **cardiac tamponade**, or excessive fluid within the pericardial cavity.

Emergency Care: Acute Cardiac Tamponade

Acute cardiac tamponade may occur when small volumes (20 to 50 mL) of fluid accumulate rapidly in the pericardium and cause a sudden decrease in cardiac output (CO). If the fluid accumulates slowly, the pericardium may stretch to accommodate several hundred milliliters of fluid. Report any suspicion of this complication to the physician immediately. Findings of cardiac tamponade include:

- Jugular venous distention
- **Paradoxical pulse**, also known as *pulsus paradoxus* (systolic blood pressure 10 mm Hg or more higher on expiration than on inspiration) (Chart 37-9)
- Decreased heart rate, dyspnea, and fatigue
- Muffled heart sounds
- Hypotension

Cardiac tamponade is an emergency! The physician may initially manage the decreased cardiac output (CO) with increased fluid volume administration while awaiting an echocardiogram or x-ray to confirm the diagnosis. Unfortunately, these tests are not always helpful because the fluid volume around the heart may be too small to visualize. Hemodynamic monitoring in a specialized critical care unit usually demonstrates compression of the heart, with all pressures (right atrial, pulmonary artery, and wedge) being similar and elevated (plateau pressures).

The physician may elect to perform a **pericardiocentesis** to remove fluid and relieve the pressure on the heart. Under echocardiographic or fluoroscopic and hemodynamic monitoring, the cardiologist inserts an 8-inch (20.3-cm), 16- or 18-gauge pericardial needle into the pericardial space. When the needle is properly positioned, a catheter is inserted and

all available pericardial fluid is withdrawn. A pericardial drain may be temporarily placed. Monitor the pulmonary artery, wedge, and right atrial pressures during the procedure. The pressures should return to normal as the fluid compressing the heart is removed, and the clinical manifestations of tamponade should resolve. In situations in which the cause of the tamponade is unknown, pericardial fluid specimens may be sent to the laboratory for culture and sensitivity tests, and cytology.

! NURSING SAFETY PRIORITY

Action Alert

After the pericardiocentesis, closely monitor the patient for the recurrence of tamponade. Pericardiocentesis alone often does not resolve acute tamponade. Be prepared to provide adequate fluid volumes to increase CO and to prepare the patient for emergency sternotomy if tamponade recurs.

If the patient has a recurrence of tamponade or recurrent effusions or adhesions from chronic pericarditis, a portion or all of the pericardium may need to be removed to allow adequate ventricular filling and contraction. The surgeon may create a pericardial window, which involves removing a portion of the pericardium to permit excessive pericardial fluid to drain into the pleural space. In more severe cases, removal of the toughened encasing pericardium (pericardiectomy) may be necessary.

RHEUMATIC CARDITIS

Pathophysiology

Rheumatic carditis, also called *rheumatic endocarditis*, is a sensitivity response that develops after an upper respiratory tract infection with group A beta-hemolytic streptococci. It occurs in almost half of patients with rheumatic fever. The precise mechanism by which the infection causes inflammatory lesions in the heart is not established; however, inflammation is evident in all layers of the heart. The inflammation results in impaired contractile function of the myocardium, thickening of the pericardium, and valvular damage.

Rheumatic carditis is characterized by the formation of Aschoff bodies (small nodules in the myocardium that are replaced by scar tissue). A diffuse cellular infiltrate also develops and may be responsible for the resulting heart failure (HF). The pericardium becomes thickened and covered with exudate, and a serosanguineous pleural effusion may develop. The most serious damage occurs to the endocardium, with inflammation of the valve leaflets developing. Hemorrhagic and fibrous lesions form along the inflamed surfaces of the valves, resulting in stenosis or regurgitation of the mitral and aortic valves (McCance et al., 2010).

PATIENT-CENTERED COLLABORATIVE CARE

Rheumatic carditis is one of the major indicators of rheumatic fever. The common manifestations are:

- Tachycardia
- **Cardiomegaly** (enlarged heart)
- Development of a new murmur or a change in an existing murmur

CHART 37-9 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Care of the Patient with Pericarditis

- Assess the nature of the patient's chest discomfort. (Pericardial pain is typically substernal. It is worse on inspiration and decreases when the patient leans forward.)
- Auscultate for a pericardial friction rub.
- Assist the patient to a position of comfort.
- Provide anti-inflammatory agents as prescribed.
- Explain that anti-inflammatory agents usually decrease the pain within 48 hours.
- Avoid the administration of aspirin and anticoagulants because these may increase the possibility of tamponade.
- Auscultate the blood pressure carefully to detect paradoxical blood pressure (*pulsus paradoxus*), a sign of tamponade:
 - Palpate the blood pressure, and inflate the cuff above the systolic pressure.
 - Deflate the cuff gradually, and note when sounds are first audible on expiration.
 - Identify when sounds are also audible on inspiration.
 - Subtract the inspiratory pressure from the expiratory pressure to determine the amount of *pulsus paradoxus* (>10 mm Hg is an indication of tamponade).
- Inspect for other indications of tamponade, including jugular venous distention with clear lungs, muffled heart sounds, and decreased cardiac output.
- Notify the physician if tamponade is suspected.

- Pericardial friction rub
- Precordial pain
- Electrocardiogram (ECG) changes (prolonged PR interval)
- Indications of heart failure (HF)
- Evidence of an existing streptococcal infection

Primary prevention is extremely important. Teach all patients to remind their health care providers to provide appropriate antibiotic therapy if they develop the indications of streptococcal pharyngitis:

- Moderate to high fever
- Abrupt onset of a sore throat
- Reddened throat with exudate
- Enlarged and tender lymph nodes

Penicillin is the antibiotic of choice for treatment. Erythromycin (Eryc, Erythromid 🍀) is the alternative for penicillin-sensitive patients.

Once a diagnosis of rheumatic fever is made, antibiotic therapy is started immediately. Teach the patient to continue the antibiotic administration for the full 10 days to prevent

reinfection. Suggest ways to manage fever, such as maintaining hydration and taking antipyretics. Encourage the patient to get adequate rest.

Explain to the patient and family that a recurrence of rheumatic carditis is most likely the result of reinfection by *Streptococcus*. Antibiotic prophylaxis is necessary for the rest of the patient's life to prevent infective endocarditis (see [Infective Endocarditis](#), p. 763).

CARDIOMYOPATHY

Pathophysiology

Cardiomyopathy is a subacute or chronic disease of cardiac muscle, and the cause may be unknown. Cardiomyopathies are classified into four categories on the basis of abnormalities in structure and function: dilated cardiomyopathy, hypertrophic cardiomyopathy, restrictive cardiomyopathy, and arrhythmogenic right ventricular cardiomyopathy ([Table 37-5](#)). Mortality at 1 year is 20% and 70% to 80% at year 8 for patients who develop heart failure (Wexler et al., 2009).

TABLE 37-5 PATHOPHYSIOLOGY, SIGNS AND SYMPTOMS, AND TREATMENT OF COMMON CARDIOMYOPATHIES

DILATED CARDIOMYOPATHY	HYPERTROPHIC CARDIOMYOPATHY	
	NONOBSTRUCTED	OBSTRUCTED
Pathophysiology Fibrosis of myocardium and endocardium Dilated chambers Mural wall thrombi prevalent	Hypertrophy of all walls Hypertrophied septum Relatively small chamber size	Same as for nonobstructed except for obstruction of left ventricular outflow tract associated with the hypertrophied septum and mitral valve incompetence
		
Signs and Symptoms Fatigue and weakness Heart failure (left side) Dysrhythmias or heart block Systemic or pulmonary emboli S ₃ and S ₄ gallops Moderate to severe cardiomegaly	Dyspnea Angina Fatigue, syncope, palpitations Mild cardiomegaly S ₄ gallop Ventricular dysrhythmias Sudden death common Heart failure	Same as for nonobstructed except with mitral regurgitation murmur Atrial fibrillation
Treatment Symptomatic treatment of heart failure Vasodilators Control of dysrhythmias Surgery: heart transplant	For both: Symptomatic treatment Beta blockers Conversion of atrial fibrillation Surgery: ventriculomyotomy or muscle resection with mitral valve replacement Nitrates and other vasodilators <i>contraindicated</i> with the obstructed form	

Dilated cardiomyopathy (DCM) is the structural abnormality most commonly seen. DCM involves extensive damage to the myofibrils and interference with myocardial metabolism. Ventricular wall thickness is normal, but both ventricles are dilated (left ventricle is usually worse) and systolic function is impaired. Causes may include alcohol abuse, chemotherapy, infection, inflammation, and poor nutrition. Decreased CO from inadequate pumping of the heart causes the patient to experience dyspnea on exertion (DOE), decreased exercise capacity, fatigue, and palpitations.

The cardinal features of **hypertrophic cardiomyopathy (HCM)** are asymmetric ventricular hypertrophy and disarray of the myocardial fibers. Left ventricular hypertrophy leads to a stiff left ventricle, which results in diastolic filling abnormalities. Obstruction in the left ventricular outflow tract is seen in most patients with HCM. In about half of patients, HCM is transmitted as a single-gene autosomal dominant trait (McCance et al., 2010). Some patients die without any symptoms, whereas others have dyspnea on exertion (DOE), syncope, dizziness, and palpitations. Many athletes who die suddenly probably had hypertrophic cardiomyopathy (Wexler et al., 2009).

Restrictive cardiomyopathy, the rarest of the cardiomyopathies, is characterized by stiff ventricles that restrict filling during diastole. Symptoms are similar to left or right heart failure (HF) or both. The disease can be primary or caused by endocardial or myocardial disease such as sarcoidosis or amyloidosis. The prognosis for this type of cardiomyopathy is poor.

Arrhythmogenic right ventricular cardiomyopathy (dysplasia) results from replacement of myocardial tissue with fibrous and fatty tissue. Although the name implies right ventricle disease, about a third of patients also have left ventricle (LV) involvement. This disease has a familial association and most often affects young adults. Some patients have symptoms, and others do not.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Findings in cardiomyopathy depend on the structural and functional abnormalities. For example, left ventricular or biventricular failure is characteristic of *dilated* cardiomyopathy (DCM). Some patients with DCM are asymptomatic for months to years and have left and/or right ventricular dilation confirmed on x-ray examination or echocardiography. Others experience sudden, pronounced symptoms of left ventricular failure, such as progressive dyspnea on exertion, orthopnea, palpitations, and activity intolerance. Right-sided HF develops late in the disease and is associated with a poor prognosis. Atrial fibrillation occurs in some patients and is associated with embolism.

The clinical picture of *hypertrophic* cardiomyopathy (HCM) results from the hypertrophied septum causing a reduced stroke volume (SV) and cardiac output (CO). Most patients are asymptomatic until late adolescence or early adulthood. The primary symptoms of HCM are exertional dyspnea, angina, and syncope. The chest pain is atypical in that it usually occurs at rest, is prolonged, has no relation to exertion, and is not relieved by the administration of nitrates.

A high incidence of ventricular dysrhythmias is associated with HCM. Sudden death occurs and may be the first manifestation of the disease.

Echocardiography, radionuclide imaging, and angiography during cardiac catheterization are performed to diagnose and differentiate cardiomyopathies.

INTERVENTIONS

The treatment of choice for the patient with cardiomyopathy varies with the type of cardiomyopathy and may include both medical and surgical interventions.

Nonsurgical Management

The care of patients with dilated or restrictive cardiomyopathy is initially the same as for HF. Drug therapy includes the use of diuretics, vasodilating agents, and cardiac glycosides to increase cardiac output (CO). Because patients are at risk for sudden death, teach them to report any palpitations, dizziness, or fainting, which might indicate a dysrhythmia. Anti-dysrhythmic drugs or implantable cardiac defibrillators may be used to control life-threatening dysrhythmias. To block inappropriate sympathetic stimulation and tachycardia, beta blockers (e.g., metoprolol) are used. If cardiomyopathy has developed in response to a toxin (such as alcohol), further exposure to that toxin must be avoided.

Management of obstructive HCM includes administering negative inotropic agents such as beta-adrenergic blocking agents (carvedilol) and calcium antagonists (diltiazem). These drugs decrease the outflow obstruction that accompanies exercise. They also decrease heart rate (HR), resulting in less angina, dyspnea, and syncope. Vasodilators, diuretics, nitrates, and cardiac glycosides are contraindicated in patients with obstructive HCM because vasodilating and positive inotropic effects may worsen the obstruction (Wexler et al., 2009). Strenuous exercise is also prohibited because it can increase the risk for sudden death.

Surgical Management

The type of surgery performed depends on the type of cardiomyopathy. The most commonly used surgical treatment for obstructive HCM involves excising a portion of the hypertrophied ventricular septum to create a wider outflow tract (**ventriculomyectomy**; also called *ventricular septal myectomy*). This procedure results in long-term improvement in activity tolerance for most patients.

Percutaneous alcohol septal ablation is another option for patients with HCM. Absolute alcohol is injected into a target septal branch of the left anterior descending coronary artery to produce a small septal infarction.

The patient with arrhythmogenic right ventricular cardiomyopathy who does not respond to drug therapy may have a radiofrequency catheter ablation or placement of an implantable defibrillator (see Chapter 36 for discussion of these procedures).

Heart transplantation (surgical replacement with a donor heart) is the treatment of choice for patients with severe DCM and may be considered for patients with restrictive cardiomyopathy. The procedure may be done also for end-stage heart disease due to coronary artery disease, valvular disease, or congenital heart disease.

Preoperative Care. Criteria for candidate selection for heart transplantation include:

- Life expectancy less than 1 year
- Age generally less than 65 years
- New York Heart Association (NYHA) class III or IV
- Normal or only slightly increased pulmonary vascular resistance
- Absence of active infection
- Stable psychosocial status
- No evidence of current drug or alcohol abuse

Once the candidate is eligible and a heart is available, provide preoperative care as described in [Chapter 16](#).

Operative Procedures. The surgeon transplants a heart from a donor with a comparable body weight and ABO compatibility into a recipient less than 6 hours after procurement. In the most common procedure (**bicaval technique**), the intact right atrium of the donor heart is preserved by anastomoses at the patient's (recipient's) superior and inferior vena cavae. In the more traditional **orthotopic** technique, cuffs of the patient's right and left atria are attached to the donor's atria. Anastomoses are made between the recipient and donor atria, aorta, and pulmonary arteries ([Fig. 37-4](#)). Because the remaining remnant of the recipient's atria contains the sinoatrial (SA) node, two unrelated P waves are visible on the ECG.

Postoperative Care. The postoperative care of the heart transplant recipient is similar to that for conventional cardiac surgery (see [Chapter 40](#)). However, the nurse must be especially observant to identify occult bleeding into the pericardial sac with the potential for tamponade (see earlier discussion of this complication on p. 766). The patient's pericardium has usually stretched considerably to accommodate the diseased, hypertrophied heart, predisposing him or her to have concealed postoperative bleeding.

The transplanted heart is denervated (disconnected from the body's autonomic nervous system) and is unresponsive to vagal stimulation. In the early postoperative phase, isoproterenol (Isuprel) may be titrated to support the HR and maintain cardiac output. Atropine, digoxin, and carotid sinus pressure are not used because they do not have their usual effects on the new heart. Denervation of the heart may cause pronounced orthostatic hypotension in the immediate postoperative phase. Caution the patient to change position slowly to help prevent this complication. Some patients also require a permanent pacemaker that is rate responsive to his or her activity level. The purpose is to increase CO and improve activity tolerance.

To suppress natural defense mechanisms (especially T- and B-cell function) and prevent transplant rejection, patients require a combination of immunosuppressants for the rest of their lives. [Chapter 19](#) describes transplant rejection and prevention in detail.

! NURSING SAFETY PRIORITY

Critical Rescue

After surgery, perform comprehensive cardiovascular and respiratory assessments frequently according to agency or heart transplant surgical protocol. [Chart 37-10](#) lists the signs and symptoms of rejection that are specific to heart transplant. Report any of these manifestations to the surgeon immediately! To detect rejection, the surgeon performs right endomyocardial biopsies at regularly scheduled intervals and whenever symptoms occur.

Be very careful about handwashing and aseptic technique because patients are immunosuppressed from drug therapy.

1. After the recipient is placed on cardiopulmonary bypass, the heart is removed.

2. The posterior walls of the recipient's left and right atria are left intact.

3. The left atrium of the donor heart is anastomosed to the recipient's residual posterior atrial walls, and the other atrial walls, the atrial septum, and the great vessels are joined.

POSTOPERATIVE RESULT

FIG. 37-4 One technique for heart transplantation.

CHART 37-10 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Assessing for Clinical Manifestations of Heart Transplant Rejection

- Shortness of breath
- Fatigue
- Fluid gain (edema, increased weight)
- Abdominal bloating
- New bradycardia
- Hypotension
- Atrial fibrillation or flutter
- Decreased activity tolerance
- Decreased ejection fraction (late sign)

Infection is the major cause of death and usually develops in the immediate post-transplant period or during treatment for acute rejection.

About 50% of patients survive 10 years after transplantation (Eisen & Ross, 2010). Many of the surviving patients have a form of coronary artery disease (CAD) called **coronary artery vasculopathy (CAV)**, which presents as diffuse plaque in the arteries of the donor heart. The cause is thought to involve a combination of immunologic and non-immunologic processes that result in vascular endothelial injury and an inflammatory response (Eisen & Ross, 2010).

Because the heart is denervated, patients do not usually experience angina. Regularly scheduled exercise tolerance tests and angiography are required to identify CAV. Only a small percentage of patients with CAV benefit from revascularization procedures like balloon angioplasty or coronary artery bypass surgery. Stents are beginning to show some promise in managing these patients. Retransplantation may be done in select patients.

To delay the development of CAV, encourage patients to follow lifestyle changes similar to those with primary CAD (see Chapter 40). The physician may prescribe a calcium channel blocker such as diltiazem (Cardizem) to prevent coronary spasm and closure. Stress the importance of strict adherence to nutritional modifications and drug regimens. Teach the patient the importance of participating in a regular exercise program. Collaborate with the physical therapist to plan the most appropriate exercise plan for the patient.

Discharge planning involves a collaborative, interdisciplinary approach. Patients require extensive health teaching for self-management and community resources for support. Counseling and support groups can help patients cope with their fear of organ rejection. Drug therapy adherence is crucial to prevent this problem. Continuing community-based care for patients with a heart transplant is similar to that for heart failure as discussed on p. 756.

NURSING CONCEPT REVIEW

What might you NOTICE if a patient is experiencing inadequate oxygenation and tissue perfusion as a result of heart failure?

- Report of shortness of breath, especially on exertion
- Report of dizziness
- Report of weight gain within days
- Syncope
- Dyspnea on exertion
- Report of palpitations
- Report of fatigue and weakness
- Disorientation or acute confusion (especially in older adults)
- Peripheral or abdominal ascites

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate oxygenation and tissue perfusion as a result of heart failure?

Perform and interpret physical assessment, including:

- Taking vital signs
- Monitoring oxygen saturation by pulse oximetry
- Performing a complete cardiovascular assessment
- Performing a complete respiratory assessment (listen for crackles or wheezes)
- Weighing patient

- Assessing cognition
- Assessing for pain or other symptoms

Respond by:

- Seeing health care provider immediately or calling 911 if patient is not in hospital setting ... OR
- Notifying physician or Rapid Response Team in hospital setting
- Raising the head of the bed to a sitting position
- Giving oxygen
- Maintaining or starting IV line
- Administering furosemide IV push (IVP) as prescribed
- Monitoring intake and output
- Giving ACE inhibitors or ARBs as prescribed IV or orally

On what should you REFLECT?

- Observe patient for increased urinary output.
- Monitor for decreased respiratory distress.
- Continue to monitor for improvement.
- Think about the possible cause(s) of the patient's heart failure.
- Think about your response to the patient.
- Develop a teaching plan for the patient to help prevent worsening or recurrent acute episodes of heart failure.

GET READY FOR THE NCLEX® EXAMINATION!**KEY POINTS**

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Provide information about continuing care for patients with heart failure (HF) after discharge to the community.
- Assess whether patients with end-stage HF have advance directives. If not, provide information about them.
- Collaborate with members of the health care team when developing and implementing a plan of care for patients with heart failure.
- Teach patients about community support groups and resources such as the American Heart Association.

Health Promotion and Maintenance

- Provide teaching about self-management at home for patients with HF (see [Table 37-4](#)).
- Monitor older adults who are taking digoxin for manifestations of toxicity. Monitor potassium levels to check for hypokalemia (see [Chart 37-5](#)).
- Teach patients taking ACE inhibitors or ARBs to change positions slowly to avoid orthostatic hypotension, especially older adults.
- Teach the patient with valvular dysfunction, cardiac infection, or cardiomyopathy the necessity of taking preventive antibiotic therapy before any invasive procedure.

Psychosocial Integrity

- Assess the patient for depression resulting from altered self-concept and anxiety.
- Assess the patient's coping skills.

Physiological Integrity

- Assess the patient for manifestations of right- and left-sided HF (see [Charts 37-1 and 37-2](#)).

- Weigh daily and record intake and output of patients with HF.
- Assess for early signs and symptoms of pulmonary edema (e.g., crackles in the lung bases, dyspnea at rest, disorientation, confusion), especially in older adults.
- Assess for symptoms of worsening HF: rapid weight gain (3 lb in a week), a decrease in exercise tolerance lasting 2 to 3 days, cold symptoms (cough) lasting more than 3 to 5 days, nocturia, development of dyspnea or angina at rest, or unstable angina.
- Monitor the HF patient on beta blockers carefully for hypotension and bradycardia.
- Monitor the pulse of patients taking digoxin before administration, and report to the health care provider a pulse that is not within the desired parameters.
- Monitor for manifestations of pulmonary edema as listed in [Chart 37-3](#).
- Place the patient in a sitting position and provide oxygen therapy at a high flow rate (unless otherwise contraindicated) if pulmonary edema is suspected.
- Recognize that home care nurses perform focused physical assessments for cardiac patients as delineated in [Chart 37-4](#).
- Monitor the patient with valvular dysfunction for atrial fibrillation, which may lead to hemostasis and mural thrombi. Monitor for an irregularly irregular cardiac rhythm, and administer warfarin as indicated.
- Assess neurovascular status frequently because emboli from valvular disease may cause strokes.
- Differentiate major types of cardiomyopathy as described in [Table 37-5](#).
- Observe for symptoms of heart transplant rejection as listed in [Chart 37-10](#).
- Provide care for patients with pericarditis as outlined in [Chart 37-9](#).

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Collaborate with interdisciplinary health care team members when providing care for patients with vascular problems.

Health Promotion and Maintenance

2. Identify risk factors for vascular problems.
3. Teach patients about lifestyle modifications to prevent vascular problems.

Physiological Integrity

4. Explain the pathophysiology of arteriosclerosis and atherosclerosis.
5. Interpret essential laboratory data related to risk for atherosclerosis.
6. Discuss the role of nutrition therapy in the management of patients with arteriosclerosis.
7. Describe the differences between essential and secondary hypertension.

8. Develop a collaborative plan of care for a patient with essential hypertension.
9. Develop a teaching plan for patients on adverse effects of drugs for hypertension and when to notify the health care provider.
10. Compare common assessment findings present in patients with peripheral arterial and peripheral venous disease.
11. Identify when venous thromboembolism (VTE) and complications of VTE occur.
12. Plan nursing interventions to help prevent VTE.
13. Describe the nurse's role in monitoring patients who are receiving anticoagulants.
14. Monitor for complications of vascular surgery.
15. Perform a focused vascular assessment.
16. Compare assessment findings associated with Raynaud's phenomenon and Buerger's disease.

The *peripheral* vascular system is essential for transporting blood to and from distal tissues in the extremities. When peripheral blood vessels are diseased or damaged, especially in the legs, arterial blood flow is impaired, preventing distal areas like the feet from being adequately *perfused* and *oxygenated*. The result can be ischemia and necrosis (cell death). Venous disease causes blood to back up into the distal areas and can lead to edema and thromboses (clots) that can become emboli, a life-threatening complication.

ARTERIOSCLEROSIS AND ATHEROSCLEROSIS

Pathophysiology

Arteriosclerosis is a thickening, or hardening, of the arterial wall that is often associated with aging. **Atherosclerosis**, a type of arteriosclerosis, involves the formation of plaque within the arterial wall and is the leading risk factor for cardiovascular disease. Usually the disease affects the larger arteries, such as coronary artery beds; aorta; carotid and

FIG. 38-1 Pathophysiology of atherosclerosis.

vertebral arteries; renal, iliac, and femoral arteries; or any combination of these.

The exact pathophysiology of atherosclerosis is not known, but the condition is thought to occur from blood vessel damage that causes an inflammatory response (see the discussion of inflammation in Chapter 19) (Fig. 38-1). After the vessel becomes inflamed, a fatty streak appears on the intimal surface (inner lining) of the artery. Through the process of cellular proliferation, collagen migrates over the fatty streak, forming a fibrous plaque. The fibrous plaque is often elevated and protrudes into the vessel lumen, partially or completely obstructing blood flow through the artery. Plaques are either stable or unstable. Unstable plaques are prone to rupture and are often clinically silent until they rupture (McCance et al., 2010).

In the final stage, the fibrous plaques become calcified, hemorrhagic, ulcerated, or thrombosed and affect all layers of the vessel. The rate of progression of the process may be influenced by genetic factors; certain chronic diseases (e.g., diabetes mellitus); and lifestyle habits, including smoking, eating habits, and level of exercise.

When *stable* plaque ruptures, thrombosis (blood clot) and constriction obstruct the vessel lumen, causing inadequate perfusion and oxygenation to distal tissues. *Unstable* plaque rupture causes more severe damage. After the rupture occurs, the exposed underlying tissue causes platelet adhesion and rapid thrombus formation. The thrombus may suddenly block a blood vessel, resulting in ischemia and infarction (e.g., myocardial infarction) (McCance et al., 2010).

TABLE 38-1 RISK FACTORS FOR ATHEROSCLEROSIS

• Low HDL-C	• Sedentary lifestyle
• High LDL-C	• Smoking
• Increased triglycerides	• Stress
• Genetic predisposition	• African-American or Hispanic ethnicity
• Diabetes mellitus	• Older adult
• Obesity	

HDL-C, High-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol.

Endothelial (intimal) injury of the major arteries of the body can be caused by many factors. Elevated levels of **lipids** (fats) like low-density lipoprotein cholesterol (LDL-C) and decreased levels of high-density lipoprotein cholesterol (HDL-C) can cause chemical injuries to the vessel wall. (Chapter 35 discusses lipids in detail.) Chemical injury can also be caused by elevated levels of toxins in the bloodstream, which may occur with renal failure or by carbon monoxide circulating in the bloodstream from cigarette smoking. The vessel wall can be weakened by the natural process of aging or by diseases such as hypertension.

Genetic predisposition and diabetes have a major effect on the development of atherosclerosis. Some patients have familial **hyperlipidemia**, an elevation of serum lipid levels. In these people, the liver makes excessive cholesterol and other fats. However, some people with hereditary atherosclerosis have a normal blood cholesterol level. The reason for the development and progression of plaque in these patients is not understood (McCance et al., 2010).

Adult patients with severe diabetes mellitus of any age frequently have premature and severe atherosclerosis from microvascular damage. The premature atherosclerosis occurs because diabetes promotes an increase in LDL-C and triglycerides (lipids) in plasma. In addition, arterial damage may result from the effect of hyperglycemia.

Other factors are indirectly related to atherosclerosis development. A list of risk factors is found in Table 38-1.

It is not known exactly how many people have atherosclerosis, but small plaques are almost always present in the arteries of young adults. The incidence can be better quantified by assessing the number of cardiovascular diseases (CVDs) that result from atherosclerosis. An estimated 81 million U.S. adults have one or more types of CVD. Coronary artery disease affects 16 million people, and stroke affects another 6 million. About half of those with CVD are older than 60 years, and many more are middle-aged (American Heart Association [AHA], 2010). The number of people affected by atherosclerosis is likely to increase as the population ages, especially as many of the 79 million “baby boomers” turn 60.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Physical Assessment/Clinical Manifestations

The assessment of a patient with atherosclerosis includes a complete cardiovascular assessment because associated heart disease is often present. Because of the high incidence of

hypertension in patients with atherosclerosis, assess the blood pressure in both arms.

Palpate pulses at all of the major sites on the body, and note any differences. *Palpate each carotid artery separately to prevent blocking blood flow to the brain!* Also feel for temperature differences in the lower extremities, and check capillary filling. Prolonged capillary filling (>3 seconds in young to middle-aged adults; >5 seconds in older adults) generally indicates poor circulation, *although this indicator is not the most reliable indicator of perfusion.* An extremity in a person with severe atherosclerotic disease may be cool or cold with a diminished or absent pulse.

Many patients with vascular disease have a bruit in the larger arteries, which can be heard with a stethoscope or Doppler probe. A **bruit** is a turbulent, swishing sound, which can be soft or loud in pitch. It is heard as a result of blood trying to pass through a narrowed artery. A bruit is considered abnormal, but it does not indicate the severity of disease. Bruits often occur in the carotid, aortic, femoral, and popliteal arteries.

NURSING SAFETY PRIORITY

Action Alert!

A decrease in intensity or a complete loss of a pulse in a patient with atherosclerosis may indicate an arterial occlusion (blockage). Immediately report pulselessness to the health care provider and document for emergency management (described later in this chapter under Acute Arterial Occlusion).

Laboratory Assessment

Patients with atherosclerosis often have elevated lipids, including cholesterol and triglycerides. Total serum *cholesterol* levels should be below 200 mg/dL. Elevated cholesterol levels are confirmed by HDL and LDL measurements. Increased low-density lipoprotein cholesterol (LDL-C) (“bad” cholesterol) levels indicate that a person is at an increased risk for atherosclerosis. Low high-density lipoprotein cholesterol (“good” cholesterol) (HDL-C) levels also indicate an increased risk. A desirable LDL-C level is one below 100 mg/dL for healthy people and below 70 mg/dL for those diagnosed with CVD or who are diabetic. A desirable HDL-C level is 40 mg/dL or above (Pagana & Pagana, 2010).

Triglyceride level may also be elevated with atherosclerosis and is an emerging lipid risk factor by the classic Adult Treatment Panel Report No. 3 (ATP III) released by the National Heart, Lung, and Blood Institute (National Cholesterol Education Program, 2002). A level of 150 mg/dL or above indicates **hypertriglyceridemia**. Women should have a level below 135 mg/dL (Pagana & Pagana, 2010). Elevated triglycerides are considered a marker for other lipoproteins. They also suggest **metabolic syndrome**, which increases the risk for coronary heart disease (see Table 40-1 and discussion in Chapter 40).

INTERVENTIONS

Atherosclerosis progresses for years before clinical manifestations occur. Adults who are at risk for the disease can often be identified through cholesterol screening and history. Because of the high incidence in the United States, low-risk people 20 years of age and older are advised to have their total serum cholesterol level evaluated at least once every 5 years.

More frequent measurements are suggested for people with multiple risk factors and those older than 40 years.

People with multiple risk factors are grouped into high-risk patient categories termed “coronary heart disease equivalents.” These groups include:

- Patients with diabetes but without signs of vascular disease
- Patients with a Framingham Heart Study 10-year absolute risk score of over 20% for coronary heart disease events
- Patients identified with multiple metabolic risk factors

People within these groups are at the same risk level as those who already have vascular disease. Testing and management recommendations from the National Cholesterol Education Program (NCEP) and ATP guidelines have a major preventive focus for people with multiple risk factors.

Interventions for patients with atherosclerosis or those at high risk for the disease focus on lifestyle changes. Teach patients about the need to make daily changes by avoiding or minimizing modifiable risk factors. *Modifiable risk factors* are those that can be changed or controlled by the patient, such as smoking, weight management, and exercise. Nutrition is one of the most important parts of the risk-reduction plan. Chapter 40 describes how to manage modifiable risk factors in detail in the Health Promotion and Maintenance section, p. 831. If lipoprotein levels do not improve after lifestyle changes, the health care provider may prescribe drug therapy to lower cholesterol and/or triglycerides.

Nutrition Therapy

The Nutrition Committee of the American Heart Association (AHA) established dietary guidelines to promote healthy dietary habits as a strategy to reduce the risk for cardiovascular disease. The guidelines, revised in 2006, focus on the need to achieve and maintain a healthy weight and make appropriate food choices. Although most research focuses on individual nutrients or foods, the AHA guidelines aim to improve overall diet to ensure nutrient adequacy and energy balance (Lichtenstein et al., 2006). The AHA recommends that people consume a variety of nutritious foods including fruits, vegetables, whole grains, fat-free and low-fat dairy products, and lean meats. Specific AHA guidelines to decrease the risk for cardiovascular disease include minimizing fat and cholesterol intake. Chapter 63 describes the most recent U.S. government dietary guidelines, which include increasing daily vegetables and decreasing dairy food fats.

To decrease serum cholesterol level, a total fat intake of less than 30% of total calories should be consumed. Less than 10% of total caloric intake should be from saturated fat, up to 10% of total calories should be from polyunsaturated fat, and 10% to 15% should come from monounsaturated fat. Cholesterol intake should also be less than 300 mg daily.

In collaboration with the dietitian as needed, teach the patient about the types of fat content in food. Meats and eggs contain mostly saturated fats and are high in cholesterol. Recommend canola (rapeseed) oil (rich in monounsaturated fat) and safflower and sunflower oil (rich in polyunsaturated oils) over highly saturated oils such as palm or coconut oil.

The focus of cholesterol management is an aggressive approach to lowering LDL-C values and raising HDL-C levels. Having an LDL-C value of less than 100 mg/dL is optimal; values of 100 to 129 mg/dL are near or less than

optimal. Patients with LDL-C values of 130 to 159 mg/dL (borderline high) are advised to follow a fat-modified diet and regular exercise regimen and increase omega-3 fatty acids in their diet or as a supplement. Increased fiber of 25 to 35 g in the daily diet is also recommended. In collaboration with the dietitian, teach patients with LDL-C values of 160 mg/dL or greater (high or very high) to follow a more structured nutritional plan aimed at decreasing saturated fat and cholesterol and, if appropriate, promoting weight loss.

For high-risk people, such as those with high cholesterol, diabetes, or CVD, the AHA recommends the NCEP Therapeutic Lifestyle Changes (TLC) diet, which outlines appropriate medical nutrition therapy. Recommendations include obtaining a patient's baseline serum cholesterol level and then retesting 6 and 12 weeks after the initial nutritional intervention. If the cholesterol level has not significantly decreased, the patient may be referred to a dietitian for instruction on the NCEP-TLC diet, which limits saturated fat to less than 7% of total calories and cholesterol to less than 200 mg/day.

Drug Therapy

For patients with elevated total and LDL-C levels that do not respond adequately to dietary intervention, the health care provider prescribes one or more lipid-lowering agents (Table 38-2). Drug choice depends on the serum lipid levels. Because most of these drugs can produce major side effects, they are generally given only when nonpharmacologic management has been unsuccessful.

A class of drugs known as *3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins)* successfully reduces total cholesterol in most patients when used for an extended period. These drugs are also referred to as *antihyperlipoproteinemics*. Examples include lovastatin (Mevacor), simvastatin (Zocor), and atorvastatin (Lipitor), which lower both LDL-C and triglyceride levels.

! NURSING SAFETY PRIORITY

Drug Alert

Statins reduce cholesterol synthesis in the liver and increase clearance of LDL-C from the blood. Therefore they are contraindicated in patients with active liver disease or during pregnancy because they can cause muscle myopathies and marked decreases in liver function. Statin drugs are discontinued if the patient has muscle cramping or elevated liver enzyme levels. Some patients also report abdominal bloating, flatulence, diarrhea, and/or constipation as side effect of these drugs.

TABLE 38-2 COMMONLY USED DRUGS FOR ATHEROSCLEROSIS

HMG-CoA Reductase Inhibitors (Statins)	Other Drugs
• Lovastatin (Mevacor) • Atorvastatin (Lipitor) • Simvastatin (Zocor) • Fluvastatin (Lescol) • Rosuvastatin (Crestor) • Pravastatin (Pravachol)	• Gemfibrozil (Lopid) • Fenofibrate (Tricor) • Ezetimibe (Zetia) • Omega-3 ethyl esters (Lovaza)
Combination Drugs	
• Ezetimibe and simvastatin (Vytorin) • Amlodipine and atorvastatin (Caduet) • Niacin and lovastatin (Advicor)	

HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A.

A different type of lipid-lowering agent, ezetimibe (Zetia), may be used in place of or in combination with statin-type drugs. This drug inhibits the absorption of cholesterol through the small intestine. Vytorin is a combination drug containing ezetimibe and simvastatin. This drug works two ways—by reducing the absorption of cholesterol and by decreasing the amount of cholesterol synthesis in the liver. Other statin combinations have been developed to improve lipid levels, such as Advicor, a combination of niacin and lovastatin. Aspirin and pravastatin are combined as Pravigard. Amlodipine (Norvasc) and atorvastatin are combined as Caduet to decrease blood pressure while decreasing triglycerides (TGs), increasing HDL, and lowering LDL. Combining drugs may improve adherence for the patient who is often taking multiple drugs.

Complementary and Alternative Therapy

Nicotinic acid or niacin (Niaspan), a B vitamin, may lower LDL-C and very-low-density lipoprotein (VLDL) cholesterol levels and increase HDL-C levels in some patients. It is used as a single agent or in combination with an acid-binding resin drug or a statin. Low doses are recommended because many patients experience flushing and a very warm feeling all over. Higher doses can result in an elevation of hepatic enzymes.

Lovaza (omega-3 ethyl esters) is approved by the Food and Drug Administration (FDA) as an adjunct to diet to reduce TGs that are greater than 500 mg/dL. This drug also decreases plaque growth and inflammation and reduces clot formation (Harris et al., 2008).

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

A client diagnosed with atherosclerosis has been prescribed simvastatin (Zocor). Which statement by the client indicates a need for further teaching?

- "I have to eat more fruits and vegetables in my diet."
- "I'll follow up with my nurse practitioner to check my lipid levels."
- "I only smoke a half-pack of cigarettes a day so I won't need to quit."
- "I'll report any leg cramps to my nurse practitioner immediately."

HYPERTENSION

Pathophysiology

According to the Seventh Joint National Committee (JNC) on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure, **hypertension** is a systolic blood pressure at or above 140 mm Hg and/or a diastolic blood pressure at or above 90 mm Hg in people who do not have diabetes mellitus. Patients with diabetes and heart disease should have a blood pressure below 130/90 (Joint National Committee, 2003). The Eighth JNC report, due to be released by the U.S. National Institutes of Health in Spring 2012, may likely recommend different values and classifications of patients who are hypertensive.

Mechanisms That Influence Blood Pressure

The systemic arterial pressure is a product of cardiac output (CO) and total peripheral vascular resistance (PVR). Cardiac output is determined by the stroke volume (SV) multiplied by heart rate (HR) ($CO = SV \times HR$). Control of peripheral

vascular resistance (i.e., vessel constriction or dilation) is maintained by the autonomic nervous system and circulating hormones, such as norepinephrine and epinephrine. Consequently, any factor that increases peripheral vascular resistance, heart rate, or stroke volume increases the systemic arterial pressure. Conversely, any factor that decreases peripheral vascular resistance, heart rate, or stroke volume decreases the systemic arterial pressure.

Stabilizing mechanisms exist in the body to exert an overall regulation of systemic arterial pressure and to prevent circulatory collapse. Four control systems play a major role in maintaining blood pressure:

- The arterial baroreceptor system
- Regulation of body fluid volume
- The renin-angiotensin/aldosterone system
- Vascular autoregulation.

Arterial baroreceptors are found primarily in the carotid sinus, aorta, and wall of the left ventricle. They monitor the level of arterial pressure and counteract a rise in arterial pressure through vagally mediated cardiac slowing and vasodilation with decreased sympathetic tone. Therefore reflex control of circulation elevates the systemic arterial pressure when it falls and lowers it when it rises. Why baroreceptor control fails in hypertension is not clear (McCance et al., 2010).
